Chapter 59

The MODECLUS Procedure

Contents

Overview: MODECLUS Procedure

The MODECLUS procedure clusters observations in a SAS data set by using any of several algorithms based on nonparametric density estimates. The data can be numeric coordinates or distances. PROC MODECLUS can perform approximate significance tests for the number of clusters and can hierarchically join nonsignificant clusters. The significance tests are empirically validated by simulations with sample sizes ranging from 20 to 2000.

PROC MODECLUS produces output data sets containing density estimates and cluster membership, various cluster statistics including approximate *p*-values, and a summary of the number of clusters generated by various algorithms, smoothing parameters, and significance levels.

Most clustering methods are biased toward finding clusters possessing certain characteristics related to size (number of members), shape, or dispersion. Methods based on the least squares criterion (Sarle 1982), such as *k*-means and Ward's minimum variance method, tend to find clusters with roughly the same number of observations in each cluster. Average linkage (see Chapter 30, "The CLUSTER Procedure") is somewhat biased toward finding clusters of equal variance. Many clustering methods tend to produce compact, roughly hyperspherical clusters and are incapable of detecting clusters with highly elongated or irregular shapes. The methods with the least bias are those based on nonparametric density estimation (Silverman 1986, pp. 130–146; Scott 1992, pp. 125–190) such as density linkage (see Chapter 30, "The CLUSTER Procedure"), Wong and Lane (1983), and Wong and Schaack (1982). The biases of many commonly used clustering methods are discussed in Chapter 11, "Introduction to Clustering Procedures."

PROC MODECLUS implements several clustering methods by using nonparametric density estimation. Such clustering methods are referred to hereafter as *nonparametric clustering methods*. The methods in PROC MODECLUS are related to, but not identical to, methods developed by Gitman (1973), Huizinga (1978), Koontz and Fukunaga (1972a, b), Koontz, Narendra, and Fukunaga (1976), Mizoguchi and Shimura (1980), Wong and Lane (1983).

Details of the algorithms are provided in the section "Clustering Methods" on page 4938.

For nonparametric clustering methods, a cluster is loosely defined as a region surrounding a local maximum of the probability density function (see the section "Significance Tests" on page 4940 for a more rigorous definition). Given a sufficiently large sample, nonparametric clustering methods are capable of detecting clusters of unequal size and dispersion and with highly irregular shapes. Nonparametric methods can also obtain good results for compact clusters of equal size and dispersion, but they naturally require larger sample sizes for good recovery than clustering methods that are biased toward finding such "nice" clusters.

For coordinate data, nonparametric clustering methods are less sensitive to changes in scale of the variables or to affine transformations of the variables than are most other commonly used clustering methods. Nevertheless, it is necessary to consider questions of scaling and transformation, since variables with large variances tend to have more of an effect on the resulting clusters than those with small variances. If two or more variables are not measured in comparable units, some type of standardization or scaling is necessary; otherwise, the distances used by the procedure might be based on inappropriate apples-and-oranges computations. For variables with comparable units of measurement, standardization or scaling might still be desirable if the scale estimates of the variables are not related to their expected importance for defining clusters. If you want two variables to have equal importance in the analysis, they should have roughly equal scale estimates. If you want one variable to have more of an effect than another, the former should be scaled to have a greater scale estimate than the latter. The STD option in the PROC MODECLUS statement scales all variables to equal variance. However, the variance is not necessarily the most appropriate scale estimate for cluster analysis. In particular, outliers should be removed before using PROC MODECLUS with the STD option. A variety of scale estimators including robust estimators are provided in the STDIZE procedure (for detailed information, see Chapter 84, "The STDIZE Procedure"). Additionally, the ACECLUS procedure provides another way to transform the variables to try to improve the separation of clusters.

Since clusters are defined in terms of local maxima of the probability density function, nonlinear transformations of the data can change the number of population clusters. The variables should be transformed so that equal differences are of equal practical importance. An interval scale of measurement is required. Or-

dinal or ranked data are generally inappropriate, since monotone transformations can produce any arbitrary number of modes.

Unlike the methods in the CLUSTER procedure, the methods in the MODECLUS procedure are not inherently hierarchical. However, PROC MODECLUS can do approximate nonparametric significance tests for the number of clusters by obtaining an approximate *p*-value for each cluster, and it can hierarchically join nonsignificant clusters.

Another important difference between the MODECLUS procedure and many other clustering methods is that you do not tell PROC MODECLUS how many clusters you want. Instead, you specify a *smoothing parameter* (see the section "Density Estimation" on page 4934) and, optionally, a significance level, and PROC MODECLUS determines the number of clusters. You can specify a list of smoothing parameters, and PROC MODECLUS performs a separate cluster analysis for each value in the list.

Getting Started: MODECLUS Procedure

This section illustrates how PROC MODECLUS can be used to examine the clusters of data in the following artificial data set.

```
data example;
   input x y @@;
   datalines;
18 18  20 22  21 20  12 23  17 12  23 25  25 20  16 27
20 13  28 22  80 20  75 19  77 23  81 26  55 21  64 24
72 26  70 35  75 30  78 42  18 52  27 57  41 61  48 64
59 72  69 72  80 80  31 53  51 69  72 81
;
```

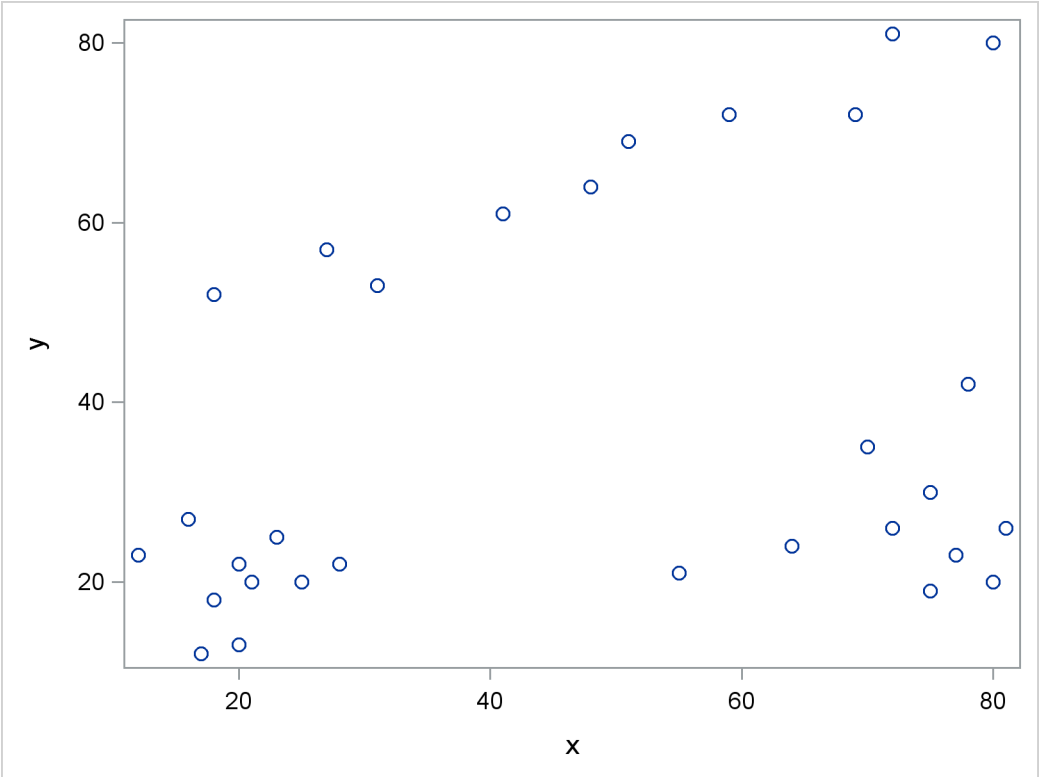
It is a good practice to plot the data to check for obvious clusters or pathologies prior to the analysis. In this example, with only two variables and a small sample size, the SGPLOT procedure in the following statements produces a scatter plot:

```
proc sgplot;
   scatter y=y x=x;
run;
```

Figure 59.1 suggests three clusters. Of these clusters, the one in the lower-left corner is the most compact, while the lower-right cluster is more dispersed.

The upper cluster is elongated and would be difficult for most clustering algorithms to identify as a single cluster. The plot also suggests that a Euclidean distance of 10 or 20 is a good initial guess for the neighborhood size in density estimation and clustering.

Figure 59.1 Scatter Plot of Data



To obtain a cluster analysis in PROC MODECLUS, you must specify the METHOD= option; for most purposes, METHOD=1 is recommended. The cluster analysis can be performed with a list of radii (R=10 15 35), as shown in the following PROC MODECLUS statement. An output data set containing the cluster membership is created with the OUT= option. The following statements produce Figure 59.2 through Figure 59.5:

```
proc modeclus data=example method=1 r=10 15 35 out=out;
run;
```

For each cluster solution, PROC MODECLUS produces a table of cluster statistics including the cluster number, the number of observations in the cluster, the maximum estimated density within the cluster, the number of observations in the cluster having a neighbor that belongs to a different cluster, and the estimated saddle density of the cluster. The results are displayed in Figure 59.2, Figure 59.3, and Figure 59.4 for three different radii. A smaller radius (R=10) yields a larger number of clusters (6), as displayed in Figure 59.2; a larger radius (R=35) includes all observations in a single cluster, as displayed in Figure 59.4. Note that all clusters in these three figures are "isolated" since their corresponding boundary frequencies are all zeros. Consequently, all the estimated saddle densities are missing. A table summarizing each cluster solution is then produced at the end, as displayed in Figure 59.5.

Figure 59.2 Results from PROC MODECLUS for METHOD=1 and R=10

The MODECLUS Procedure

The MODECLUS Procedure

Cluster Summary

R	Number of Clusters	Frequency of Unclassified Objects
10	6	0
15	3	0
35	1	0

The OUT= data set contains a complete copy of the input data set for each cluster solution. By using a BY statement in the following PROC SGPLOT statement, you can examine the differences in cluster memberships for each radius as shown in Figure 59.6 through Figure 59.8:

```
proc sgplot data=out noautolegend;
   scatter y=y x=x / group=cluster markerchar=cluster;
   by _r_;
run;
```

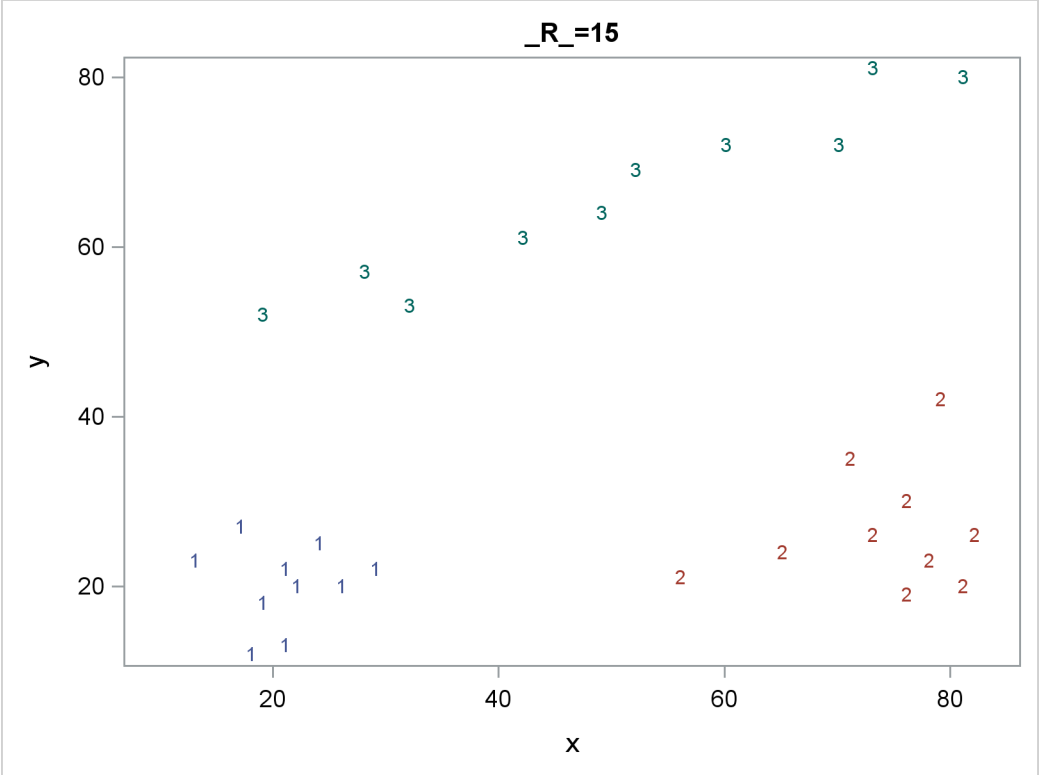

Figure 59.8 Scatter Plots of Cluster Memberships with _R_=35

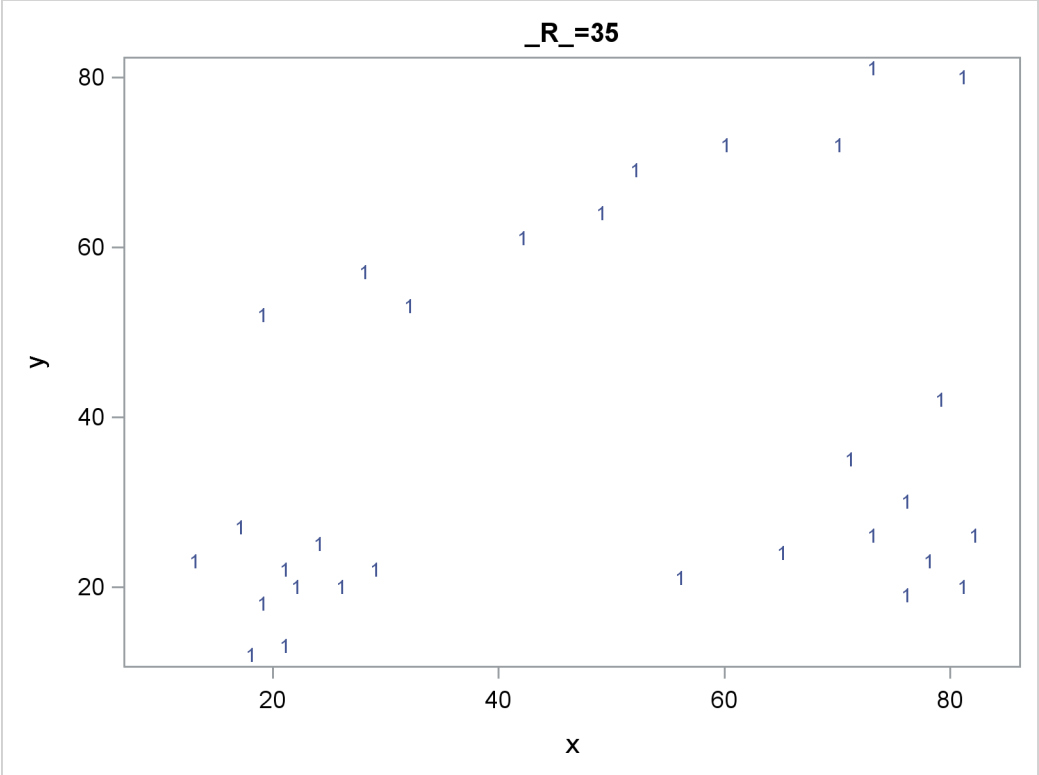

Syntax: MODECLUS Procedure

The following statements invoke the MODECLUS procedure:

PROC MODECLUS < *options* > **;**
BY *variables* **;**
FREQ *variable* **;**
ID *variable* **;**
VAR *variables* **;**

The PROC MODECLUS statement is required. All other statements are optional.

PROC MODECLUS Statement

PROC MODECLUS < *options* > **;**

The PROC MODECLUS statement starts the MODECLUS procedure. The options available with the PROC MODECLUS statement are summarized in Table 59.1 and discussed in the following sections.

Table 59.1 Summary of PROC MODECLUS Statement Options

Option	Description
Specify input and output data sets	
DATA=	Specifies input data set name
OUT=	Specifies output data set name for observations
OUTCLUS=	Specifies output data set name for clusters
OUTSUM=	Specifies output data set name for cluster solutions
Specify variables in output data sets	
CLUSTER=	Specifies variable in the OUT= and OUTCLUS= data sets identifying clusters
DENSITY=	Specifies variable in the OUT= data set containing density estimates
OUTLENGTH=	Specifies length of variables in the output data sets
Summarize and process coordinate data before clustering	
SIMPLE	Requests simple statistics
STANDARD	Standardizes the variables to mean 0 and standard deviation 1
Specify smoothing parameters	
DK=	Specifies number of neighbors to use for *k*th-nearest-neighbor density estimation
CK=	Specifies number of neighbors to use for clustering
K=	specifies number of neighbors to use for *k*th-nearest-neighbor density estimation and clustering
DR=	Specifies radius of the sphere of support for uniform-kernel density estimation

Table 59.1 *continued*

Option	Description
CR=	Specifies radius of the neighborhood for clustering
R=	Specifies radius of the sphere of support for uniform-kernel density estimation and the neighborhood clustering
Specify density estimation options	
CASCADE=	Specifies number of times the density estimates are to be cascaded
DIMENSION=	Specifies dimensionality to be used when computing density estimates
AM	Uses arithmetic means for cascading density estimates
HM	Uses harmonic means for cascading density estimates
SUM	Uses sums for cascading density estimates
Specify clustering methods and options	
DOCK=	Dissolves clusters with *n* or fewer members
EARLY	Stops the analysis after obtaining a solution with either no cluster or a single cluster
JOIN=	Requests that nonsignificant clusters be hierarchically joined
MAXCLUSTERS=	Specifies maximum number of clusters to be obtained with METHOD=6
METHOD=	Specifies clustering method to use
MODE=	Specifies minimum members for either cluster to be designated a modal cluster when two clusters are joined using METHOD=5
POWER=	Specifies power of the density used with METHOD=6
TEST	Specifies approximate significance tests for the number of clusters
THRESHOLD=	Specifies assignment threshold used with METHOD=6
Specify the output display options	
ALL	Produces all optional output
BOUNDARY	Displays the density and cluster membership of observations with neighbors belonging to a different cluster
CORE	Retains the neighbor lists for each observation in memory
CROSS	Displays the estimated cross validated log density of each observation
CROSSLIST	Displays the estimated density and cluster membership of each observation
LOCAL	Displays estimates of local dimensionality and writes them to the OUT=data set
NEIGHBOR	Displays the neighbors of each observation
NOPRINT	Suppresses the display of the output
NOSUMMARY	Suppresses the display of the summary of the number of clusters, number of unassigned observations, and maximum *p*-value for each analysis
SHORT	Suppresses the display of statistics for each cluster
TRACE	Traces the cluster assignments when METHOD=6

You can specify at least one of the following options for smoothing parameters for density estimation: DK=, K=, DR=, or R=. To obtain a cluster analysis, you can specify the METHOD= option and at least one of the following smoothing parameters for clustering: CK=, K=, CR=, or R=. If you want significance tests for the number of clusters, you should specify either the DR= or R= option. If none of the smoothing parameters is specified, the MODECLUS procedure provides a default value for the R= option. See the section "Density Estimation" on page 4934 for the formula of a reasonable first guess for R= and a discussion of smoothing parameters.

You can specify lists of values for the DK=, CK=, K=, DR=, CR=, and R= options. Numbers in the lists can be separated by blanks or commas. You can include in the lists one or more items of the form *start* TO *stop* BY *increment*. Each list can contain either one value or the same number of values as in every other list that contains more than one value. If a list has only one value, that value is used in combination with all the values in longer lists. If two or more lists have more than one value, then one analysis is done by using the first value in each list, another analysis is done by using the second value in each list, and so on.

You can specify the following options in the PROC MODECLUS statement.

ALL

produces all optional output.

AM

specifies arithmetic means for cascading density estimates. See the description of the CASCADE= option.

BOUNDARY

displays the density and cluster membership of observations with neighbors belonging to a different cluster.

CASCADE=*n*

CASC=*n*

specifies the number of times the density estimates are to be cascaded (see the section "Density Estimation" on page 4934). The default value 0 performs no cascading.

You can specify a list of values for the CASCADE= option. Each value in the list is combined with each combination of smoothing parameters to produce a separate analysis.

CK=*n*

specifies the number of neighbors to use for clustering. The number of neighbors should be at least two but less than the number of observations. See the section "Density Estimation" on page 4934 for details.

CLUSTER=*name*

provides a name for the variable in the OUT= and OUTCLUS= data sets identifying clusters. The default name is CLUSTER.

CORE

keeps the neighbor lists for each observation in the computer memory to make small problems run faster.

CR=*n*

specifies the radius of the neighborhood for clustering. See the section "Density Estimation" on page 4934 for details.

CROSS

computes the likelihood cross validation criterion (Silverman 1986, pp. 52–55). This option appears to be of limited usefulness. See the section "Density Estimation" on page 4934 for details.

CROSSLIST

displays the cross validated log density of each observation.

DATA=*SAS-data-set*

specifies the input data set containing observations to be clustered. If you omit the DATA= option, the most recently created SAS data set is used.

If the data set is TYPE=DISTANCE, the data are interpreted as a distance matrix. The number of variables must equal the number of observations in the data set or in each BY group. The distances are assumed to be Euclidean, but the procedure accepts other types of distances or dissimilarities. Unlike the CLUSTER procedure, PROC MODECLUS uses the entire distance matrix, not just the lower triangle; the distances are not required to be symmetric. The neighbors of a given observation are determined solely from the distances in that observation. Missing values are considered infinite. Various distance measures can be computed from coordinate data by using the DISTANCE procedure (for detailed information, see Chapter 33, "The DISTANCE Procedure").

If the data set is not TYPE=DISTANCE, the data are interpreted as coordinates in a Euclidean space, and Euclidean distances are computed. The variables can be discrete or continuous and should be at the interval level of measurement.

Data set types such as TYPE=DISTANCE do not persist when you copy or modify a data set. You must specify the TYPE= data set option for the new data set, as in the following example:

```
data dist2(type=distance);
   set dist;
run;
```

If you do not specify the TYPE=DISTANCE data set option, the new data set is the default TYPE=DATA. If you use the new data set in a procedure that accepts both TYPE=DATA or TYPE=DISTANCE data sets (such as PROC CLUSTER or PROC MODECLUS), the results will be incorrect.

DENSITY=*name*

provides a name for the variable in the OUT= data set containing density estimates. The default name is DENSITY.

DIMENSION=*n*

DIM=*n*

specifies the dimensionality to be used when computing density estimates. The default is the number of variables if the data are coordinates; the default is 1 if the data are distances.

DK=*n*

specifies the number of neighbors to use for *k*th-nearest-neighbor density estimation. The number of neighbors should be at least two but less than the number of observations. See the section "Density Estimation" on page 4934 for details.

DOCK=*n*

dissolves clusters with *n* or fewer members by making the members unassigned.

DR=*n*

specifies the radius of the sphere of support for uniform-kernel density estimation. See the section "Density Estimation" on page 4934 for details.

EARLY

stops the cluster analysis after obtaining either a solution with no cluster or a solution with one cluster to which all observations are assigned. The smoothing parameters should be specified in increasing order. This can reduce the computer time required for the analysis but might occasionally miss some multiple-cluster solutions.

HM

uses harmonic means for cascading density estimates. See the description of the CASCADE= option for details.

JOIN<=*p*>

requests that nonsignificant clusters be hierarchically joined. The JOIN option implies the TEST option. After each solution is obtained, the cluster with the largest approximate *p*-value is either joined to a neighboring cluster or, if there is no neighboring cluster, dissolved by making all of its members unassigned. After two clusters are joined, an analysis of the remaining clusters is displayed.

If you do not specify a *p*-value with the JOIN= option, joining continues until only one cluster remains, and the results are written to the output data sets after each analysis. If you specify a *p*-value with the JOIN= option, joining continues until the greatest approximate *p*-value is less than the value given in the JOIN= option, and only if there is more than one cluster are the results for that analysis written to the output data sets.

Any value of *p* less than 1E−8 is set to 1E−8.

K=*n*

specifies the number of neighbors to use for *k*th-nearest-neighbor density estimation and clustering. The number of neighbors should be at least two but less than the number of observations. Specifying K=*n* is equivalent to specifying both DK=*n* and CK=*n*. See the section "Density Estimation" on page 4934 for details.

LIST

displays the estimated density and cluster membership of each observation.

LOCAL

requests estimates of local dimensionality (Tukey and Tukey 1981, pp. 236–237).

MAXCLUSTERS=*n*

MAXC=*n*

specifies the maximum number of clusters to be obtained with the METHOD=6 option. By default, there is no fixed limit.

METHOD=*n*

MET=*n*

M=*n*

specifies what clustering method to use. Since these methods do not have widely recognized names, the methods are indicated by numbers from 0 to 6. The methods are described in the section "Clustering Methods" on page 4938. For most purposes, METHOD=1 is recommended, although METHOD=6 might occasionally produce better results in return for considerably greater computer time and space requirements. METHOD=1 is not good for discrete coordinate data with only a few equally spaced values. In this case, METHOD=6 or METHOD=3 works better. METHOD=4 or METHOD=5 is less desirable than other methods when there are ties, since a general characteristic of agglomerative hierarchical clustering methods is that the results are indeterminate in the presence of ties.

You must specify the METHOD= option to obtain a cluster analysis.

You can specify a list of values for the METHOD= option. Each value in the list is combined with each combination of smoothing and cascading parameters to produce a separate cluster analysis.

MODE=*n*

specifies that when two clusters are joined using the METHOD=5 option (no other methods are affected by the MODE= option), each must have at least *n* members for either cluster to be designated a modal cluster. In any case, each cluster must also have a maximum density greater than the fusion density for either cluster to be designated a modal cluster. If you specify the K= option, the default value of the MODE= option is the same as the value of the K= option because the use of *k*th-nearest-neighbor density estimation limits the resolution that can be obtained for clusters with fewer than *k* members. If you do not specify the K= option, the default is MODE=2. If you specify MODE=0, the default value is used instead of 0. If you specify a FREQ statement, the MODE= value is compared to the number of observations in each cluster, not to the sum of the frequencies.

NEIGHBOR

displays the neighbors of each observation in a table called "Nearest Neighbor List." See Nearest Neighbor List for information displayed in the table.

NOPRINT

suppresses the display of the output. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 20, "Using the Output Delivery System," for more information.

NOSUMMARY

suppresses the display of the summary of the number of clusters, number of unassigned observations, and maximum *p*-value for each analysis.

OUT=*SAS-data-set*

specifies the output data set containing the input data plus density estimates, cluster membership, and variables identifying the type of solution. There is an output observation corresponding to each input observation for each solution. Therefore, the OUT= data set can be very large.

If you want to create a permanent SAS data set, you must specify a two-level name. For details about OUT= data sets, see the section "Output Data Sets" on page 4947. See *SAS Language Reference: Concepts* for more information about permanent SAS data sets.

OUTCLUS=*SAS-data-set*

OUTC=*SAS-data-set*

specifies the output data set containing an observation corresponding to each cluster in each solution. The variables identify the solution and contain statistics describing the clusters.

If you want to create a permanent SAS data set, you must specify a two-level name. For details about OUTCLUS= data sets, see the section "Output Data Sets" on page 4947. See *SAS Language Reference: Concepts* for more information about permanent SAS data sets.

OUTSUM=*SAS-data-set*

OUTS=*SAS-data-set*

specifies the output data set containing an observation corresponding to each cluster solution, giving the number of clusters and the number of unclassified observations for that solution.

If you want to create a permanent SAS data set, you must specify a two-level name. For details about OUTSUM= data sets, see the section "Output Data Sets" on page 4947. See *SAS Language Reference: Concepts* for more information about permanent SAS data sets.

OUTLENGTH=*n*

OUTL=*n*

specifies the length of those output variables that are not copied from the input data set but are created by PROC MODECLUS.

The OUTLENGTH= option applies only to the following variables that appear in all of the output data sets: _K_, _DK_, _CK_, _R_, _DR_, _CR_, _CASCAD_, _METHOD_, _NJOIN_, and _LOCAL_.

The minimum value is 2 or 3, depending on the operating system. The maximum value is 8. The default value is 8.

POWER=*n*

POW=*n*

specifies the power of the density used with the METHOD=6 option. The default value is 2.

R=*n*

specifies the radius of the sphere of support for uniform-kernel density estimation and the neighborhood for clustering. Specifying R=*n* is equivalent to specifying both DR=*n* and CR=*n*. See the section "Density Estimation" on page 4934 for details.

SHORT

suppresses the display of statistics for each cluster.

SIMPLE

S

displays means, standard deviations, skewness, kurtosis, and a coefficient of bimodality. The SIMPLE option applies only to coordinate data.

STANDARD

STD

standardizes the variables to mean 0 and standard deviation 1. The STANDARD option applies only to coordinate data.

SUM

uses sums for cascading density estimates. See the description of the CASCADE= option for details.

TEST

performs approximate significance tests for the number of clusters. The R= or DR= option must also be specified with a nonzero value to obtain significance tests.

The significance tests performed by PROC MODECLUS are valid only for simple random samples, and they require at least 20 observations per cluster to have enough power to be of any use. See the section "Significance Tests" on page 4940 for details.

THRESHOLD=*n*

THR=*n*

specifies the assignment threshold used with the METHOD=6 option. The default is 0.5.

TRACE

traces the process of cluster assignments when METHOD=6 is specified.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC MODECLUS to obtain separate analyses on observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the MODECLUS procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

FREQ Statement

FREQ *variable* **;**

If one variable in the input data set represents the frequency of occurrence for other values in the observation, specify the variable's name in a FREQ statement. PROC MODECLUS then treats the data set as if each observation appeared *n* times, where *n* is the value of the FREQ variable for the observation. Nonintegral values of the FREQ variable are truncated to the largest integer less than the FREQ value.

ID Statement

ID *variable* **;**

The values of the ID variable identify observations in the displayed results and in the OUT= data set. If you omit the ID statement, each observation is identified by its observation number, and a variable called _OBS_ is written to the OUT= data set containing the original observation numbers.

VAR Statement

VAR *variables* **;**

The VAR statement specifies numeric variables to be used in the cluster analysis. If you omit the VAR statement, all numeric variables not specified in other statements are used.

Details: MODECLUS Procedure

Density Estimation

See Silverman (1986) or Scott (1992) for an introduction to nonparametric density estimation.

PROC MODECLUS uses hyperspherical uniform kernels of fixed or variable radius. The density estimate at a point is computed by dividing the number of observations within a sphere centered at the point by the product of the sample size and the volume of the sphere. The size of the sphere is determined by the smoothing parameters that you are required to specify.

For fixed-radius kernels, specify the radius as a Euclidean distance with either the DR= or R= option. For variable-radius kernels, specify the number of neighbors desired within the sphere with either the DK= or K= option; the radius is then the smallest radius that contains at least the specified number of observations

including the observation at which the density is being estimated. If you specify both the DR= or R= option and the DK= or K= option, the radius used is the maximum of the two indicated radii; this is useful for dealing with outliers.

It is convenient to refer to the sphere of support of the kernel at observation x_i as the *neighborhood* of x_i. The observations within the neighborhood of x_i are the *neighbors* of x_i. In some contexts, x_i is considered a neighbor of itself, but in other contexts it is not. The following notation is used in this chapter:

x_i	the ith observation
d(x,y)	the distance between points x and y
n	the total number of observations in the sample
n_i	the number of observations within the neighborhood of x_i, including x_i itself
n_i^-	the number of observations within the neighborhood of x_i, not including x_i itself
N_i	the set of indices of neighbors of x_i, including i
N_i^-	the set of indices of neighbors of x_i, not including i
v_i	the volume of the neighborhood of x_i
r_i	the radius of the neighborhood of x_i
$\hat{f}_i$	the estimated density at x_i
$\hat{f}_i^-$	the cross validated density estimate at x_i
C_k	the set of indices of observations assigned to cluster k
v	the number of variables or the dimensionality
s_l	standard deviation of the lth variable

The estimated density at x_i is

$$\hat{f}_i = \frac{n_i}{n v_i}$$

which indicates the number of neighbors of x_i divided by the product of the sample size and the volume of the neighborhood at x_i, where

$$v_i = \frac{\pi^{\frac{v}{2}} {r_i}^v}{\Gamma(\frac{v}{2}+1)}$$

and Γ can be computed in a DATA step by using the GAMMA function. Note that $v = 1$ for distance data.

The density estimates provided by uniform kernels are not quite as good as those provided by some other types of kernels, but they are quite satisfactory for clustering. The significance tests for the number of clusters require the use of fixed-size uniform kernels.

There is no simple answer to the question of which smoothing parameter to use (Silverman 1986, pp. 43–61, 84–88, 98–99). It is usually necessary to try several different smoothing parameters. A reasonable first guess for the K= option is in the range of 0.1 to 1 times $n^{4/(v+4)}$, smaller values being suitable for higher dimensionalities. A reasonable first guess for the R= option in many coordinate data sets is given by

$$\left[\frac{2^{v+2}(v+2)\Gamma(\frac{v}{2}+1)}{n v^2}\right]^{1/(v+4)} \sqrt{\sum_{l=1}^{v} s_l^2}$$

which can be computed in a DATA step by using the GAMMA function for Γ. The MODECLUS procedure also provides this first guess as a default smoothing parameter if none of the options (DR=, CR=, R=, DK=, CK=, and K=) is specified. This formula is derived under the assumption that the data are sampled from a multivariate normal distribution and, therefore, tend to be too large (oversmooth) if the true distribution is multimodal. Robust estimates of the standard deviations might be preferable if there are outliers. If the data are distances, the factor $\sqrt{\sum s_l{}^2}$ can be replaced by an average root-mean-squared Euclidean distance divided by $\sqrt{2}$. To prevent outliers from appearing as separate clusters, you can also specify K=2 or CK=2 or, more generally, K=*m* or CK=*m*, $m \geq 2$, which in most cases forces clusters to have at least *m* members.

If the variables all have unit variance (for example, if you specify the STD option), you can use Table 59.2 to obtain an initial guess for the R= option.

Table 59.2 Reasonable First Guess for R= for Standardized Data

Number	Number of Variables									
of Obs	1	2	3	4	5	6	7	8	9	10
20	1.01	1.36	1.77	2.23	2.73	3.25	3.81	4.38	4.98	5.60

100	0.73	1.04	1.41	1.82	2.28	2.77	3.29	3.83	4.40	4.99
150	0.68	0.97	1.33	1.73	2.18	2.66	3.17	3.71	4.27	4.85
200	0.64	0.93	1.28	1.67	2.11	2.58	3.09	3.62	4.17	4.75
350	0.57	0.85	1.18	1.56	1.98	2.44	2.93	3.45	4.00	4.56
500	0.53	0.80	1.12	1.49	1.91	2.36	2.84	3.35	3.89	4.45
750	0.49	0.74	1.06	1.42	1.82	2.26	2.74	3.24	3.77	4.32
1000	0.46	0.71	1.01	1.37	1.77	2.20	2.67	3.16	3.69	4.23
1500	0.43	0.66	0.96	1.30	1.69	2.11	2.57	3.06	3.57	4.11
2000	0.40	0.63	0.92	1.25	1.63	2.05	2.50	2.99	3.49	4.03

One data-based method for choosing the smoothing parameter is likelihood cross validation (Silverman 1986, pp. 52–55). The cross validated density estimate at an observation is obtained by omitting the observation from the computations:

$$\hat{f}_i^- = \frac{n_i^-}{n v_i}$$

The (log) likelihood cross validation criterion is then computed as

$$\sum_{i=1}^{n} \log \hat{f}_i^-$$

The suggested smoothing parameter is the one that maximizes this criterion. With fixed-radius kernels, likelihood cross validation oversmooths long-tailed distributions; for purposes of clustering, it tends to undersmooth short-tailed distributions. With *k*-nearest-neighbor density estimation, likelihood cross validation is useless because it almost always indicates *k*=2.

Cascaded density estimates are obtained by computing initial kernel density estimates and then, at each observation, taking the arithmetic mean, harmonic mean, or sum of the initial density estimates of the observations within the neighborhood. The cascaded density estimates can, in turn, be cascaded, and so on. Let ${}_k\hat{f}_i$ be the density estimate at x_i cascaded k times. For all types of cascading, ${}_0\hat{f}_i = \hat{f}_i$. If the cascading is done by arithmetic means, then, for $k \geq 0$,

$$ {}_{k+1}\hat{f}_i = \sum_{j \in N_i} {}_k\hat{f}_j / n_i $$

For harmonic means,

$$ {}_{k+1}\hat{f}_i = \left(\sum_{j \in N_i} {}_k\hat{f}_j^{-1} / n_i \right)^{-1} $$

and for sums,

$$ {}_{k+1}\hat{f}_i = \left(\sum_{j \in N_i} {}_k\hat{f}_j^{k+1} \right)^{\frac{1}{k+2}} $$

To avoid cluttering formulas, the symbol $\hat{f}_i$ is used in the rest of the chapter to denote the density estimate at x_i whether cascaded or not, since the clustering methods and significance tests do not depend on the degree of cascading.

Cascading increases the smoothness of the estimates with less computation than would be required by increasing the smoothing parameters to yield a comparable degree of smoothness. For population densities with bounded support and discontinuities at the boundaries, cascading improves estimates near the boundaries. Cascaded estimates, especially using sums, might be more sensitive to the local covariance structure of the distribution than are the uncascaded kernel estimates. Cascading seems to be useful for detecting very nonspherical clusters. Cascading was suggested by Tukey and Tukey (1981, p. 237). Additional research into the properties of cascaded density estimates is needed.

Clustering Methods

The number of clusters is a function of the smoothing parameters. The number of clusters tends to decrease as the smoothing parameters increase, but the relationship is not strictly monotonic. Generally, you should specify several different values of the smoothing parameters to see how the number of clusters varies.

The clustering methods used by PROC MODECLUS use spherical clustering neighborhoods of fixed or variable radius that are similar to the spherical kernels used for density estimation. For fixed-radius neighborhoods, specify the radius as a Euclidean distance with either the CR= or R= option. For variable-radius neighborhoods, specify the number of neighbors desired within the sphere with either the CK= or K= option; the radius is then the smallest radius that contains at least the specified number of observations including the observation for which the neighborhood is being determined. However, in the following descriptions of clustering methods, an observation is not considered to be one of its own neighbors. If you specify both the CR= or R= option and the CK= or K= option, the radius used is the maximum of the two indicated radii; this is useful for dealing with outliers. In this section, the symbols N_i, N_i^-, n_i, and n_i^- refer to clustering neighborhoods, not density estimation neighborhoods.

METHOD=0

Begin with each observation in a separate cluster. For each observation and each of its neighbors, join the cluster to which the observation belongs with the cluster to which the neighbor belongs. This method does not use density estimates. With a fixed clustering radius, the clusters are those obtained by cutting the single linkage tree at the specified radius (see Chapter 30, "The CLUSTER Procedure").

METHOD=1

Begin with each observation in a separate cluster. For each observation, find the nearest neighbor with a greater estimated density. If such a neighbor exists, join the cluster to which the observation belongs with the cluster to which the specified neighbor belongs.

Next, consider each observation with density estimates equal to that of one or more neighbors but not less than the estimate at any neighbor. Join the cluster containing the observation with (1) each cluster containing a neighbor of the observation such that the maximum density estimate in the cluster equals the density estimate at the observation and (2) the cluster containing the nearest neighbor of the observation such that the maximum density estimate in the cluster exceeds the density estimate at the observation.

This method is similar to the classification or assignment stage of algorithms described by Gitman (1973) and Huizinga (1978).

METHOD=2

Begin with each observation in a separate cluster. For each observation, find the neighbor with the greatest estimated density exceeding the estimated density of the observation. If such a neighbor exists, join the cluster to which the observation belongs with the cluster to which the specified neighbor belongs.

Observations with density estimates equal to that of one or more neighbors but not less than the estimate at any neighbor are treated the same way as they are in METHOD=1.

This method is similar to the first stage of an algorithm proposed by Mizoguchi and Shimura (1980).

METHOD=3

Begin with each observation in a separate cluster. For each observation, find the neighbor with greater estimated density such that the slope of the line connecting the point on the estimated density surface at the observation with the point on the estimated density surface at the neighbor is a maximum. That is, for observation x_i, find a neighbor x_j such that $(\hat{f}_j - \hat{f}_i)/\mathrm{d}(x_j, x_i)$ is a maximum. If this slope is positive, join the cluster to which observation x_i belongs with the cluster to which the specified neighbor x_j belongs. This method was invented by Koontz, Narendra, and Fukunaga (1976).

Observations with density estimates equal to that of one or more neighbors but not less than the estimate at any neighbor are treated the same way as they are in METHOD=1. The algorithm suggested for this situation by Koontz, Narendra, and Fukunaga (1976) might fail for flat areas in the estimated density that contain four or more observations.

METHOD=4

This method is equivalent to the first stage of two-stage density linkage (see Chapter 30, "The CLUSTER Procedure") without the use of the MODE=option.

METHOD=5

This method is equivalent to the first stage of two-stage density linkage (see Chapter 30, "The CLUSTER Procedure") with the use of the MODE=option.

METHOD=6

Begin with all observations unassigned.

Step 1: Form a list of seeds, each seed being a single observation such that the estimated density of the observation is not less than the estimated density of any of its neighbors. If you specify the MAXCLUSTERS=*n* option, retain only the *n* seeds with the greatest estimated densities.

Step 2: Consider each seed in decreasing order of estimated density, as follows:

1. If the current seed has already been assigned, proceed to the next seed. Otherwise, form a new cluster consisting of the current seed.
2. Add to the cluster any unassigned seed that is a neighbor of a member of the cluster or that shares a neighbor with a member of the cluster; repeat until no unassigned seed satisfies these conditions.
3. Add to the cluster all neighbors of seeds that belong to the cluster.

4. Consider each unassigned observation. Compute the ratio of the sum of the $p-1$ powers of the estimated density of the neighbors that belong to the current cluster to the sum of the $p-1$ powers of the estimated density of all of its neighbors, where p is specified by the POWER= option and is 2 by default. Let x_i be the current observation, and let k be the index of the current cluster. Then this ratio is

$$r_{ik} = \frac{\sum_{j \in N_i \cap C_k} \hat{f}_j^{p-1}}{\sum_{j \in N_i} \hat{f}_j^{p-1}}$$

(The sum of the $p-1$ powers of the estimated density of the neighbors of an observation is an estimate of the integral of the pth power of the density over the neighborhood.) If r_{ik} exceeds the maximum of 0.5 and the value of the THRESHOLD= option, add the observation x_i to the current cluster k. Repeat until no more observations can be added to the current cluster.

Step 3: (This step is performed only if the value of the THRESHOLD= option is less than 0.5.) Form a list of unassigned observations in decreasing order of estimated density. Repeat the following actions until the list is empty:

1. Remove the first observation from the list, such as observation x_i.
2. For each cluster k, compute r_{ik}.
3. If the maximum over clusters of r_{ik} exceeds the value of the THRESHOLD= option, assign observation x_i to the corresponding cluster and insert all observations of which the current observation is a neighbor into the list, keeping the list in decreasing order of estimated density.

METHOD=6 is related to a method invented by Koontz and Fukunaga (1972a) and discussed by Koontz and Fukunaga (1972b).

Significance Tests

Significance tests require that a fixed-radius kernel be specified for density estimation via the DR= or R= option. You can also specify the DK= or K= option, but only the fixed radius is used for the significance tests.

The purpose of the significance tests is as follows: given a simple random sample of objects from a population, obtain an estimate of the number of clusters in the population such that the probability in repeated sampling that the estimate exceeds the true number of clusters is not much greater than α, $1\% \leq \alpha \leq 10\%$. In other words, a sequence of null hypotheses of the form

$H_0^{(i)}$: The number of population clusters is i or less

where $i = 1, 2, \cdots, n$, is tested against the alternatives such as

$H_a^{(i)}$: The number of population clusters exceeds i

with a maximum experimentwise error rate of approximately α. The tests protect you from overestimating the number of population clusters. It is impossible to protect against underestimating the number of population clusters without introducing much stronger assumptions than are used here, since the number of population clusters could conceivably exceed the sample size.

The method for conducting significance tests is as follows:

1. Estimate densities by using fixed-radius uniform kernels.
2. Obtain preliminary clusters by a "valley-seeking" method. Other clustering methods could be used but would yield less power.
3. Compute an approximate p-value for each cluster by comparing the estimated maximum density in the cluster with the estimated maximum density on the cluster boundary.
4. Repeatedly join the least significant cluster with a neighboring cluster until all remaining clusters are significant.
5. Estimate the number of population clusters as the number of significant sample clusters.
6. The preceding steps can be repeated for any number of different radii, and the estimate of the number of population clusters can be taken to be the maximum number of significant sample clusters for any radius.

This method has the following useful features:

- No distributional assumptions are required.
- The choice of smoothing parameter is not critical since you can try any number of different values.
- The data can be coordinates or distances.
- Time and space requirements for the significance tests are no worse than those for obtaining the clusters.
- The power is high enough to be useful for practical purposes.

The method for computing the p-values is based on a series of plausible approximations. There are as yet no rigorous proofs that the method is infallible. Neither are there any asymptotic results. However, simulations for sample sizes ranging from 20 to 2000 indicate that the p-values are almost always conservative. The only case discovered so far in which the p-values are liberal is a uniform distribution in one dimension for which the simulated error rates exceed the nominal significance level only slightly for a limited range of sample sizes.

To make inferences regarding population clusters, it is first necessary to define what is meant by a cluster. For clustering methods that use nonparametric density estimation, a cluster is usually loosely defined as a region surrounding a local maximum of the probability density function or a maximal connected set of local

maxima. This definition might not be satisfactory for very rough densities with many local maxima. It is not applicable at all to discrete distributions for which the density does not exist. As another example in which this definition is not intuitively reasonable, consider a uniform distribution in two dimensions with support in the shape of a figure eight (including the interior). This density might be considered to contain two clusters even though it does not have two distinct modes.

These difficulties can be avoided by defining clusters in terms of the local maxima of a smoothed probability density or mass function. For example, define the neighborhood distribution function (NDF) with radius r at a point x as the probability that a randomly selected point will lie within a radius r of x—that is, the probability integral over a hypersphere of radius r centered at x:

$$s(x) \quad = \quad P(\mathrm{d}(x, X) <= r)$$

where X is the random variable being sampled, r is a user-specified radius, and d(x,y) is the distance between points x and y.

The NDF exists for all probability distributions. You can select the radius according to the degree of resolution required. The minimum-variance unbiased estimate of the NDF at a point x is proportional to the uniform-kernel density estimate with corresponding support.

You can define a *modal region* as a maximal connected set of local maxima of the NDF. A cluster is a connected set containing exactly one modal region. This definition seems to give intuitively reasonable results in most cases. An exception is a uniform density on the perimeter of a square. The NDF has four local maxima. There are eight local maxima along the perimeter, but running PROC MODECLUS with the R= option would yield four clusters since the two local maxima at each corner are separated by a distance equal to the radius. While this density does indeed have four distinctive features (the corners), it is not obvious that each corner should be considered a cluster.

The number of population clusters depends on the radius of the NDF. The significance tests in PROC MODECLUS protect against overestimating the number of clusters at any specified radius. It is often useful to look at the clustering results across a range of radii. A plot of the number of sample clusters as a function of the radius is a useful descriptive display, especially for high-dimensional data (Wong and Schaack 1982).

If a population has two clusters, it must have two modal regions. If there are two modal regions, there must be a "valley" between them. It seems intuitively desirable that the boundary between the two clusters should follow the bottom of this valley. All the clustering methods in PROC MODECLUS are designed to locate the estimated cluster boundaries in this way, although methods 1 and 6 seem to be much more successful at this than the others. Regardless of the precise location of the cluster boundary, it is clear that the maximum of the NDF along the boundary between two clusters must be strictly less than the value of the NDF in either modal region; otherwise, there would be only a single modal region; according to Hartigan and Hartigan (1985), there must be a "dip" between the two modes. PROC MODECLUS assesses the significance of a sample cluster by comparing the NDF in the modal region with the maximum of the NDF along the cluster boundary. If the NDF has second-order derivatives in the region of interest and if the boundary between the two clusters is indeed at the bottom of the valley, then the maximum value of the NDF along the boundary occurs at a saddle point. Hence, this test is called a *saddle test*. This term is intended to describe any test for clusters that compares modal densities with saddle densities, not just the test currently implemented in the MODECLUS procedure.

The obvious estimate of the maximum NDF in a sample cluster is the maximum estimated NDF at an observation in the cluster. Let $m(k)$ be the index of the observation for which the maximum is attained in cluster k.

Estimating the maximum NDF on the cluster boundary is more complicated. One approach is to take the maximum NDF estimate at an observation in the cluster that has a neighbor belonging to another cluster. This method yields excessively large estimates when the neighborhood is large. Another approach is to try to choose an object closer to the boundary by taking the observation with the maximum sum of estimated densities of neighbors belonging to a different cluster. After some experimentation, it is found that a combination of these two methods works well. Let B_k be the set of indices of observations in cluster k that have neighbors belonging to a different cluster, and compute

$$\max_{i \in B_k} \left(0.2 \hat{f}_i n_i + \sum_{j \in N_i - C_k} \hat{f}_j \right)$$

Let $s(k)$ be the index of the observation for which the maximum is attained.

Using the notation $\#(S)$ for the cardinality of set S, let

$$\begin{aligned}
n_{ij}^- &= \#(N_i^- \cap N_j^-) \\
c_m(k) &= n_{m(k)}^- - n_{m(k)s(k)}^- \\
c_s(k) &= n_{s(k)}^- - n_{m(k)s(k)}^- \text{ if } B_k \neq \emptyset, \\
&= 0 \text{ otherwise} \\
q_k &= 1/2 \text{ if } B_k \neq \emptyset, \\
&= 2/3 \text{ otherwise} \\
z_k &= \frac{c_m(k) - q_k(c_m(k) + c_s(k)) - 1/2}{\sqrt{q_k(1-q_k)(c_m(k) + c_s(k))}} \\
u &= \left\lceil (0.2 + 0.05\sqrt{n}) \sum_{i:n_i > 1} \frac{1}{n_i + 1} \right\rceil
\end{aligned}$$

Let $R(u)$ be a random variable distributed as the range of a random sample of u observations from a standard normal distribution. Then the approximate p-value p_k for cluster k is

$$p_k = Pr(z_k > R(u)/\sqrt{2})$$

If points $m(k)$ and $s(k)$ are fixed a priori, z_k would be the usual approximately normal test statistic for comparing two binomial random variables. In fact, $m(k)$ and $s(k)$ are selected in such a way that $c_m(k)$ tends to be large and $c_s(k)$ tends to be small. For this reason, and because there might be a large number of clusters, each with its own z_k to be tested, each z_k is referred to the distribution of $R(u)$ instead of a standard normal distribution. If the tests are conducted for only one radius and if u is chosen equal to n, then the p-values are very conservative because (1) you are not making all possible pairwise comparisons of observations in the sample and (2) n_i^- and n_j^- are positively correlated if the neighborhoods overlap. In the

formula for u, the summation overcorrects somewhat for the conservativeness due to correlated n_i^-'s. The factor $0.2 + 0.05\sqrt{n}$ is empirically estimated from simulation results to adjust for the use of more than one radius.

If the JOIN option is specified, the least significant cluster (the cluster with the smallest z_k) is either dissolved or joined with a neighboring cluster. If no members of the cluster have neighbors belonging to a different cluster, all members of the cluster are unassigned. Otherwise, the cluster is joined to the neighboring cluster such that the sum of density estimates of neighbors of the estimated saddle point belonging to it is a maximum. Joining clusters increases the power of the saddle test. For example, consider a population with two well-separated clusters. Suppose that, for a certain radius, each population cluster is divided into two sample clusters. None of the four sample clusters is likely to be significant, but after the two sample clusters corresponding to each population cluster are joined, the remaining two clusters can be highly significant.

The saddle test implemented in PROC MODECLUS has been evaluated by simulation from known distributions. Some results are given in the following three tables. In Table 59.3, samples of 20 to 2000 observations are generated from a one-dimensional uniform distribution. For sample sizes of 1000 or less, 2000 samples are generated and analyzed by PROC MODECLUS. For a sample size of 2000, only 1000 samples are generated. The analysis is done with at least 20 different values of the R= option spread across the range of radii most likely to yield significant results. The six central columns of the table give the observed error rates at the nominal error rates (α) at the head of each column. The standard errors of the observed error rates are given at the bottom of the table. The observed error rates are conservative for $\alpha \leq 5\%$, but they increase with α and become slightly liberal for sample sizes in the middle of the range tested.

Table 59.3 Observed Error Rates (%) for Uniform Distribution

Sample Size	Nominal Type 1 Error Rate						Number of Simulations
	1	2	5	10	15	20	
20	0.00	0.00	0.00	0.60	11.65	27.05	2000
50	0.35	0.70	4.50	10.95	20.55	29.80	2000
100	0.35	0.85	3.90	11.05	18.95	28.05	2000
200	0.30	1.35	4.00	10.50	18.60	27.05	2000
500	0.45	1.05	4.35	9.80	16.55	23.55	2000
1000	0.70	1.30	4.65	9.55	15.45	19.95	2000
2000	0.40	1.10	3.00	7.40	11.50	16.70	1000
Standard	0.22	0.31	0.49	0.67	0.80	0.89	2000
Error	0.31	0.44	0.69	0.95	1.13	1.26	1000

All unimodal distributions other than the uniform that have been tested, including normal, Cauchy, and exponential distributions and uniform mixtures, have produced much more conservative results. Table 59.4 displays results from a unimodal mixture of two normal distributions with equal variances and equal sampling probabilities and with means separated by two standard deviations. Any greater separation would produce a bimodal distribution. The observed error rates are quite conservative.

Table 59.4 Observed Error Rates (%) for Normal Mixture with 2σ Separation

Sample Size	Nominal Type 1 Error Rate						Number of Simulations
	1	2	5	10	15	20	
100	0.0	0.0	0.0	1.0	2.0	4.0	200
200	0.0	0.0	0.0	2.0	3.0	3.0	200
500	0.0	0.0	0.5	0.5	0.5	0.5	200

All distributions in two or more dimensions that have been tested yield extremely conservative results. For example, a uniform distribution on a circle yields observed error rates that are never more than one-tenth of the nominal error rates for sample sizes up to 1000. This conservatism is due to the fact that, as the dimensionality increases, more and more of the probability lies in the tails of the distribution (Silverman 1986, p. 92), and the saddle test used by PROC MODECLUS is more conservative for distributions with pronounced tails. This applies even to a uniform distribution on a hypersphere because, although the density does not have tails, the NDF does.

Since the formulas for the significance tests do not involve the dimensionality, no problems are created when the data are linearly dependent. Simulations of data in nonlinear subspaces (the circumference of a circle or surface of a sphere) have also yielded conservative results.

Table 59.5 displays results in terms of power for identifying two clusters in samples from a bimodal mixture of two normal distributions with equal variances and equal sampling probabilities separated by four standard deviations. In this simulation, PROC MODECLUS never indicated more than two significant clusters.

Table 59.5 Power (%) for Normal Mixture with 4σ Separation

Sample Size	Nominal Type 1 Error Rate						Number of Simulations
	1	2	5	10	15	20	
20	0.0	0.0	0.0	2.0	37.5	68.5	200
35	0.0	13.5	38.5	48.5	64.0	75.5	200
50	17.5	26.0	51.5	67.0	78.5	84.0	200
75	25.5	36.0	58.5	77.5	85.5	89.5	200
100	40.0	54.5	72.5	84.5	91.5	92.5	200
150	70.5	80.0	92.0	97.0	100.0	100.0	200
200	89.0	96.0	99.5	100.0	100.0	100.0	200

The saddle test is not as efficient as excess-mass tests for multimodality (Müller and Sawitzki 1991; Polonik 1993). However, there is not yet a general approximation for the distribution of excess-mass statistics to circumvent the need for simulations to do significance tests. See Minnotte (1992) for a review of tests for multimodality.

Computational Resources

The MODECLUS procedure stores coordinate data in memory if there is enough space. For distance data, only one observation at a time is in memory.

PROC MODECLUS constructs lists of the neighbors of each observation. The total space required is $12 \sum n_i$ bytes, where n_i is based on the largest neighborhood required by any analysis. The lists are stored in a SAS utility data set unless you specify the CORE option. You might get an error message from the SAS System or from the operating system if there is not enough disk space for the utility data set. Clustering method 6 requires a second list that is always stored in memory.

For coordinate data, the time required to construct the neighbor lists is roughly proportional to $v(\log n)(\sum n_i) \log(\sum n_i / n)$. For distance data, the time is roughly proportional to $n^2 \log(\sum n_i / n)$.

The time required for density estimation is proportional to $\sum n_i$ and is usually small compared to the time required for constructing the neighbor lists.

Clustering methods 0 through 3 are quite efficient, requiring time proportional to $\sum n_i$. Methods 4 and 5 are slower, requiring time roughly proportional to $(\sum n_i) \log(\sum n_i)$. Method 6 can also be slow, but the time requirements depend very much on the data and the particular options specified. Methods 4, 5, and 6 also require more memory than the other methods.

The time required for significance tests is roughly proportional to $g \sum n_i$, where g is the number of clusters.

PROC MODECLUS can process data sets of several thousand observations if you specify reasonable smoothing parameters. Very small smoothing values produce many clusters, whereas very large values produce many neighbors; either case can require excessive time or space.

Missing Values

If the data are coordinates, observations with missing values are excluded from the analysis.

If the data are distances, missing values are treated as infinite. The neighbors of each observation are determined solely by the distances in that observation. The distances are not required to be symmetric, and there is no check for symmetry; the neighbors of each observation are determined only from the distances in that observation. This treatment of missing values is quite different from that of the CLUSTER procedure, which ignores the upper triangle of the distance matrix.

Output Data Sets

The OUT= data set contains one complete copy of the input data set for each cluster solution. There are additional variables identifying each solution and giving information about individual observations. Solutions with only one remaining cluster when JOIN=*p* is specified are omitted from the OUT= data set (see the description of the JOIN= option). The OUT= data set can be extremely large, so it is advisable to specify the DROP= data set option to exclude unnecessary variables.

The OUTCLUS= or OUTC= data set contains one observation for each cluster in each cluster solution. The variables identify the solution and provide statistics describing the cluster.

The OUTSUM= or OUTS= data set contains one observation for each cluster solution. The variables identify the solution and provide information about the solution as a whole.

The following variables can appear in all of the output data sets:

- _K_, which is the value of the K= option for the current solution. This variable appears only if you specify the K= option.
- _DK_, which is the value of the DK= option for the current solution. This variable appears only if you specify the DK= option.
- _CK_, which is the value of the CK= option for the current solution. This variable appears only if you specify the CK= option.
- _R_, which is the value of the R= option for the current solution. This variable appears only if you specify the R= option.
- _DR_, which is the value of the DR= option for the current solution. This variable appears only if you specify the DR= option.
- _CR_, which is the value of the CR= option for the current solution. This variable appears only if you specify the CR= option.
- _CASCAD_, which is the number of times the density estimates have been cascaded for the current solution. This variable appears only if you specify the CASCADE= option.
- _METHOD_, which is the value of the METHOD= option for the current solution. This variable appears only if you specify the METHOD= option.
- _NJOIN_, which is the number of clusters that are joined or dissolved in the current solution. This variable appears only if you specify the JOIN option.
- _LOCAL_, which is the local dimensionality estimate of the observation. This variable appears only if you specify the LOCAL option.

The OUT= data set contains the following variables:

- the variables from the input data set
- _OBS_, which is the observation number from the input data set. This variable appears only if you omit the ID statement.
- DENSITY, which is the estimated density at the observation. This variable can be renamed by the DENSITY= option.
- CLUSTER, which is the number of the cluster to which the observation is assigned. This variable can be renamed by the CLUSTER= option.

The OUTCLUS= data set contains the following variables:

- the BY variables, if any
- _NCLUS_, which is the number of clusters in the solution
- CLUSTER, which is the number of the current cluster
- _FREQ_, which is the number of observations in the cluster
- _MODE_, which is the maximum estimated density in the cluster
- _BFREQ_, which is the number of observations in the cluster with neighbors belonging to a different cluster
- _SADDLE_, which is the estimated saddle density for the cluster
- _MC_, which is the number of observations within the fixed-radius density-estimation neighborhood of the modal observation. This variable appears only if you specify the TEST or JOIN option.
- _SC_, which is the number of observations within the fixed-radius density-estimation neighborhood of the saddle observation. This variable appears only if you specify the TEST or JOIN option.
- _OC_, which is the number of observations within the overlap of the two previous neighborhoods. This variable appears only if you specify the TEST or JOIN option.
- _Z_, which is the approximate z statistic for the cluster. This variable appears only if you specify the TEST or JOIN option.
- _P_, which is the approximate p-value for the cluster. This variable appears only if you specify the TEST or JOIN option.

The OUTSUM= data set contains the following variables:

- the BY variables, if any
- _NCLUS_, which is the number of clusters in the solution
- _UNCL_, which is the number of unclassified observations
- _CROSS_, which is the likelihood cross validation criterion if you specify the CROSS or CROSSLIST option

Displayed Output

If you specify the SIMPLE option and the data are coordinates, PROC MODECLUS displays the following simple descriptive statistics for each variable:

- the mean
- the standard deviation
- the skewness
- the kurtosis
- a coefficient of bimodality (see Chapter 30, "The CLUSTER Procedure")

If you specify the NEIGHBOR option, PROC MODECLUS displays a list of neighbors for each observation. The table contains the following items:

- the observation number or ID value of the observation
- the observation number or ID value of each of its neighbors
- the distance to each neighbor

If you specify the CROSSLIST option, PROC MODECLUS produces a table of information regarding cross validation of the density estimates. Each table has a row for each observation. For each observation, the following are displayed:

- the observation number or ID value of the observation
- the radius of the neighborhood
- the number of neighbors
- the estimated log density
- the estimated cross validated log density

If you specify the LOCAL option, PROC MODECLUS produces a table of information regarding estimates of local dimensionality. Each table has a row for each observation. For each observation, the following are displayed:

- the observation number or ID value of the observation
- the radius of the neighborhood
- the estimated local dimensionality

If you specify the LIST option, PROC MODECLUS produces a table listing the observations within each cluster. The table includes the following items:

- the cluster number
- the observation number or ID value of the observation

- the estimated density
- the sum of the density estimates of observations within the neighborhood that belong to the same cluster
- the sum of the density estimates of observations within the neighborhood that belong to a different cluster
- the sum of the density estimates of all the observations within the neighborhood
- the ratio of the sum of the density estimates for the same cluster to the sum of all the density estimates in the neighborhood

If you specify the LIST option and there are unassigned objects, PROC MODECLUS produces a table listing those observations. The table includes the following items:

- the observation number or ID value of the observation
- the estimated density
- the ratio of the sum of the density estimates for the same cluster to the sum of the density estimates in the neighborhood for all other clusters

If you specify the BOUNDARY option, PROC MODECLUS produces a table listing the observations in each cluster that have a neighbor belonging to a different cluster. The table includes the following items:

- the observation number or ID value of the observation
- the estimated density
- the cluster number
- the ratio of the sum of the density estimates for the same cluster to the sum of the density estimates in the neighborhood for all other clusters

If you do not specify the SHORT option, PROC MODECLUS produces a table of cluster statistics including the following items:

- the cluster number
- the cluster frequency (the number of observations in the cluster)
- the maximum estimated density within the cluster
- the number of observations in the cluster having a neighbor that belongs to a different cluster
- the estimated saddle density of the cluster

If you specify the TEST or JOIN option, the table of cluster statistics includes the following items pertaining to the saddle test:

- the number of observations within the fixed-radius density-estimation neighborhood of the modal observation
- the number of observations within the fixed-radius density-estimation neighborhood of the saddle observation

- the number of observations within the overlap of the two preceding neighborhoods
- the z statistic for comparing the preceding counts
- the approximate p-value

If you do not specify the NOSUMMARY option, PROC MODECLUS produces a table summarizing each cluster solution containing the following items:

- the smoothing parameters and cascade value
- the number of clusters
- the frequency of unclassified objects
- the likelihood cross validation criterion if you specify the CROSS or CROSSLIST option

If you specify the JOIN option, the summary table also includes the following items:

- the number of clusters joined
- the maximum p-value of any cluster in the solution

If you specify the TRACE option, PROC MODECLUS produces a table for each cluster solution that lists each observation along with its cluster membership as it is reassigned from the "Old" cluster to the "New" cluster. This reassignment is described in **Step 1** through **Step 3** of the section "METHOD=6" on page 4939. Each table has a row for each observation. For each observation, the following are displayed:

- the observation number or ID value of the observation
- the estimated density
- the "Old" cluster membership. 0 represents an unassigned observation and –1 represents a seed.
- the "New" cluster membership
- "Ratio," which is documented in the section "METHOD=6" on page 4939. The following character values can also be displayed:

  "M" means the observation is a mode

  "S" means the observation is a seed

  "N" means the neighbor of a mode or seed, for which the ratio is not computed

ODS Table Names

PROC MODECLUS assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 59.6.

For more information about ODS, see Chapter 20, "Using the Output Delivery System."

All of the ODS tables in Table 59.6 are created by specifying the PROC MODECLUS statement.

Table 59.6 ODS Tables Produced by PROC MODECLUS

ODS Table Name	Description	Option
BoundaryFreq	Boundary objects information	BOUNDARY or ALL
ClusterList	Cluster listing, cluster ID, frequency, density etc.	LIST or ALL
ClusterStats	Cluster statistics	default
	Cluster statistics, significance test statistics	TEST, JOIN, or ALL
ClusterSummary	Cluster summary	default
	Cluster summary, crossvalidation criterion	CROSS, CROSSLIS, or ALL
	Cluster summary, clusters joined information	JOIN or ALL
CrossList	Cross validated log density	CROSSLIST
ListLocal	Local dimensionality estimates	LOCAL
Neighbor	Nearest neighbor list	NEIGHBOR or ALL
SimpleStatistics	Simple statistics	SIMPLE or ALL
Trace	Trace of clustering algorithm (METHOD=6 only)	TRACE or ALL when METHOD=6
UnassignObjects	Information about unassigned objects	LIST or ALL

Examples: MODECLUS Procedure

Example 59.1: Cluster Analysis of Samples from Univariate Distributions

This example uses pseudo-random samples from a uniform distribution, an exponential distribution, and a bimodal mixture of two normal distributions. Results are presented in Output 59.1.1 through Output 59.1.18 as plots displaying both the true density and the estimated density, as well as cluster membership.

The following statements produce Output 59.1.1 through Output 59.1.4:

```
title 'Modeclus Example with Univariate Distributions';
title2 'Uniform Distribution';

data uniform;
   drop n;
   true=1;
   do n=1 to 100;
      x=ranuni(123);
      output;
   end;
run;

proc modeclus data=uniform m=1 k=10 20 40 60 out=out short;
   var x;
run;

proc sgplot data=out noautolegend;
   y2axis label='True' values=(0 to 2 by 1.);
   yaxis values=(0 to 3 by 0.5);
   scatter y=density x=x / markerchar=cluster group=cluster;
   pbspline y=true x=x / y2axis nomarkers lineattrs=(thickness= 1);
   by _K_;
run;

proc modeclus data=uniform m=1 r=.05 .10 .20 .30 out=out short;
   var x;
run;

proc sgplot data=out noautolegend;
   y2axis label='True' values=(0 to 2 by 1.);
   yaxis values=(0 to 2 by 0.5);
   scatter y=density x=x / markerchar=cluster group=cluster;
   pbspline y=true x=x / y2axis nomarkers lineattrs=(thickness= 1);
   by _R_;
run;
```

Example 59.2: Cluster Analysis of Flying Mileages between Ten American Cities

This example uses distance data and illustrates the use of the TRANSPOSE procedure and the DATA step to fill in the upper triangle of the distance matrix. A data set containing a table of flying mileages between 10 U.S. cities is available in the Sashelp library. The results are displayed in Output 59.2.1 through Output 59.2.3.

The following statements produce Output 59.2.1:

```
title 'Modeclus Analysis of 10 American Cities';
title2 'Based on Flying Mileages';

*-----Fill in Upper Triangle of Distance Matrix---------------;
proc transpose data=sashelp.mileages out=tran;
   copy city;
run;

data mileages(type=distance drop=col: _: i);
   merge sashelp.mileages tran;
   array var[10] atlanta--washingtondc;
   array col[10];
   do i = 1 to 10;
      var[i] = sum(var[i], col[i]);
   end;
run;

*-----Clustering with K-Nearest-Neighbor Density Estimates-----;
proc modeclus data=mileages all m=1 k=3;
   id CITY;
run;
```

Example 59.3: Cluster Analysis with Significance Tests

This example uses artificial data containing two clusters. One cluster is from a circular bivariate normal distribution. The other is a ring-shaped cluster that completely surrounds the first cluster. Without significance tests, the ring is divided into several sample clusters for any degree of smoothing that yields reasonable density estimates. The JOIN= option puts the ring back together. Output 59.3.1 displays a short summary generated from the first PROC MODECLUS statement. Output 59.3.2 contains a series of tables produced from the second PROC MODECLUS statement. The lack of *p*-value in the JOIN= option makes joining continue until only one cluster remains (see the description of the JOIN= option). The cluster memberships are then plotted as displayed in Output 59.3.1 through Output 59.3.8.

The following statements produce Output 59.3.1 through Output 59.3.8:

```
title  'Modeclus Analysis with the JOIN= option';
title2 'A Normal Cluster Surrounded by a Ring Cluster';

data circle; keep x y;
   c=1;
   do n=1 to 30;
      x=rannor(5);
      y=rannor(5);
      output;
   end;

   c=2;
   do n=1 to 300;
      x=rannor(5);
      y=rannor(5);
      z=rannor(5)+8;
      l=z/sqrt(x**2+y**2);
      x=x*l;
      y=y*l;
      output;
   end;
run;
```

```
proc modeclus data=circle m=1 r=1 to 3.5 by .25 join=20 short;
run;

proc modeclus data=circle m=1 r=2.5 join out=out;
run;

proc sgplot data=out noautolegend;
   yaxis values=(-10 to 10 by 5);
   xaxis values=(-15 to 15 by 5);
   scatter y=y x=x / group=cluster Markerchar=cluster;
   by _NJOIN_;
run;
```

Example 59.4: Cluster Analysis: Hertzsprung-Russell Plot

This example uses computer-generated data to mimic a Hertzsprung-Russell plot (Struve and Zebergs 1962, p. 259) of the temperature and luminosity of stars. The data are plotted and displayed in Output 59.4.1. It appears that there are two main groups of stars and a collection of isolated stars. The long straggling group of points appearing diagonally across the figure represents the main group of stars; the more compact group in the top-right corner contains giant stars. The JOIN= option is specified at a 0.05 significance level with various smoothing parameters. The CK=5 option is specified in order to prevent the numerous outliers from forming separate clusters. The results from PROC MODECLUS is displayed in Output 59.4.2. The cluster memberships are then plotted by PROC SGPLOT, as displayed in Output 59.4.3 through Output 59.4.5.

Note that the graphic output from PROC SGPLOT in Output 59.4.3 is not available when _R_ = 2.5 because only one cluster remains after joining at a 5% significance level, and the results are not written to the OUT= data set. See the description of the JOIN= option). for more information.

The following statements produce Output 59.4.1 through Output 59.4.5:

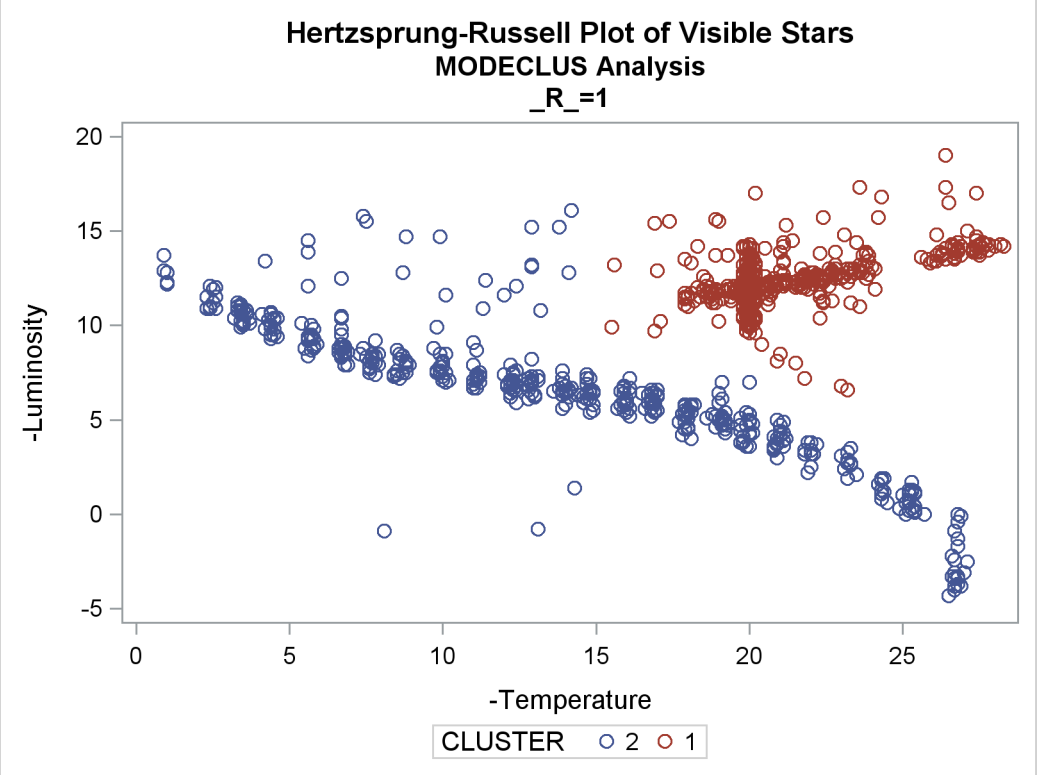
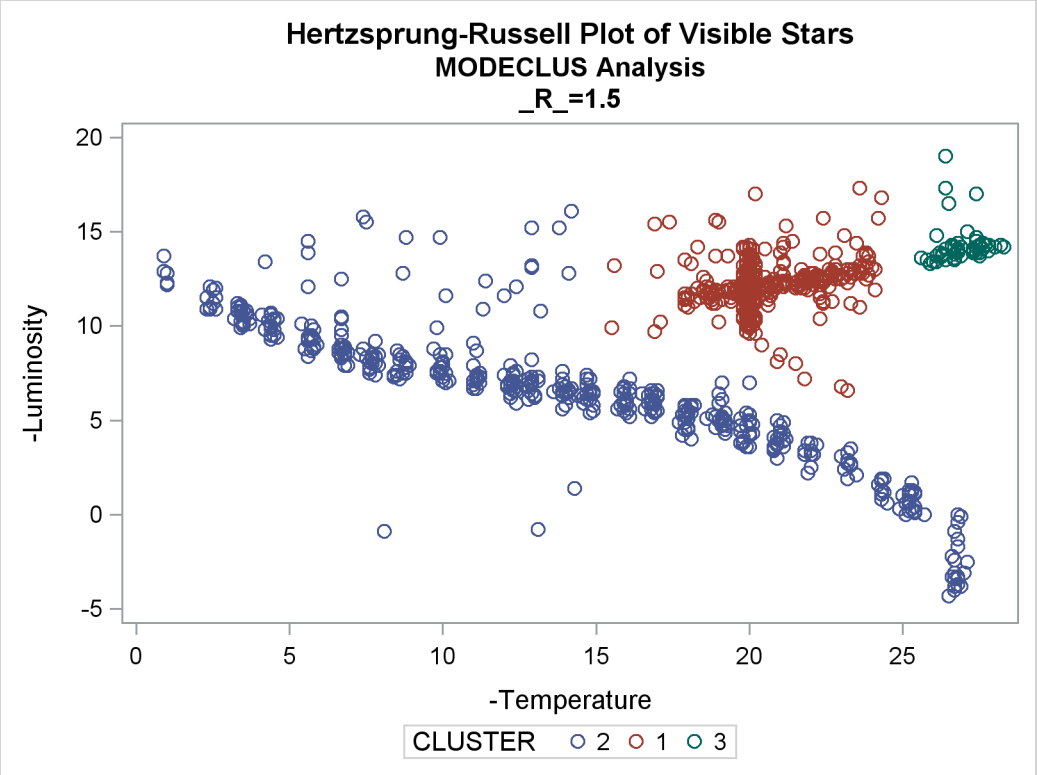
Cluster Summary

R	CK	Number of Clusters Joined	Maximum P-value	Number of Clusters	Frequency of Unclassified Objects
1	5	14	0.0001	2	0
1.5	5	6	0.0000	3	0
2	5	4	0.0000	2	0
2.5	5	2	0.0000	1	0

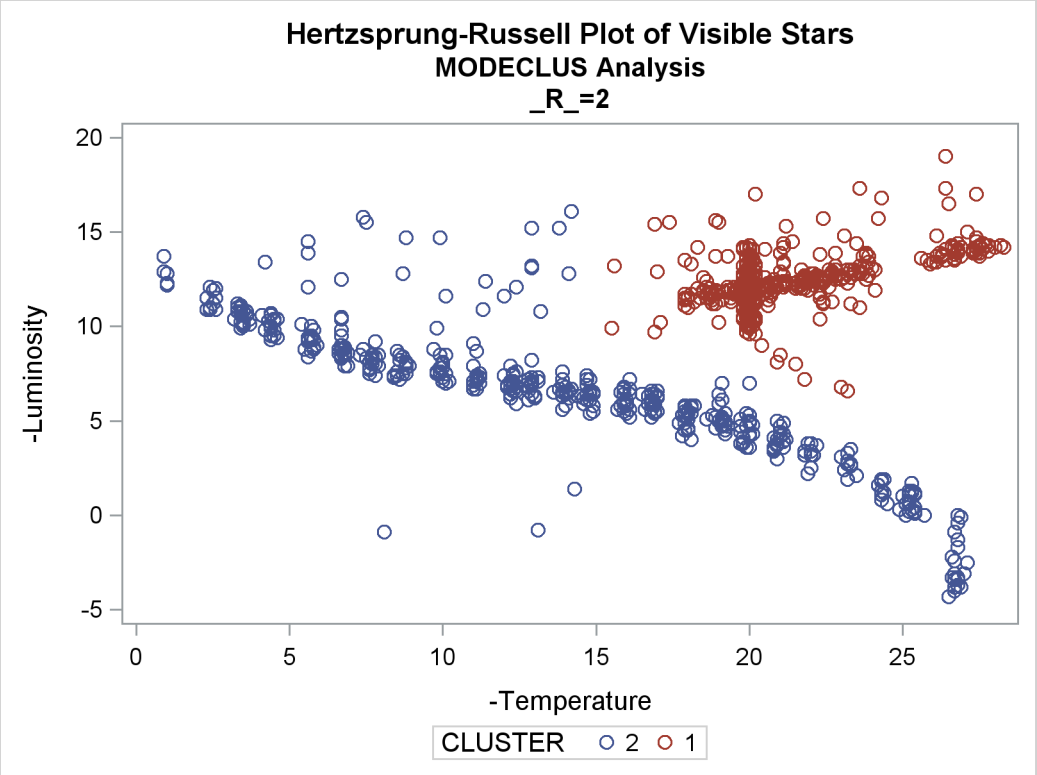
Output 59.4.3 Scatter Plots of Cluster Memberships by _R_= 1



Output 59.4.4 Scatter Plots of Cluster Memberships by _R_= 1.5



Output 59.4.5 Scatter Plots of Cluster Memberships by _R_=2



Example 59.5: Using the TRACE Option When METHOD=6

To illustrate how the TRACE option can help you to understand the clustering process when METHOD=6 is specified, the following data set is created with 12 observations:

```
data test;
   input x @@;
   datalines;
1 2 3 4 5 7.5 9 11.5 13 14.5 15 16
;
```

The first five observations seem to be close to each other, and the last five observations seem to be close to each other. Observation 6 is separated from the first five observations with a (Euclidean) distance of 2.5, and the same distance separates observation 7 from the last five observations. Observations 6 and 7 differ by 1.5.

Suppose METHOD=6 with a radius of 2.5 is chosen for the cluster analysis. You can specify the TRACE option to understand how each observation is assigned.

The following statements produce Output 59.5.1 and Output 59.5.2:

```
/*-- METHOD=6 with TRACE and THRESHOLD=0.5 (default) --*/
title 'METHOD=6 with TRACE and THRESHOLD=0.5 (default)';

proc modeclus data=test method=6 r=2.5 trace short out=out;
   var x;
run;

title2 'Plot of DENSITY*X=CLUSTER';

proc sgplot data=out;
   scatter y=density x=x / group=cluster datalabel=_obs_;
run;
```

Output 59.5.1 Partial Output of METHOD=6 with TRACE and Default THRESHOLD=

METHOD=6 with TRACE and THRESHOLD=0.5 (default)

The MODECLUS Procedure
R=2.5 METHOD=6

Trace of Clustering Algorithm

Obs	Density	Cluster Old	Cluster New	Ratio
3	0.0833333	−1	1	M
2	0.0666667	0	1	N
4	0.0666667	0	1	N
5	0.0666667	0	1	N
1	0.0500000	0	1	N
6	0.0500000	0	1	0.571
7	0.0500000	−1	1	0.500
9	0.0666667	−1	2	M
8	0.0500000	0	2	N
10	0.0666667	−1	2	S
12	0.0500000	0	2	N
11	0.0666667	−1	2	S

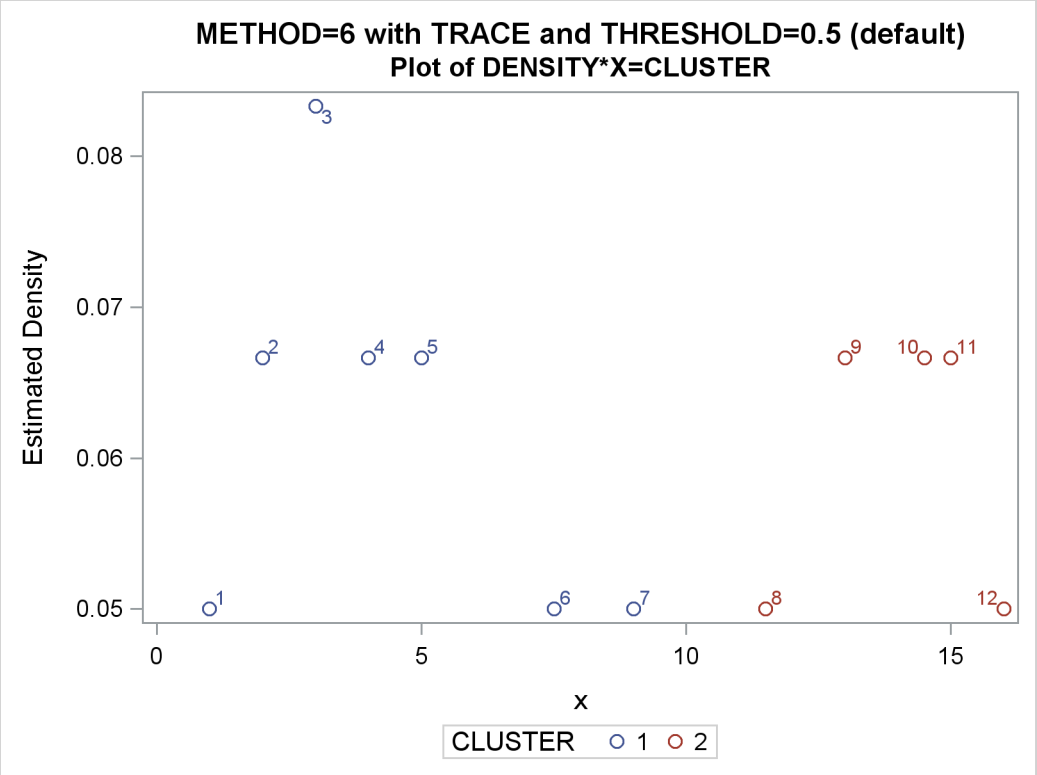
METHOD=6 with TRACE and THRESHOLD=0.5 (default)

The MODECLUS Procedure

Cluster Summary

R	Number of Clusters	Frequency of Unclassified Objects
2.5	2	0

Output 59.5.2 Density Plot



Note that in Output 59.5.1, observation 7 is originally a seed (indicated by a value of –1 in the "Old" column) and then assigned to cluster 1. This is because the ratio of observation 7 to cluster 1 is 0.5 and is not less than the default value of the THRESHOLD= option (0.5).

If the value of the THRESHOLD= option is increased to 0.55, observation 7 should be excluded from cluster 1 and the cluster membership of observation 7 is changed.

The following statements produce Output 59.5.3 and Output 59.5.4:

```
/*-- METHOD=6 with TRACE and THRESHOLD=0.55 --*/
title 'METHOD=6 with TRACE and THRESHOLD=0.55';

proc modeclus data=test method=6 r=2.5 trace threshold=0.55 short out=out;
   var x;
run;

title2 'Plot of DENSITY*X=CLUSTER with TRACE and THRESHOLD=0.55';

proc sgplot data=out;
   scatter y=density x=x / group=cluster datalabel=_obs_;
run;
```

Output 59.5.3 Partial Output of METHOD=6 with TRACE and THRESHOLD=.55

METHOD=6 with TRACE and THRESHOLD=0.55

The MODECLUS Procedure
R=2.5 METHOD=6

Trace of Clustering Algorithm

Obs	Density	Cluster Old	Cluster New	Ratio
3	0.0833333	-1	1	M
2	0.0666667	0	1	N
4	0.0666667	0	1	N
5	0.0666667	0	1	N
1	0.0500000	0	1	N
6	0.0500000	0	1	0.571
9	0.0666667	-1	2	M
8	0.0500000	0	2	N
10	0.0666667	-1	2	S
12	0.0500000	0	2	N
11	0.0666667	-1	2	S
7	0.0500000	-1	2	S

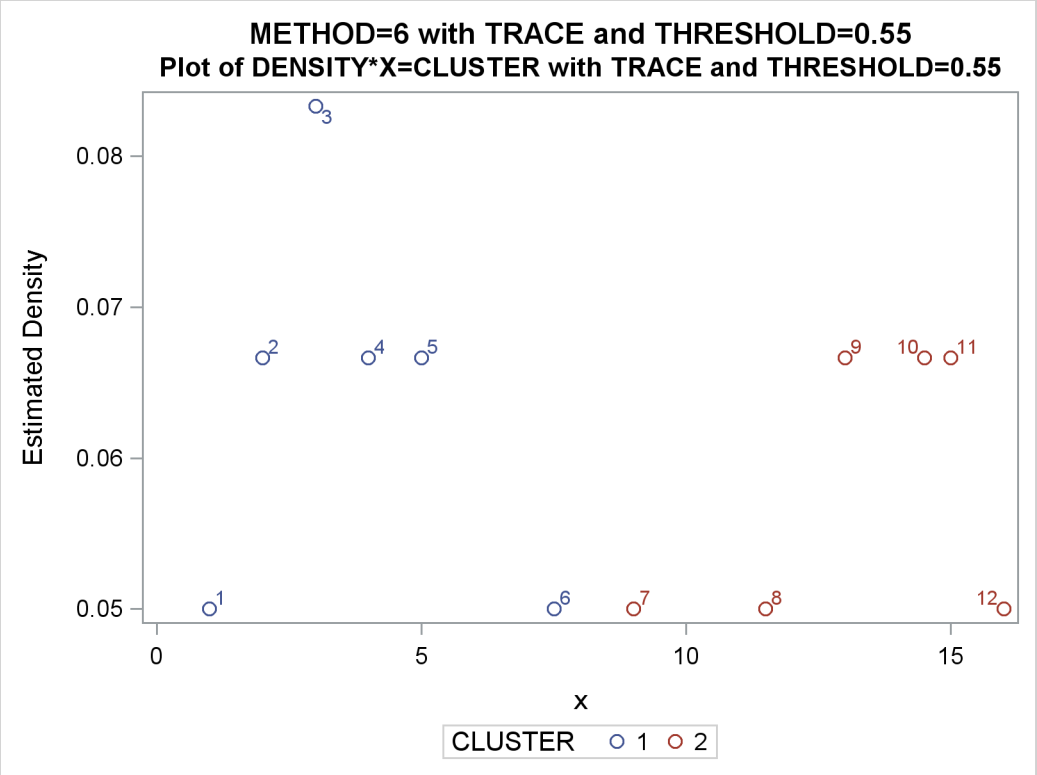
METHOD=6 with TRACE and THRESHOLD=0.55

The MODECLUS Procedure

Cluster Summary

R	Number of Clusters	Frequency of Unclassified Objects
2.5	2	0

Output 59.5.4 Density Plot



In Output 59.5.3, observation 7 is a seed that is excluded by cluster 1 because its ratio to cluster 1 is less than 0.55. Being a neighbor of a member (observation 8) of cluster 2, observation 7 eventually joins cluster 2 even though it remains a "SEED." (See **Step 2.2** in the section "METHOD=6" on page 4939.)

Chapter 60

The MULTTEST Procedure

Contents

Overview: MULTTEST Procedure

The MULTTEST procedure addresses the multiple testing problem. This problem arises when you perform many hypothesis tests on the same data set. Carrying out multiple tests is often reasonable because of the cost of obtaining data, the discovery of new aspects of the data, and the many alternative statistical methods. However, a disadvantage of multiple testing is the greatly increased probability of declaring false significances.

For example, suppose you carry out 10 hypothesis tests at the 5% level, and you assume that the distributions of the p-values from these tests are uniform and independent. Then, the probability of declaring a particular test significant under its null hypothesis is 0.05, but the probability of declaring at least 1 of the 10 tests significant is 0.401. If you perform 20 hypothesis tests, the latter probability increases to 0.642. These high chances illustrate the danger of multiple testing.

PROC MULTTEST approaches the multiple testing problem by adjusting the p-values from a family of hypothesis tests. An adjusted p-value is defined as the smallest significance level for which the given hypothesis would be rejected, when the entire family of tests is considered. The decision rule is to reject the null hypothesis when the adjusted p-value is less than α. For most methods, this decision rule controls the *familywise error rate* at or below the α level. However, the *false discovery rate* controlling procedures control the false discovery rate at or below the α level.

PROC MULTTEST provides the following p-value adjustments:

- Bonferroni
- Šidák
- step-down methods
- Hochberg
- Hommel
- Fisher and Stouffer combination
- bootstrap
- permutation
- adaptive methods
- false discovery rate
- positive FDR

The Bonferroni and Šidák adjustments are simple functions of the raw p-values. They are computationally quick, but they can be too conservative. Step-down methods remove some conservativeness, as do the step-up methods of Hochberg (1988), and the adaptive methods. The bootstrap and permutation adjustments resample the data with and without replacement, respectively, to approximate the distribution of the minimum p-value of all tests. This distribution is then used to adjust the individual raw p-values. The bootstrap and permutation methods are computationally intensive but appealing in that, unlike the other methods, correlations and distributional characteristics are incorporated into the adjustments (Westfall and Young 1989; Westfall et al. 1999).

PROC MULTTEST handles data arising from a multivariate one-way ANOVA model, possibly stratified, with continuous and discrete response variables; it can also accept raw p-values as input data. You can per-

form a *t* test for the mean for continuous data with or without a homogeneity assumption, and the following statistical tests for discrete data:

- Cochran-Armitage linear trend test
- Freeman-Tukey double arcsine test
- Peto mortality-prevalence (log-rank) test
- Fisher exact test

The Cochran-Armitage and Peto tests have exact versions that use permutation distributions and asymptotic versions that use an optional continuity correction. Also, with the exception of the Fisher exact test, you can use a stratification variable to construct Mantel-Haenszel-type tests. All of the previously mentioned tests can be one- or two-sided.

As in the GLM procedure, you can specify linear contrasts that compare means or proportions of the treated groups. The output contains summary statistics and regular and multiplicity-adjusted *p*-values. You can create output data sets containing raw and adjusted *p*-values, test statistics and other intermediate calculations, permutation distributions, and resampling information.

The MULTTEST procedure uses ODS Graphics to create graphs as part of its output. For general information about ODS Graphics, see Chapter 21, "Statistical Graphics Using ODS."

The GLIMMIX, GLM, MIXED, and LIFETEST procedures, and other procedures that implement the ESTIMATE, LSMEANS, LSMESTIMATE, and SLICE statements, also adjust their results for multiple tests. For more information, see the documentation for these procedures and statements, and Westfall et al. (1999).

Getting Started: MULTTEST Procedure

Drug Example

Suppose you conduct a small study to test the effect of a drug on 15 subjects. You randomly divide the subjects into three balanced groups receiving 0 mg, 1 mg, and 2 mg of the drug, respectively. You carry out the experiment and record the presence or absence of 10 side effects for each subject. Your data set is as follows:

```
data Drug;
   input Dose$ SideEff1-SideEff10;
   datalines;
0MG  0   0   1   0   0   1   0   0   0   0
0MG  0   0   0   0   0   0   0   0   0   1
0MG  0   0   0   0   0   0   0   0   1   0
0MG  0   0   0   0   0   0   0   0   0   0
0MG  0   1   0   0   0   0   0   0   0   0
1MG  1   0   0   1   0   1   0   0   1   0
1MG  0   0   0   1   1   0   0   1   0   1
```

```
1MG  0   1   0   0   0   0   1   0   0   0
1MG  0   0   1   0   0   0   0   0   0   1
1MG  1   0   1   0   0   0   0   1   0   0
2MG  0   1   1   1   0   1   1   1   0   1
2MG  1   1   1   1   1   1   0   1   1   0
2MG  1   0   0   1   0   1   1   0   1   0
2MG  0   1   1   1   1   0   1   1   1   1
2MG  1   0   1   0   1   1   1   0   0   1
;
```

The increasing incidence of 1s for higher dosages in the preceding data set provides an initial visual indication that the drug has an effect. To explore this statistically, you perform an analysis in which the possibility of side effects increases linearly with drug level. You can analyze the data for each side effect separately, but you are concerned that, with so many tests, there might be a high probability of incorrectly declaring some drug effects significant. You want to correct for this multiplicity problem in a way that accounts for the discreteness of the data and for the correlations between observations on the same unit.

PROC MULTTEST addresses these concerns by processing all of the data simultaneously and adjusting the *p*-values. The following statements perform a typical analysis:

```
ods graphics on;
proc multtest bootstrap nsample=20000 seed=41287 notables
              plots=PByTest(vref=0.05 0.1);
   class Dose;
   test ca(SideEff1-SideEff10);
   contrast 'Trend' 0 1 2;
run;
ods graphics off;
```

This analysis uses the BOOTSTRAP option to adjust the *p*-values. The NSAMPLE= option requests 20,000 samples for the bootstrap analysis, and the starting seed for the random number generator is 41287. The NOTABLES option suppresses the display of summary statistics for each side effect and drug level combination. The PLOTS= option displays a visual summary of the unadjusted and adjusted *p*-values against each test, and the VREF= option adds reference lines to the display.

The CLASS statement is used to specify the grouping variable, Dose. The **ca(sideeff1-sideeff10)** specification in the TEST statement requests a Cochran-Armitage linear trend test for all 10 characteristics. The CONTRAST statement gives the coefficients for the linear trend test.

The "Model Information" table in Figure 60.1 describes the statistical tests performed by PROC MULTTEST. For this example, PROC MULTTEST carries out a two-tailed Cochran-Armitage linear trend test with no continuity correction or strata adjustment. This test is performed on the raw data and on 20,000 bootstrap samples.

Figure 60.1 Output Summary for the MULTTEST Procedure

The Multtest Procedure

Model Information

Test for discrete variables	Cochran-Armitage
Z-score approximation used	Everywhere
Continuity correction	0
Tails for discrete tests	Two-tailed
Strata weights	None
P-value adjustment	Bootstrap
Number of resamples	20000
Seed	41287

The "Contrast Coefficients" table in Figure 60.2 displays the coefficients for the Cochran-Armitage test. They are 0, 1, and 2, as specified in the CONTRAST statement.

Figure 60.2 Coefficients Used in the MULTTEST Procedure

Contrast Coefficients

	Dose		
Contrast	0MG	1MG	2MG
Trend	0	1	2

The "p-Values" table in Figure 60.3 lists the *p*-values for the drug example. The Raw column lists the *p*-values for the Cochran-Armitage test on the original data, and the Bootstrap column provides the bootstrap adjustment of the raw *p*-values.

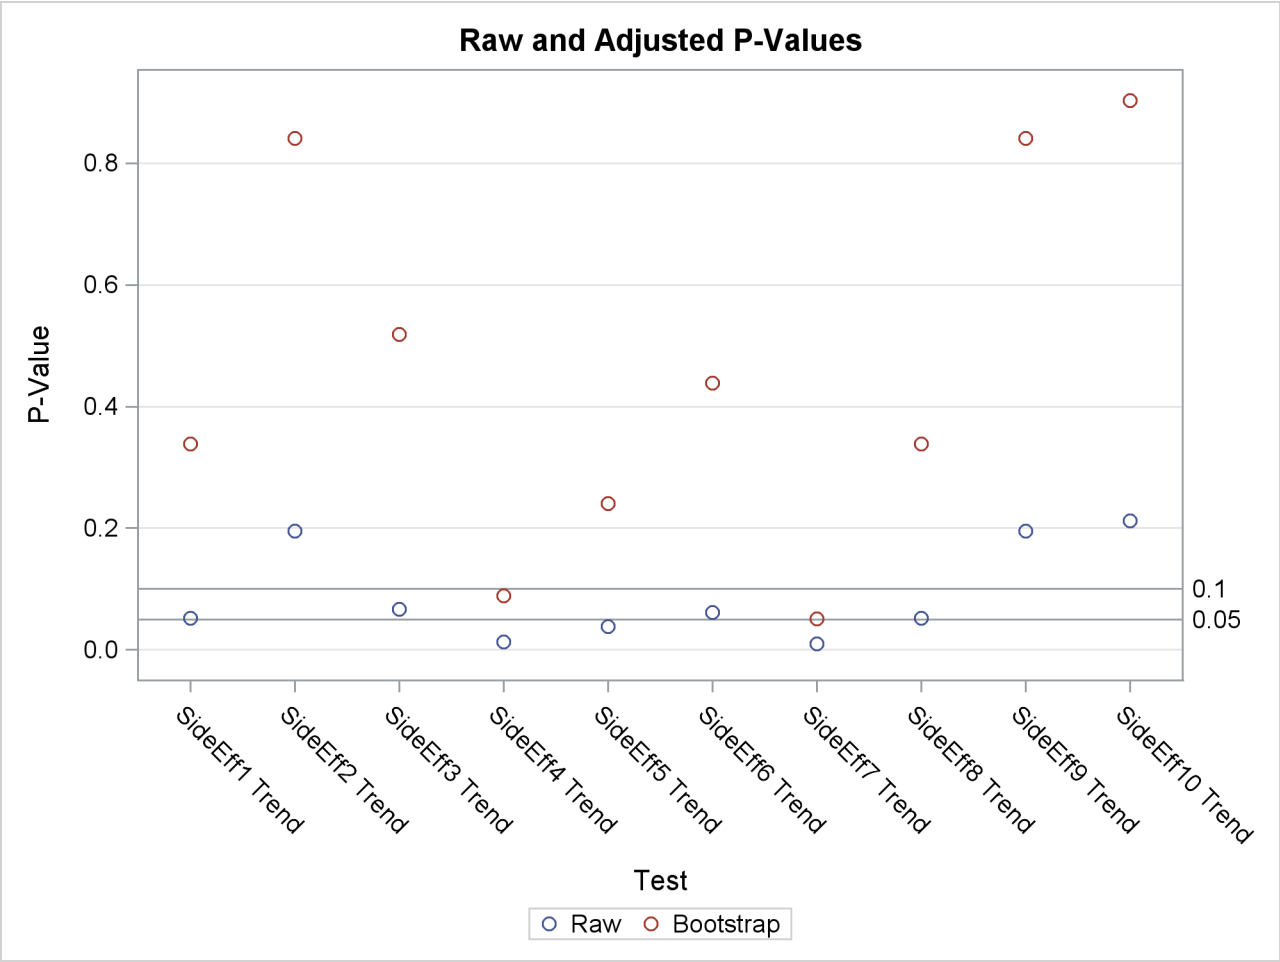
Note that the raw *p*-values lead you to reject the null hypothesis of no linear trend for 3 of the 10 characteristics at the 5% level and 7 of the 10 characteristics at the 10% level. The bootstrap *p*-values, however, lead to this conclusion for 0 of the 10 characteristics at the 5% level and only 2 of the 10 characteristics at the 10% level; you can also see this in Figure 60.4.

Figure 60.3 Summary of *p*-Values for the MULTTEST Procedure

p-Values

Variable	Contrast	Raw	Bootstrap
SideEff1	Trend	0.0519	0.3388
SideEff2	Trend	0.1949	0.8403
SideEff3	Trend	0.0662	0.5190
SideEff4	Trend	0.0126	0.0884
SideEff5	Trend	0.0382	0.2408
SideEff6	Trend	0.0614	0.4383
SideEff7	Trend	0.0095	0.0514
SideEff8	Trend	0.0519	0.3388
SideEff9	Trend	0.1949	0.8403
SideEff10	Trend	0.2123	0.9030

Figure 60.4 Adjusted *p*-Values



The bootstrap adjustment gives the probability of observing a *p*-value as extreme as each given *p*-value, considering all 10 tests simultaneously. This adjustment incorporates the correlation of the raw *p*-values, the discreteness of the data, and the multiple testing problem. Failure to account for these issues can certainly lead to misleading inferences for these data.

Syntax: MULTTEST Procedure

The following statements are available in PROC MULTTEST:

PROC MULTTEST < *options* > **;**
BY *variables* **;**
CLASS *variable* **;**
CONTRAST *'label' values* **;**
FREQ *variable* **;**
STRATA *variable* **;**
TEST *name (variables* < */ options* >*)* **;**

Statements following the PROC MULTTEST statement can appear in any order. The CLASS and TEST statements are required unless the INPVALUES= option is specified.

The syntax of each statement is described in the following section in alphabetical order after the description of the PROC MULTTEST statement.

PROC MULTTEST Statement

PROC MULTTEST < *options* > **;**

The PROC MULTTEST statement invokes the MULTTEST procedure and specifies the *p*-value adjustments. The options available in the PROC MULTTEST statement are listed in Table 60.1 grouped by their function, and are described in alphabetical order following the table.

Table 60.1 PROC MULTTEST Statement Options by Function

Option	Description
FWE-Controlling *p*-Value Adjustments	
ADAPTIVEHOLM	Computes the adaptive step-down Bonferroni adjustment
ADAPTIVEHOCHBERG	Computes the adaptive step-up Bonferroni adjustment
BONFERRONI	Computes the Bonferroni adjustment
BOOTSTRAP	Computes the bootstrap min-p adjustment
FISHER_C	Computes Fisher's combination adjustment
HOCHBERG	Computes the step-up Bonferroni adjustment
HOMMEL	Computes Hommel's adjustment
HOLM	Computes the step-down Bonferroni adjustment
PERMUTATION	Computes the permutation min-p adjustment
SIDAK	Computes Šidák's adjustment
STEPBON	Computes the step-down Bonferroni adjustment
STEPBOOT	Computes the step-down bootstrap adjustment
STEPPERM	Computes the step-down permutation adjustment
STEPSID	Computes the step-down Šidák adjustment
STOUFFER	Computes the Stouffer-Liptak combination adjustment

Table 60.1 *continued*

Option	Description
FDR-Controlling *p*-Value Adjustments	
ADAPTIVEFDR	Computes the adaptive linear step-up adjustment
DEPENDENTFDR	Computes the linear step-up adjustment under dependence
FDR	Computes the linear step-up adjustment
FDRBOOT	Computes the linear step-up bootstrap min-*p* adjustment
FDRPERM	Computes the linear step-up permutation min-*p* adjustment
PFDR	Computes the positive FDR adjustment
Input/Output Data Sets	
DATA=	Names the input data set
INPVALUES=	Names the input data set of raw *p*-values
OUT=	Names the output data set
OUTPERM=	Names the output permutation data set
OUTSAMP=	Names the output resample data set
Displayed Output Options	
NOPRINT	Suppresses all tables
NOTABLES	Suppresses variable tables
NOZEROS	Suppresses zero tables for CLASS variables
NOPVALUE	Suppresses the "p-Values" table
PLOTS	Requests ODS Graphics
Resampling Options	
CENTER	Mean-centers continuous variables before resampling
NOCENTER	Does not mean-center continuous variables before resampling
NSAMPLE=	Specifies the number of resamples
RANUNI	Specifies a different random number generator
SEED=	Specifies the seed for resampling
CLASS Variable Options	
NOZEROS	Suppresses zero tables for CLASS variables
ORDER=	Specifies CLASS variable order
Computational Options	
EPSILON=	Specifies the comparison value
NTRUENULL=	Specifies the estimation method for the number of true nulls
PTRUENULL=	Specifies the estimation method for the proportion of true nulls

You can specify the following options in the PROC MULTTEST statement.

ADAPTIVEHOCHBERG
AHOC

requests adjusted *p*-values by using the Hochberg and Benjamini (1990) adaptive step-up Bonferroni method. See the section "Adaptive Adjustments" on page 5038 for more details.

ADAPTIVEHOLM
AHOLM

requests adjusted *p*-values by using the Hochberg and Benjamini (1990) adaptive step-down Bonferroni method. See the section "Adaptive Adjustments" on page 5038 for more details.

ADAPTIVEFDR
AFDR

requests adjusted *p*-values by using the Benjamini and Hochberg (2000) adaptive linear step-up method. See the section "Adaptive False Discovery Rate" on page 5040 for more details.

BONFERRONI
BON

specifies that the Bonferroni adjustments (number of tests × *p*-value) be computed for each test. These adjustments can be extremely conservative and should be viewed with caution. When exact tests are specified via the PERMUTATION= option in the TEST statement, the actual permutation distributions are used, resulting in a much less conservative version of this procedure (Westfall and Wolfinger 1997). See the section "Bonferroni" on page 5035 for more details.

BOOTSTRAP
BOOT

specifies that the *p*-values be adjusted by using the bootstrap method to resample vectors (Westfall and Young 1993). Resampling is performed with replacement and independently within levels of the STRATA variable. Continuous variables are mean-centered by default prior to resampling; specify the NOCENTER option to change this. See the section "Bootstrap" on page 5036 for more details. The BOOTSTRAP option is not allowed with the Peto test.

If the PERMUTATION= suboption is used with the CA test in the TEST statement, the exact permutation distribution is recomputed for each bootstrap sample. **CAUTION:** This can be very time-consuming. It is preferable to use permutation resampling when permutation base tests are used.

CENTER

requests that continuous variables be mean-centered prior to resampling. The default action is to mean-center for bootstrap resampling and not to mean-center for permutation resampling.

DATA=*SAS-data-set*

names the input SAS data set to be used by PROC MULTTEST. The default is to use the most recently created data set. The DATA= and INPVALUES= options cannot both be specified.

DEPENDENTFDR
DFDR

requests adjusted *p*-values by using the method of Benjamini and Yekateuli (2001). See the section "Dependent False Discovery Rate" on page 5040 for more details.

EPSILON=*number*

specifies the amount by which two *p*-values must differ to be declared unequal. The value *number* must be between 0 and 1; the default value is 1000 times the machine epsilon, which is approximately 1E–12. For SAS 9.1 and earlier releases the default value was 1E–8. See Westfall and Young (1993, pp. 165–166) for more information.

FDR
LSU

requests adjusted *p*-values by using the linear step-up method of Benjamini and Hochberg (1995). These *p*-values do not control the familywise error rate, but they do control the false discovery rate in some cases. See the section "False Discovery Rate Controlling Adjustments" on page 5039 for more details.

FDRBOOT<(β)>

A bootstrap-resampling false discovery rate controlling method due to Yekateuli and Benjamini (1999). This method uses the same resampling algorithm as the BOOTSTRAP option. Every resample is saved in order to compute a quantile of the resampled p-values; therefore, this method can use a lot of memory. The parameter β designates that a $100(1-\beta)$th quantile is used in the computations for determining the adjustments; by default, $\beta = 0.05$. See the section "False Discovery Rate Resampling Adjustments" on page 5040 for details.

FDRPERM<(β)>

A permutation-resampling false discovery rate controlling method due to Yekateuli and Benjamini (1999). This method uses the same resampling algorithm as the PERMUTATION option. Every resample is saved in order to compute a quantile of the resampled p-values; therefore, this method can use a lot of memory. The parameter β designates that a $100(1-\beta)$th quantile is used in the computations for determining the adjustments; by default, $\beta = 0.05$. See the section "False Discovery Rate Resampling Adjustments" on page 5040 for details.

FISHER_C

FIC

requests adjusted p-values by using Fisher's combination method. See the section "Fisher Combination" on page 5038 for more details.

HOCHBERG

HOC

requests adjusted p-values by using the step-up Bonferroni method due to Hochberg (1988). See the section "Hochberg" on page 5038 for more details.

HOMMEL

HOM

requests adjusted p-values by using the method of Hommel (1988). See the section "Hommel" on page 5037 for more details.

HOLM

is an alias for the STEPBON adjustment.

INPVALUES< *(pvalue-name)* **>=***SAS-data-set*

names an input SAS data set that includes a variable containing raw p-values. The MULTTEST procedure adjusts the collection of raw p-values for multiplicity. Resampling-based adjustments are not permitted with this type of data input. The CLASS, CONTRAST, FREQ, STRATA, and TEST statements are ignored when an INPVALUES= data set is specified. The INPVALUES= and DATA= options cannot both be specified. The *pvalue-name* enables you to specify the name of the p-value column from your data set. By default, *pvalue-name*='raw_p'. The INPVALUES= data set can contain variables in addition to the raw p-values variable; see Example 60.5 for an example.

LIPTAK

is an alias for the STOUFFER adjustment.

NOCENTER

requests that continuous variables not be mean-centered prior to resampling. The default action is to mean-center for bootstrap resampling and not to mean-center for permutation resampling.

NOPRINT
suppresses the normal display of results. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 20, "Using the Output Delivery System," for more information.

NOPVALUE
suppresses the display of the "p-Values" table of raw and adjusted p-values. This option is most useful when you are adjusting many tests and need to create only an OUT= data set or display graphics.

NOTABLES
suppresses display of the "Discrete Variable Tabulations" and "Continuous Variable Tabulations" tables.

NOZEROS
suppresses display of tables having zero occurrences for all CLASS levels.

NSAMPLE=*number*

N=*number*
specifies the number of resamples for use with the resampling methods. The value *number* must be a positive integer; by default, 20,000 resamples are used. Large values of *number* (20,000 or more) are usually recommended for accuracy, but long execution times can result, particularly with large data sets.

NTRUENULL=*keyword* | *value*

M0=*keyword* | *value*
Controls the method used to estimate the number of true NULL hypotheses (m_0) for the adaptive methods. This option is ignored unless one of the adaptive methods is specified. By default, PROC MULTTEST uses the DECREASESLOPE method for the ADAPTIVEHOLM and ADAPTIVEHOCHBERG adjustments, and the LOWESTSLOPE method for ADAPTIVEFDR adjustment. For the PFDR adjustment, the SPLINE method is attempted first. If the estimate is nonpositive or if the slope of the spline at the last λ is greater than 0.1 times the range of the fitted spline values, then the BOOTSTRAP method is used.

You can specify a positive integer as the *value*, or you can specify one of the *keywords* in the following list. Alternatively, you can specify the proportion of true NULL hypotheses by using the PTRUENULL= option. Suppose you have m tests with ordered p-values $p_{(1)} \leq \ldots \leq p_{(m)}$, and define $q_{(i)} = 1 - p_{(i)}$.

BOOTSTRAP< (*bootstrap-options***) >** uses the bootstrap method of Storey and Tibshirani (2003). Compute the proportion of true null hypotheses $\hat{\pi}_0(\lambda) = \frac{m - N(\lambda) + f}{(1-\lambda)m}$ for $\lambda \in L = \{0, 0.05, \ldots, 0.95\}$, where $N(\lambda)$ is the number of p-values less than or equal to λ, and $f = 1$ for the finite-sample case; otherwise $f = 0$. For each λ, bootstrap on the p-values to form B bootstrap versions $\hat{\pi}_0^b(\lambda), b = 1, \ldots, B$, and choose the λ that yields the minimum $\widehat{\mathrm{MSE}}(\lambda) = \frac{1}{B}\sum_{b=1}^{B}(\hat{\pi}_0^b(\lambda) - \min_{\lambda' \in L}\hat{\pi}_0(\lambda'))^2$. The available *bootstrap-options* are as follows:

FINITE modifies the computations for the finite-sample case of the PFDR option, described on page 5018.

NBOOT=*B* specifies the number of bootstrap resamples of the raw p-values for the λ computations. NBOOT= 10,000 by default; B must be a positive integer.

NLAMBDA=*n* specifies that the "optimal" λ is the value in $\{0, \frac{1}{n}, \ldots, \frac{n-1}{n}\}$ that minimizes the MSE. NLAMBDA= 20 by default; *n* must be an integer greater than 1.

DECREASESLOPE uses the method of Schweder and Spjøtvoll (1982) as modified by Hochberg and Benjamini (1990). Let b_i be the slope of the least squares line fit to $\{q_{(m)}, \ldots, q_{(m-i+1)}\}$ and through the origin, for $i = 1, \ldots, m$. Find the first $i = m-1, m-2, \ldots, 1$ such that $b_i < b_{i+1}$. Then $\hat{m}_0 = \text{ceil}(\frac{1}{b_{i+1}} - 1)$.

KSTEST<(β**)>** uses the Kolmogov-Smirnov uniformity test method of Turkheimer, Smith, and Schmidt (2001). Let $k_{min} = 1, k_{max} = m$, and the Kolmogorov-Smirnov statistic $D = \max(q_{(i)} - i/(m+1)(\sqrt{k} + 0.12 + 0.11/\sqrt{k}))$. If D is greater than the upper-tail probability (Press et al. 1992), then $k_{max} = k, k = \text{floor}((k_{min} + k)/2)$; otherwise, let $k_{min} = k, k = \text{floor}((k + k_{max})/2)$. Repeat until $k = k_{min}$. Next compute the slope b of the weighted least squares regression line on the k smallest $q_{(i)}$ by using weights $w_i = i(k - i + 1)/((k+1)^2(k+2))$. Then $\hat{m}_0 = \text{ceil}(\frac{1}{b} - 1)$.

LEASTSQUARES uses a linear least squares method to search for the correct cutpoint. For each $i = 0, \ldots, m$ compute the SSE of the least squares line through the origin fitting $\{q_{(m)}, \ldots, q_{(m-i+1)}\}$, let b_i be the slope of this line, and add the SSE of the unconstrained least squares line through the rest of the qs. For $i = 0$ compute the SSE for the unconstrained line. The argument i that minimizes the SSE is the cutpoint: if $i = 0$ then $\hat{m}_0 = 0$; if $i = m$ then $\hat{m}_0 = m$; otherwise $\hat{m}_0 = \text{ceil}(\frac{1}{b_i} - 1)$.

LOWESTSLOPE uses the lowest slope method of Benjamini and Hochberg (2000). Find the first $i = 1, \ldots, m$ such that $b_i = q_{(i)}/(m-i+1)$ decreases. Then $\hat{m}_0 = \text{floor}(\min(\frac{1}{b_i} + 1, m))$.

MEANDIFF uses the mean of differences method of Hsueh, Chen, and Kodell (2003). Let $\bar{d}_i = \frac{q_{(m-i+1)}}{i}$ and estimate $\hat{m}_0^i = \frac{1}{\bar{d}_i} - 1$. Start from $i = m$ and proceed downward until the first time $\hat{m}_0^{i-1} \geq \hat{m}_0^i$ occurs.

SPLINE<(*spline-options***)>** uses the cubic spline method of Storey and Tibshirani (2003). For each $\lambda \in \{0, \frac{1}{n}, \frac{2}{n}, \ldots, \frac{n-1}{n}\}$ compute $\hat{\pi}_0(\lambda) = \frac{\#\{p_i > \lambda\}}{m(1-\lambda)}$. Let $\widehat{f}(\lambda)$ be the natural cubic spline with 3 degrees of freedom of $\hat{\pi}_0(\lambda)$ versus λ. Estimate $\hat{\pi}_0$ by taking the spline value at the last λ: $\hat{\pi}_0 = \hat{\pi}_0(\frac{n-1}{n})$, so that $\hat{m}_0 = m\hat{\pi}_0$. The available *spline-options* are as follows:

DF=*df* sets the degrees of freedom of the spline, where *df* is a nonnegative integer. The default is DF=3.

DFCONV=*number* specifies the absolute change in spline degrees of freedom value for concluding convergence. If $|df_i - df_{i+1}| <$ *number* (or if the SPCONV= criterion is satisfied), then convergence is declared. *number* must be between 0 and 1; by default, *number* is 1000 times the square root of machine epsilon, which is about 1E–5.

FINITE modifies the computations for the finite-sample case of the PFDR option, described on page 5018.

MAXITER=*n* specifies the maximum number of golden-search iterations used to find a spline with DF=*df* degrees of freedom. By default, MAXITER= 100; *number* must be a nonnegative integer.

NLAMBDA=*n* computes $\hat{\pi}_0(\lambda)$ for $\lambda \in \{0, \frac{1}{n}, \frac{2}{n}, \ldots, \frac{n-1}{n}\}$ for the spline fit. By default, NLAMBDA= 20; *number* must be an integer greater than 1.

SPCONV=*number* specifies the absolute change in smoothing parameter value for concluding convergence of the spline. If $|sp_i - sp_{i+1}| < number$ (or if the DFCONV= criterion is satisfied), then convergence is declared. By default, *number* equals the square root of the machine epsilon, which is about 1E–8.

In all cases $\hat{m}_0$ is constrained to lie between 0 and m; if the computed $\hat{m}_0 = 0$, then the adaptive adjustments do not produce results. If you specify $\hat{m}_0 > m$, then it is reduced to m. Values of $\hat{m}_0$ are displayed in the "Estimated Number of True Null Hypotheses" table.

ORDER=DATA | FORMATTED | FREQ | INTERNAL
specifies the order in which to sort the levels of the classification variables (which are specified in the CLASS statement). This option applies to the levels for all classification variables, except when you use the (default) ORDER=FORMATTED option with numeric classification variables that have no explicit format. With this option, the levels of such variables are ordered by their internal value.

The ORDER= option can take the following values:

Value of ORDER=	Levels Sorted By
DATA	Order of appearance in the input data set
FORMATTED	External formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ	Descending frequency count; levels with the most observations come first in the order
INTERNAL	Unformatted value

By default, ORDER=FORMATTED. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine-dependent. For more information about sorting order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

OUT=*SAS-data-set*
names the output SAS data set containing variable names, contrast names, intermediate calculations, and all associated *p*-values. See "OUT= Data Set" on page 5043 for more information.

OUTPERM=*SAS-data-set*
names the output SAS data set containing entire permutation distributions (upper-tail probabilities) for all tests when the PERMUTATION= option is specified. See "OUTPERM= Data Set" on page 5044 for more information. **CAUTION:** This data set can be very large.

OUTSAMP=*SAS-data-set*
names the output SAS data set containing information from the resampled data sets when resampling is performed. See "OUTSAMP= Data Set" on page 5044 for more information. **CAUTION:** This data set can be very large.

PDATA=*SAS-data-set*
is an alias for the INPVALUES= option.

PERMUTATION
PERM
computes adjusted p-values in identical fashion as the BOOTSTRAP option, with the exception that PROC MULTTEST resamples without replacement rather than with replacement. Resampling is performed independently within levels of the STRATA variable. Continuous variables are not mean-centered prior to resampling; specify the CENTER to change this. See the section "Bootstrap" on page 5036 for more details. The PERMUTATION option is not allowed with the Peto test.

PFDR<(*options* **)>**
computes the "q-values" $\hat{q}_\lambda(p_i)$ of Storey (2002) and Storey, Taylor, and Siegmund (2004). PROC MULTTEST treats these "q-values" as adjusted p-values. The computations depend on selecting a parameter λ and an estimation method for the false discovery rate; see the section "Positive False Discovery Rate" on page 5041 for computational details. The available *options* for choosing the method are as follows:

FINITE estimates the false discovery rate with $\widehat{\text{pFDR}}$ or $\widehat{\text{FDR}}$ for the finite-sample case with independent null p-values.

POSITIVE estimates the false discovery rate with $\widehat{\text{pFDR}}$ instead of the default $\widehat{\text{FDR}}$.

The available options for controlling the λ search are the *bootstrap-options* (page 5015), the *spline-options* (page 5016), and the following options:

LAMBDA=*number* specifies a $\lambda \in [0, 1)$ and does not perform the bootstrap or spline searches for an "optimal" λ.

MAXLAMBDA=*number* stops the NLAMBDA= search sequence for the bootstrap and spline searches when this *number* is reached. The *number* must be in [0, 1]. This option is ignored if the LAMBDA= option is specified.

PLOTS<(*global-plot-options***)>=***plot-request*<*(options)*>
PLOTS<(*global-plot-options***)>=(***plot-request*<*(options)*>< . . . *plot-request*<*(options)*>>**)**
controls the plots produced through ODS Graphics. If you specify only one *plot-request*, you can omit the parentheses. For example, the following statements are valid specifications of the PLOTS= option:

```
plots = all
plots = (rawprob adjusted)
plots(sigonly) = (rawprob adjusted(unpack))
```

ODS Graphics must be enabled before requesting plots. For example:

```
ods graphics on;
proc multtest plots=adjusted inpvalues=a pfdr;
run;
ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section "Enabling and Disabling ODS Graphics" on page 612 in Chapter 21, "Statistical Graphics Using ODS."

By default, no graphs are created; you must specify the PLOTS= option to make graphs. You need at least two tests to produce a graph. If you are not using an INPVALUES= data set, then each test is given a name constructed as "variable-name contrast-label". If you specify a MEAN test in the TEST statement, the *t*-test names are prefixed with "Mean:". See Example 60.6 for examples of the ODS graphical displays.

The following *global-plot-options* are available:

UNPACKPANELS | UNPACK suppresses paneling. By default, the plots produced with the ADJUSTED and RAWPROB options are grouped in a single display, called a *panel*. Specify UNPACK to display each plot separately.

SIGONLY<=*number***>** displays only those tests with adjusted *p*-values $\leq$ *number*, where $0 \leq$ *number* ≤ 1. By default, *number* $= 0.05$.

The following *plot-requests* are available:

ADJUSTED<(UNPACK)> displays a 2×2 panel of adjusted *p*-value plots similar to those Storey and Tibshirani (2003) developed for use with the PFDR *p*-value adjustment method. The plots of the adjusted *p*-values by the raw *p*-values and the adjusted *p*-values by their rank show the effect of the adjustments. The plot of the proportion of adjusted *p*-values $\leq$ each adjusted *p*-value and the plot of the expected number of false positives (the proportion significant multiplied by the adjusted *p*-value) versus the proportion significant show the effect of choosing different significance levels. The UNPACK option unpanels the display.

ALL produces all appropriate plots. You can specify other options with ALL; for example, to display all plots and unpack the RAWPROB plots you can specify **`plots=(all rawprob(unpack))`**.

LAMBDA displays plots of the MSE and the estimated number of true nulls against the λ parameter when the NTRUENULL=SPLINE or NTRUENULL=BOOTSTRAP option is in effect.

NONE suppresses all plots.

PBYTEST<(*options***)>** displays the adjusted *p*-values for each test. The available options are as follows:

NOTESTNAME displays the number of the test instead of the test name on the axis, which is useful when you have many tests.

VREF=*number-list* displays reference lines at the *p*-values specified in the *number-list*. The values in the *number-list* must be between 0 and 1; otherwise they are ignored. You can specify a single value or a list of values; for example, **`vref=0.1 0 to 0.05 by 0.01`** displays reference lines at each of the values {0.01, 0.02, 0.03, 0.04, 0.05, and 0.1}.

RAWPROB<(UNPACK)> displays a uniform probability plot of 1 minus the raw *p*-values (Schweder and Spjøtvoll 1982) along with a histogram. If m_0 is the number of true null hypotheses among the m tests, the points on the left side of the plot should be approximately linear with slope $\frac{1}{m_0+1}$. This graphic is displayed when an adaptive *p*-value adjustment

method is requested in order to see if the NTRUENULL= estimate is appropriate. The UNPACK option unpanels the display.

PTRUENULL=*keyword* | *value*

PI0=*keyword* | *value*

is alias for the NTRUENULL= option, except that you can specify the proportion of true null hypotheses as a *value* between 0 and 1, instead of specifying the number of true null hypotheses. The available *keywords* are also the NTRUENULL= options described on page 5015.

RANUNI

requests the random number generator used in releases prior to SAS 9.2. Beginning with SAS 9.2, the random number generator is the Mersenne Twister, which has better performance when bootstrapping. Changes in the bootstrap- or permutation-adjusted *p*-values from prior releases are due to unimportant sampling differences.

SEED=*number*

S=*number*

specifies the initial seed for the random number generator used for resampling. The value for *number* must be an integer. If you do not specify a seed, or if you specify a value less than or equal to zero, then PROC MULTTEST uses the time of day from the computer's clock to generate an initial seed. For more details about seed values, see *SAS Language Reference: Concepts*.

SIDAK

SID

computes the Šidák adjustment for each test. These adjustments take the form

$$1 - (1 - p)^m$$

where p is the raw p-value and m is the number of tests. These are slightly less conservative than the Bonferroni adjustments, but they still should be viewed with caution. When exact tests are specified via the PERMUTATION= option in the TEST statement, the actual permutation distributions are used, resulting in a much less conservative version of this procedure (Westfall and Wolfinger 1997). See the section "Šidák" on page 5035 for more details.

STEPBON

HOLM

requests adjusted *p*-values by using the step-down Bonferroni method of Holm (1979). See the section "Step-Down Methods" on page 5036 for more details.

STEPBOOT

requests that adjusted *p*-values be computed by using bootstrap resampling as described under the BOOTSTRAP option, but in step-down fashion. See the section "Step-Down Methods" on page 5036 for more details.

STEPPERM

requests that adjusted *p*-values be computed by using permutation resampling as described under the PERMUTATION option, but in step-down fashion. See the section "Step-Down Methods" on page 5036 for more details.

STEPSID
requests adjusted *p*-values by using the Šidák method as described in the SIDAK option, but in step-down fashion. See the section "Step-Down Methods" on page 5036 for more details.

STOUFFER
LIPTAK
requests adjusted *p*-values by using the Stouffer-Liptak combination method. See the section "Stouffer-Liptak Combination" on page 5038 for more details.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC MULTTEST to obtain separate analyses on observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the MULTTEST procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

You can specify one or more *variables* in the input data set on the BY statement.

Since sorting the data changes the order in which PROC MULTTEST reads observations, this can affect the sorting order for the levels of the CLASS variable if you have specified ORDER=DATA in the PROC MULTTEST statement. This, in turn, affects specifications in the CONTRAST statements.

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variable* < / **TRUNCATE** > **;**

The CLASS statement is required unless the INPVALUES= option is specified. The CLASS statement specifies a single variable (character or numeric) used to identify the groups for the analysis. For example,

if the variable Treatment defines different levels of a treatment that you want to compare, then you would specify the following statements:

```
class Treatment;
```

The CLASS variable can be either character or numeric. By default, class levels are determined from the entire set of formatted values of the CLASS variable. The order of the class levels used by PROC MULTTEST corresponds to the order of their formatted values; this order can be changed with the ORDER= option in the PROC MULTTEST statement.

NOTE: Prior to SAS 9, class levels were determined by using no more than the first 16 characters of the formatted values. To revert to this previous behavior you can specify the TRUNCATE option in the CLASS statement.

In any case, you can use formats to group values into levels. See the discussion of the FORMAT procedure in the *Base SAS Procedures Guide* and the discussions of the FORMAT statement and SAS formats in *SAS Formats and Informats: Reference*. You can adjust the order of CLASS variable levels with the ORDER= option in the PROC MULTTEST statement. You need to be aware of the order when using the CONTRAST statement, and you should check the "Contrast Coefficients" table to verify that it is suitable.

You can specify the following option in the CLASS statement after a slash (/):

TRUNCATE
specifies that class levels should be determined by using only up to the first 16 characters of the formatted values of CLASS variables. When formatted values are longer than 16 characters, you can use this option to revert to the levels as determined in releases prior to SAS 9.

CONTRAST Statement

CONTRAST *'label' values* **;**

This statement is used to identify tests between the levels of the CLASS variable; in particular, it is used to specify the coefficients for the trend tests. The *label* is a string naming the contrast; it contains a maximum of 21 characters. The *values* are scoring coefficients across the CLASS variable levels.

You can specify multiple CONTRAST statements, thereby specifying multiple contrasts for each variable. Multiplicity adjustments are computed for all contrasts and all variables simultaneously. The coefficients are applied to the ordered CLASS variables; this order can be changed with the ORDER= option in the PROC MULTTEST statement. For example, consider a four-group experiment with CLASS variable levels A1, A2, B1, and B2 denoting two levels of two treatments. The following statements produce three linear trend tests for each variable identified in the TEST statement. PROC MULTTEST computes the multiplicity adjustments over the entire collection of tests, which is three times the number of variables.

```
contrast 'a vs b'    -1 -1  1  1;
contrast 'a linear'  -1  1  0  0;
contrast 'b linear'   0  0 -1  1;
```

As another example, consider an animal carcinogenicity experiment with dose levels 0, 4, 8, 16, and 50. You can specify a trend test with the indicated scoring coefficients by using the following statement:

```
contrast 'arithmetic trend' 0 4 8 16 50;
```

Multiplicity-adjusted *p*-values are then computed over the collection of variables identified in the TEST statement. See Lagakos and Louis (1985) for guidelines on the selection of contrast-scoring values.

When a Fisher test is specified in the TEST statement, the CONTRAST statement coefficients are used to group the CLASS variable's levels. Groups with a -1 contrast coefficient are combined and compared with groups with a 1 contrast coefficient for each test, and groups with a 0 coefficient are not included in the contrast. For example, the following statements compute Fisher exact tests for (a) control versus the combined treatment groups, (b) control versus the first treatment group, and (c) control versus the third treatment group:

```
contrast 'c vs all' 1 -1 -1 -1;
contrast 'c vs t1'  1 -1  0  0;
contrast 'c vs t3'  1  0  0 -1;
```

Multiplicity adjustments are then computed over the entire collection of tests and variables. Only -1, 1, and 0 are acceptable CONTRAST coefficients when the Fisher test is specified; PROC MULTTEST ignores the CONTRAST statement if any other coefficients appear.

If you specify the FISHER test and no CONTRAST statements, then all contrasts of control versus treatment are automatically generated, with the first level of the CLASS variable deemed to be the control. In this case, the control level is assigned the value 1 in each contrast and the other treatment levels are assigned -1. You should therefore use the LOWERTAILED option to test for higher success rates in the treatment groups.

For tests other than FISHER, CONTRAST values are $0, 1, 2, \ldots$ by default. If you specify the CA or PETO test with the PERMUTATION= option, then your CONTRAST coefficients must be integer valued.

For *t* tests for the mean of continuous data (and for the FT tests), the contrast coefficients are centered to have mean $= 0$. The resulting centered scoring coefficients are then applied to the sample means (or to the double-arcsine-transformed proportions in the case of the FT tests).

FREQ Statement

FREQ *variable* **;**

The FREQ statement names a variable that provides frequencies for each observation in the DATA= data set. Specifically, if n is the value of the FREQ variable for a given observation, then that observation is used n times.

If the value of the FREQ variable is missing or is less than 1, the observation is not used in the analysis. If the value is not an integer, only the integer portion is used.

STRATA Statement

STRATA *variable* **;**

The STRATA statement identifies a single variable to use as a stratification variable in the analysis. This yields tests similar to those discussed in Mantel and Haenszel (1959) and Hoel and Walburg (1972) for binary data and pooled-means tests for continuous data. For example, when you test for prevalence in a carcinogenicity study, it is common to stratify on intervals of the time of death; the first level of the stratification variable might represent weeks 0−52, the second might represent weeks 53−80, and so on. In multicenter clinical studies, each level of the stratification variable might represent a particular center.

The following option is available in the STRATA statement after a slash (/):

WEIGHT=*keyword*

specifies the type of strata weighting to use when computing the Freeman-Tukey and *t* tests. Valid *keywords* are SAMPLESIZE, HARMONIC, and EQUAL. SAMPLESIZE requests weights proportional to the within-stratum sample sizes, and is the default method even if the WEIGHT= option is not specified. HARMONIC sets up weights equal to the harmonic mean of the nonmissing within-stratum CLASS sizes, and is similar to a Type 2 analysis in PROC GLM. EQUAL specifies equal weights, and is similar to a Type 3 analysis in PROC GLM.

TEST Statement

TEST *name (variables </ options>)* **;**

The TEST statement is required unless the INPVALUES= option is specified. The TEST statement identifies statistical tests to be performed and the discrete and continuous variables to be tested. The following tests are permitted as *name* in the TEST statement.

CA

requests the Cochran-Armitage linear trend tests for group comparisons. The test variables should take the value 0 for a failure and 1 for a success. PERMUTATION= option can be used to request an exact permutation test; otherwise, a Z-score approximation is used. The CONTINUITY= option can be used to specify a continuity correction for the Z-score approximation.

FISHER

requests Fisher exact tests for comparing two treatment groups. The test variables should take the value 0 for a failure and 1 for a success.

FT

requests Z-score CA tests based upon the Freeman-Tukey double arcsine transformation of the frequencies. The test variables should take the value 0 for a failure and 1 for a success.

MEAN

requests the *t* test for the mean. The test variables can take on any numeric values.

PETO

requests the Peto mortality-prevalence test. The test variables should take the value 0 for a nonoccurrence, 1 for an incidental occurrence, and 2 for a fatal occurrence. The TIME= option should be used with the Peto test to specify an integer-valued variable giving the age at death. The CONTINUITY= option can be used to specify a continuity correction for the test.

If the value of a TEST variable is invalid, the observation is not used in the analysis. You can specify two tests only if one of them is MEAN. For example, the following statement is valid:

```
test ca(d1-d2) mean(c1-c2);
```

But specifying both CA and FT, as shown in the following statement, is invalid:

```
test ca(d1-d2) ft(d1-d2);
```

You can specify the following options in the TEST statement (some apply to only one test).

BINOMIAL

uses the binomial variance estimate for CA and Peto tests in their asymptotic normal approximations. The default is to use the hypergeometric variance.

CONTINUITY=*number*

C=*number*

specifies *number* as a particular continuity correction for the Z-score approximation in the CA and Peto tests. The default is 0.

LOWERTAILED

LOWER

is used to make all tests lower-tailed. All tests are two-tailed by default.

PERMUTATION=*number*

PERM=*number*

computes p-values for the CA and Peto tests by using exact permutation distributions when marginal success or failure totals within a stratum are *number* or less. You can specify *number* as a nonnegative integer. For totals greater than *number* (or when the PERMUTATION= option is omitted), PROC MULTTEST uses standard normal approximations with a continuity correction chosen to approximate the permutation distribution. PROC MULTTEST computes the appropriate convolution distributions when you use the STRATA statement along with the PERMUTATION= option.

DDFM= POOLED | SATTERTHWAITE

specifies whether the MEAN test uses a homogeneity assumption (DDFM=POOLED, the default) or deals with heterogeneous variances (DDFM=SATTERTHWAITE). See "*t* Test for the Mean" on page 5032 for more information.

TIME=*variable*

identifies the Peto test variable containing the age at death, which must be integer valued. If the TIME= option is omitted, all ages are assumed to equal 1.

UPPERTAILED

UPPER

is used to make all tests upper-tailed. All tests are two-tailed by default.

Details: MULTTEST Procedure

Statistical Tests

The following section discusses the statistical tests performed in the MULTTEST procedure. For continuous data, a t test for the mean (MEAN) is available. For discrete variables, available tests are the Cochran-Armitage linear trend test (CA), the Freeman-Tukey double arcsine test (FT), the Peto mortality-prevalence test (PETO), and the Fisher exact test (FISHER).

Throughout this section, the discrete and continuous variables are denoted by S_{vgsr} and X_{vgsr}, respectively, where v is the variable, g is the treatment group, s is the stratum, and r is the replication. Let m_{vgs} denote the sample size for a binary variable v within group g and stratum s. A plus sign $(+)$ subscript denotes summation over an index. Note that the tests are invariant to the location and scale of the contrast coefficients t_g.

Cochran-Armitage Linear Trend Test

The Cochran-Armitage linear trend test (Cochran 1954; Armitage 1955; Agresti 2002) is implemented by using a Z-score approximation, an exact permutation distribution, or a combination of both.

Z-Score Approximation

The pooled probability estimate for variable v and stratum s is

$$p_{vs} = \frac{S_{v+s+}}{m_{v+s}}$$

The expected value (under constant within-stratum treatment probabilities) for variable v, group g, and stratum s is

$$E_{vgs} = m_{vgs} p_{vs}$$

Letting t_g denote the contrast trend coefficients specified by the CONTRAST statement, the test statistic for variable v has numerator

$$N_v = \sum_s \sum_g t_g (S_{vgs+} - E_{vgs})$$

The binomial variance estimate for this statistic is

$$V_v = \sum_s p_{vs}(1 - p_{vs}) \sum_g m_{vgs}(t_g - \bar{t}_{vs})^2$$

where

$$\bar{t}_{vs} = \sum_g \frac{m_{vgs} t_g}{m_{v+s}}$$

The hypergeometric variance estimate (the default) is

$$V_v = \sum_s \{m_{v+s}/(m_{v+s}-1)\} p_{vs}(1-p_{vs}) \sum_g m_{vgs}(t_g - \bar{t}_{vs})^2$$

For any strata s with $m_{v+s} \leq 1$, the contribution to the variance is taken to be zero.

PROC MULTTEST computes the Z-score statistic

$$Z_v = \frac{N_v}{\sqrt{V_v}}$$

The p-value for this statistic comes from the standard normal distribution. Whenever a 0 is computed for the denominator, the p-value is set to 1. This p-value approximates the probability obtained from the exact permutation distribution, discussed in the following text.

The Z-score statistic can be continuity-corrected to better approximate the permutation distribution. With continuity correction c, the upper-tailed p-value is computed from

$$Z_v = \frac{N_v - c}{\sqrt{V_v}}$$

For two-tailed, noncontinuity-corrected tests, PROC MULTTEST reports the p-value as $2\min(p, 1-p)$, where p is the upper-tailed p-value. The same formula holds for the continuity-corrected test, with the exception that when the noncontinuity-corrected Z and the continuity-corrected Z have opposite signs, the two-tailed p-value is 1.

When the PERMUTATION= option is specified and no STRATA variable is specified, PROC MULTTEST uses a continuity correction selected to optimally approximate the upper-tail probability of permutation distributions with smaller marginal totals (Westfall and Lin 1988). Otherwise, the continuity correction is specified by the CONTINUITY= option in the TEST statement.

The CA Z-score statistic is the Hoel-Walburg (Mantel-Haenszel) statistic reported by Dinse (1985).

Exact Permutation Test

When you use the PERMUTATION= option for CA in the TEST statement, PROC MULTTEST computes the exact permutation distribution of the trend score

$$T_v = \sum_s \sum_g t_g S_{vgs+}$$

where the contrast trend coefficients t_g must be integer valued. The observed value of this trend is compared to the permutation distribution to obtain the p-value

$$p_v = \Pr(X \geq \text{ observed } T_v)$$

where X is a random variable from the permutation distribution and where upper-tailed tests are requested. This probability can be viewed as a binomial probability, where the within-stratum probabilities are constant and where the probability is conditional with respect to the marginal totals S_{v+s+}. It also can be considered a rerandomization probability.

Because the computations can be quite time-consuming with large data sets, specifying the PERMUTATION=*number* option in the TEST statement limits the situations where PROC MULTTEST computes the

exact permutation distribution. When marginal total success or total failure frequencies exceed *number* for a particular stratum, the permutation distribution is approximated by a continuity-corrected normal distribution. You should be cautious when using the PERMUTATION= option in conjunction with bootstrap resampling because the permutation distribution is recomputed for each bootstrap sample. This recomputation is not necessary with permutation resampling.

The permutation distribution is computed in two steps:

1. The permutation distributions of the trend scores are computed within each stratum.
2. The distributions are convolved to obtain the distribution of the total trend.

As long as the total success or failure frequency does not exceed *number* for any stratum, the computed distributions are exact. In other words, if $S_{v+s+} \leq number$ or $(m_{v+s} - S_{v+s+}) \leq number$ for all s, then the permutation trend distribution for variable v is computed exactly.

In step 1, the distribution of the within-stratum trend

$$\sum_g t_g S_{vgs+}$$

is computed by using the multivariate hypergeometric distribution of the S_{vgs+}, provided *number* is not exceeded. This distribution can be written as

$$\Pr(S_{v1s+}, S_{v2s+}, \ldots, S_{vGs+}) = \prod_{g=1}^{G} \frac{\begin{pmatrix} m_{vgs} \\ S_{vgs+} \end{pmatrix}}{\begin{pmatrix} m_{v+s} \\ S_{v+s+} \end{pmatrix}}$$

The distribution of the within-stratum trend is then computed by summing these probabilities over appropriate configurations. For further information about this technique, see Bickis and Krewski (1986) and Westfall and Lin (1988). In step 2, the exact convolution distribution is obtained for the trend statistic summed over all strata having totals that meet the threshold criterion. This distribution is obtained by applying the fast Fourier transform to the exact within-stratum distributions. A description of this general method can be found in Pagano and Tritchler (1983) and Good (1987).

The convolution distribution of the overall trend is then computed by convolving the exact distribution with the distribution of the continuity-corrected standard normal approximation. To be more specific, let S_1 denote the subset of stratum indices that satisfy the threshold criterion, and let S_2 denote the subset of indices that do not satisfy the criterion. Let T_{v1} denote the combined trend statistic from the set S_1, which has an exact distribution obtained from Fourier analysis as previously outlined, and let T_{v1} denote the combined trend statistic from the set S_2. Then the distribution of the overall trend $T_v = T_{v1} + T_{v2}$ is obtained by convolving the analytic distribution of T_{v1} with the continuity-corrected normal approximation for T_{v2}. Using the notation from the section "Z-Score Approximation" on page 5026, this convolution can be written as

$$\begin{aligned} \Pr(T_{v1} + T_{v2} \geq u) &= \sum_{u1} \Pr(T_{v1} + T_{v2} \geq u \mid T_{v1} = u1) \Pr(T_{v1} = u1) \\ &\approx \sum_{u1} \Pr(Z \geq z) \Pr(T_{v1} = u1) \end{aligned}$$

where Z is a standard normal random variable, and

$$z = \frac{1}{\sqrt{V_v}} \left(u - u1 - \sum_{S_2} p_{vs} \sum_g t_g m_{vgs} - c \right)$$

In this expression, the summation of s in V_v is over S_2, and c is the continuity correction discussed under the Z-score approximation.

When a two-tailed test is requested, the expected trend is computed

$$E_v = \sum_s \sum_g t_g E_{vgs}$$

The two-tailed p-value is reported as the permutation tail probability for the observed trend T_v plus the permutation tail probability for $2E_v - T_v$, the reflected trend.

Freeman-Tukey Double Arcsine Test

For this test, the contrast trend coefficients $t_1, \ldots, t_G$ are centered to the values $c_1, \ldots, c_G$, where $c_g = t_g - \bar{t}, \bar{t} = \sum_g t_g / G$, and G is the number of groups. The numerator of this test statistic is

$$N_v = \sum_s w_{vs} \sum_g c_g f(S_{vgs+}, m_{vgs})$$

where the weights w_{vs} take on three different types of values depending upon your specification of the WEIGHT= option in the STRATA statement. The default value is the within-strata sample size m_{v+s}, ensuring comparability with the ordinary CA trend statistic. WEIGHT=HARMONIC sets w_{vs} equal to the harmonic mean

$$\left[\left(\sum_g \frac{1}{m_{vgs}} \right) / G^* \right]^{-1}$$

where G^* is the number of nonmissing groups and the summation is over only the nonmissing elements. The harmonic means analysis places more weight on the smaller sample sizes than does the default sample size method, and is similar to a Type 2 analysis in PROC GLM. WEIGHT=EQUAL sets $w_{vs} = 1$ for all v and s, and is similar to a Type 3 analysis in PROC GLM.

The function $f(r, n)$ is the double arcsine transformation:

$$f(r, n) = \arcsin\left(\sqrt{\frac{r}{n+1}} \right) + \arcsin\left(\sqrt{\frac{r+1}{n+1}} \right)$$

The variance estimate is

$$V_v = \sum_s w_{vs}^2 \sum_g \frac{c_g^2}{m_{vgs} + \frac{1}{2}}$$

The test statistic is

$$Z_v = \frac{N_v}{\sqrt{V_v}}$$

The Freeman-Tukey transformation and its variance are described by Freeman and Tukey (1950) and Miller (1978). Since its variance is not weighted by the pooled probabilities, as is the CA test, the FT test can be more useful than the CA test for tests involving only a subset of the groups.

Peto Mortality-Prevalence Trend Test

The Peto test is a modified Cochran-Armitage procedure incorporating mortality and prevalence information. The Peto test is computed like two Cochran-Armitage Z-score approximations, one for prevalence and one for mortality (Peto, Pike, and Day 1980). It represents a special case in PROC MULTTEST because the data structure requirements are different, and the resampling methods used for adjusting p-values are not valid. The TIME= option variable is required to specify "death" times or, more generally, times of occurrence. In addition, the test variables must assume one of the following three values:

- 0 = no occurrence
- 1 = incidental occurrence
- 2 = fatal occurrence

Use the TIME= option variable to define the mortality strata, and use the STRATA statement variable to define the prevalence strata.

In the following notation, the subscript v represents the variable, g represents the treatment group, s represents the stratum, and t represents the time. Recall that a plus sign $(+)$ in a subscript location denotes summation over that subscript.

Let S^P_{vgs} be the number of incidental occurrences, and let m^P_{vgs} be the total sample size for variable v in group g, stratum s, excluding fatal tumors.

Let S^F_{vgt} be the number of fatal occurrences in time period t, and let m^F_{vgt} be the number of patients alive at the end of time $t-1$.

The pooled probability estimates are given by

$$\begin{aligned} p^P_{vs} &= \frac{S^P_{v+s}}{m^P_{v+s}} \\ p^F_{vt} &= \frac{S^F_{v+t}}{m^F_{v+t}} \end{aligned}$$

The expected values are

$$\begin{aligned} E^P_{vgs} &= m^P_{vgs} p^P_{vs} \\ E^F_{vgt} &= m^F_{vgt} p^F_{vt} \end{aligned}$$

Let t_g denote a contrast trend coefficient, and define the numerator terms as follows:

$$N_v^P = \sum_s \sum_g t_g \left(S_{vgs}^P - E_{vgs}^P \right)$$
$$N_v^F = \sum_t \sum_g t_g \left(S_{vgt}^F - E_{vgt}^F \right)$$

Define the denominator variance terms by using the binomial variance:

$$V_v^P = \sum_s p_{vs}^P \left(1 - p_{vs}^P\right) \left[\left(\sum_g m_{vgs}^P {t_g}^2 \right) - \frac{1}{m_{v+s}^P} \left(\sum_g m_{vgs}^P t_g \right)^2 \right]$$
$$V_v^F = \sum_s p_{vt}^F \left(1 - p_{vt}^F\right) \left[\left(\sum_g m_{vgt}^F {t_g}^2 \right) - \frac{1}{m_{v+t}^F} \left(\sum_g m_{vgt}^F t_g \right)^2 \right]$$

The hypergeometric variances (the default) are calculated by weighting the within-strata variances as discussed in the section "Z-Score Approximation" on page 5026.

The Peto statistic is computed as

$$Z_v = \frac{N_v^P + N_v^F - c}{\sqrt{V_v^P + V_v^F}}$$

where c is a continuity correction. The p-value is determined from the standard normal distribution unless the PERMUTATION=*number* option is used. When you use the PERMUTATION= option for PETO in the TEST statement, PROC MULTTEST computes the "discrete approximation" permutation distribution described by Mantel (1980) and Soper and Tonkonoh (1993). Specifically, the permutation distribution of $\sum_s \sum_g t_g S_{vgs}^P + \sum_t \sum_g t_g S_{vgt}^F$ is computed, assuming that $\{\sum_g t_g S_{vgs}^P\}$ and $\{\sum_g t_g S_{vgt}^F\}$ are independent over all s and t. Note that the contrast trend coefficients t_g must be integer valued. The p-values are exact under this independence assumption. However, the independence assumption is valid only asymptotically, which is why these p-values are called "approximate."

An exact permutation distribution is available only under the assumption of equal risk of censoring in all treatment groups; even then, computing this distribution can be cumbersome. Soper and Tonkonoh (1993) describe situations where the discrete approximation distribution closely fits the exact permutation distribution.

Fisher Exact Test

The CONTRAST statement in PROC MULTTEST enables you to compute Fisher exact tests for two-group comparisons. No stratification variable is allowed for this test. Note, however, that the FISHER exact test is a special case of the exact permutation tests performed by PROC MULTTEST and that these permutation

tests allow a stratification variable. Recall that contrast coefficients can be -1, 0, or 1 for the Fisher test. The frequencies and sample sizes of the groups scored as -1 are combined, as are the frequencies and sample sizes of the groups scored as 1. Groups scored as 0 are excluded. The -1 group is then compared with the 1 group by using the Fisher exact test.

Letting x and m denote the frequency and sample size of the 1 group, and letting y and n denote those of the -1 group, the p-value is calculated as

$$\Pr(X \geq x \mid X + Y = x + y) = \sum_{i=x}^{m} \frac{\binom{m}{i}\binom{n}{x+y-i}}{\binom{m+n}{x+y}}$$

where X and Y are independent binomially distributed random variables with sample sizes m and n and common probability parameters. The hypergeometric distribution is used to determine the stated probability; Yates (1984) discusses this technique. PROC MULTTEST computes the two-tailed p-values by adding probabilities from both tails of the hypergeometric distribution. The first tail is from the observed x and y, and the other tail is chosen so that the resulting probability is as large as possible without exceeding the probability from the first tail. If the variable being tested has only one level, then the p-value is set to 1.

t Test for the Mean

For continuous variables, PROC MULTTEST automatically centers the contrast trend coefficients, as in the Freeman-Tukey test. These centered coefficients c_g are then used to form a t statistic contrasting the within-group means. Let n_{vgs} denote the sample size within group g and stratum s; it depends on variable v only when there are missing values. Determine the weights w_{vs} as in the Freeman-Tukey test with n_{vgs} replacing m_{vgs}. Define

$$\bar{X}_{vgs+} = \frac{1}{n_{vgs}} \sum_{r} X_{vgsr}$$

as the sample mean within a group-and-stratum combination, and let μ_{vgs} denote the treatment means. Write the null hypothesis as

$$\sum_{s} w_{vs} \sum_{g} c_g \mu_{vgs} = 0$$

Also define

$$s_v^2 = \frac{\sum_{s}\sum_{g}\sum_{r} \left(X_{vgsr} - \bar{X}_{vgs+}\right)^2}{\sum_{s}\sum_{g} \left(n_{vgs} - 1\right)}$$

as the pooled sample variance.

Homogeneous Variance

Assuming constant variance for all group-and-stratum combinations, the t statistic for the mean is

$$M_v = \frac{\sum_s w_{vs} \sum_g c_g \bar{X}_{vgs+}}{\sqrt{s_v^2 \left(\sum_s w_{vs}^2 \sum_g \frac{c_g^2}{n_{vgs}} \right)}}$$

Then under the null hypothesis and assuming normality, independence, and homoscedasticity, M_v follows a t distribution with $df_p = \sum_s \sum_g \left(n_{vgs} - 1 \right)$ degrees of freedom.

Whenever a denominator of 0 is computed, the p-value is set to 1. When missing data force $n_{vgs} = 0$, the contribution to the denominator of the pooled variance is 0 and not -1. This is also true for the degrees of freedom.

Heterogeneous Variance

If you do not assume constant variance for all group-and-stratum combinations, then the approximate t test is

$$M_v = \frac{\sum_s w_{vs} \sum_g c_g \bar{X}_{vgs+}}{\sqrt{\sum_s w_{vs}^2 \sum_g c_g^2 \frac{s_{vgs}^2}{n_{vgs}}}}$$

Under the null hypothesis and assuming normality and independence, the Satterthwaite (1946) approximation for the degrees of freedom of the t test is given by

$$df_s = \frac{\left(\sum_s w_{vs}^2 \sum_g c_g^2 \frac{s_{vgs}^2}{n_{vgs}} \right)^2}{\sum_s \sum_g \frac{\left(w_{vs}^2 c_g^2 \frac{s_{vgs}^2}{n_{vgs}} \right)^2}{n_{vgs} - 1}}$$

under the restriction $1 \leq df_s \leq \sum_s \sum_g n_{vgs}$.

Whenever a denominator of 0 for M_v is computed, the p-value is set to 1. If the denominator for df_s is computed as 0, then set $df_s = df_p$. When missing data force $n_{vgs} = 0$, that group-and-stratum combination does not contribute to the df_s computation.

p-Value Adjustments

Suppose you test m null hypotheses, $H_{01}, \ldots, H_{0m}$, and obtain the p-values $p_1, \ldots, p_m$. Denote the ordered p-values as $p_{(1)} \leq \ldots \leq p_{(m)}$ and order the tests appropriately: $H_{0(1)}, \ldots, H_{0(m)}$. Suppose you know m_0 of the null hypotheses are true and $m_1 = m - m_0$ are false. Let R indicate the number of null hypotheses rejected by the tests, where V of these are incorrectly rejected (that is, V tests are Type I errors) and $R - V$ are correctly rejected (so $m_1 - R + V$ tests are Type II errors). This information is summarized in the following table:

	Null Is Rejected	**Null Is Not Rejected**	**Total**
Null Is True	V	$m_0 - V$	m_0
Null Is False	$R - V$	$m_1 - R + V$	m_1
Total	R	$m - R$	m

The *familywise error rate* (FWE) is the overall Type I error rate for all the comparisons (possibly under some restrictions); that is, it is the maximum probability of incorrectly rejecting one or more null hypotheses:

$$\text{FWE} = \Pr(V > 0)$$

The FWE is also known as the *maximum experimentwise error rate* (MEER), as discussed in the section "Pairwise Comparisons" on page 3236 of Chapter 41, "The GLM Procedure."

The *false discovery rate* (FDR) is the expected proportion of incorrectly rejected hypotheses among all rejected hypotheses:

$$\begin{aligned}\text{FDR} &= E\left(\frac{V}{R}\right) \quad \text{where } \frac{V}{R} = 0 \text{ when } V = R = 0 \\ &= E\left(\frac{V}{R} \mid R > 0\right) \Pr(R > 0)\end{aligned}$$

Under the overall null hypothesis (all the null hypotheses are true), the FDR=FWE since $V = R$ gives $E\left(\frac{V}{R}\right) = 1 \times \Pr\left(\frac{V}{R} = 1\right) = \Pr(V > 0)$. Otherwise, FDR is always less than FWE, and an FDR-controlling adjustment also controls the FWE. Another definition used is the *positive* false discovery rate:

$$\text{pFDR} = E\left(\frac{V}{R} \mid R > 0\right)$$

The p-value adjustment methods discussed in the following sections attempt to correct the raw p-values while controlling either the FWE or the FDR. Note that the methods might impose some restrictions in order to achieve this; restrictions are discussed along with the methods in the following sections. Discussions and comparisons of some of these methods are given in Dmitrienko et al. (2005), Dudoit, Shaffer, and Boldrick (2003), Westfall et al. (1999), and Brown and Russell (1997).

Familywise Error Rate Controlling Adjustments

PROC MULTTEST provides several p-value adjustments to control the familywise error rate. *Single-step* adjustment methods are computed without reference to the other hypothesis tests under consideration. The

available single-step methods are the Bonferroni and Šidák adjustments, which are simple functions of the raw p-values that try to distribute the significance level α across all the tests, and the bootstrap and permutation resampling adjustments, which require the raw data. The Bonferroni and Šidák methods are calculated from the permutation distributions when exact permutation tests are used with the CA or Peto test.

Stepwise tests, or *sequentially rejective* tests, order the hypotheses in *step-up* (least significant to most significant) or *step-down* fashion, then sequentially determine acceptance or rejection of the nulls. These tests are more powerful than the single-step tests, and they do not always require you to perform every test. However, PROC MULTTEST still adjusts every p-value. PROC MULTTEST provides the following stepwise p-value adjustments: step-down Bonferroni (Holm), step-down Šidák, step-down bootstrap and permutation resampling, Hochberg's (1988) step-up, Hommel's (1988), Fisher's combination method, and the Stouffer-Liptak combination method. Adaptive versions of Holm's step-down Bonferroni and Hochberg's step-up Bonferroni methods, which require an estimate of the number of true null hypotheses, are also available.

Liu (1996) shows that all single-step and stepwise tests based on marginal p-values can be used to construct a *closed* test (Marcus, Peritz, and Gabriel 1976; Dmitrienko et al. 2005). Closed testing methods not only control the familywise error rate at size α, but are also more powerful than the tests on which they are based. Westfall and Wolfinger (2000) note that several of the methods available in PROC MULTTEST are closed—namely, the step-down methods, Hommel's method, and Fisher's combination; see that reference for conditions and exceptions.

All methods except the resampling methods are calculated by simple functions of the raw p-values or marginal permutation distributions; the permutation and bootstrap adjustments require the raw data. Because the resampling techniques incorporate distributional and correlational structures, they tend to be less conservative than the other methods.

When a resampling (bootstrap or permutation) method is used with only one test, the adjusted p-value is the bootstrap or permutation p-value for that test, with no adjustment for multiplicity, as described by Westfall and Soper (1994).

Bonferroni

The Bonferroni p-value for test $i, i = 1, \ldots, m$ is simply $\tilde{p}_i = mp_i$. If the adjusted p-value exceeds 1, it is set to 1. The Bonferroni test is conservative but always controls the familywise error rate.

If the unadjusted p-values are computed by using exact permutation distributions, then the Bonferroni adjustment for p_i is $\tilde{p}_i = p_1^* + \cdots + p_m^*$, where p_j^* is the largest p-value from the permutation distribution of test j satisfying $p_j^* \leq p_i$, or 0 if all permutational p-values of test j are greater than p_i. These adjustments are much less conservative than the ordinary Bonferroni adjustments because they incorporate the discrete distributional characteristics. However, they remain conservative in that they do not incorporate correlation structures between multiple contrasts and multiple variables (Westfall and Wolfinger 1997).

Šidák

A technique slightly less conservative than Bonferroni is the Šidák p-value (Šidák 1967), which is $\tilde{p}_i = 1 - (1 - p_i)^m$. It is exact when all of the p-values are uniformly distributed and independent, and it is conservative when the test statistics satisfy the positive orthant dependence condition (Holland and Copenhaver 1987).

If the unadjusted p-values are computed by using exact permutation distributions, then the Šidák adjustment for p_i is $\tilde{p}_i = 1 - (1 - p_1^*) \cdots (1 - p_m^*)$, where the p_j^* are as described previously. These adjustments are less conservative than the corresponding Bonferroni adjustments, but they do not incorporate correlation structures between multiple contrasts and multiple variables (Westfall and Wolfinger 1997).

Bootstrap

The bootstrap method creates pseudo-data sets by sampling observations with replacement from each within-stratum pool of observations. An entire data set is thus created, and p-values for all tests are computed on this pseudo-data set. A counter records whether the minimum p-value from the pseudo-data set is less than or equal to the actual p-value for each base test. (If there are m tests, then there are m such counters.) This process is repeated a large number of times, and the proportion of resampled data sets where the minimum pseudo-p-value is less than or equal to an actual p-value is the adjusted p-value reported by PROC MULTTEST. The algorithms are described in Westfall and Young (1993).

In the case of continuous data, the pooling of the groups is not likely to re-create the shape of the null hypothesis distribution, since the pooled data are likely to be multimodal. For this reason, PROC MULTTEST automatically mean-centers all continuous variables prior to resampling. Such mean-centering is akin to resampling residuals in a regression analysis, as discussed by Freedman (1981). You can specify the NOCENTER option if you do not want to center the data.

The bootstrap method implicitly incorporates all sources of correlation, from both the multiple contrasts and the multivariate structure. The adjusted p-values incorporate all correlations and distributional characteristics. This method always provides weak control of the familywise error rate, and it provides strong control when the *subset pivotality* condition holds; that is, for any subset of the null hypotheses, the joint distribution of the p-values for the subset is identical to that under the complete null (Westfall and Young 1993).

Permutation

The permutation-style-adjusted p-values are computed in identical fashion as the bootstrap-adjusted p-values, with the exception that the within-stratum resampling is performed without replacement instead of with replacement. This produces a rerandomization analysis such as in Brown and Fears (1981) and Heyse and Rom (1988). In the spirit of rerandomization analyses, the continuous variables are not centered prior to resampling. This default can be overridden by using the CENTER option.

The permutation method implicitly incorporates all sources of correlation, from both the multiple contrasts and the multivariate structure. The adjusted p-values incorporate all correlations and distributional characteristics. This method always provides weak control of the familywise error rate, and it provides strong control of the familywise error rate under the *subset pivotality* condition, as described in the preceding section.

Step-Down Methods

Step-down testing is available for the Bonferroni, Šidák, bootstrap, and permutation methods. The benefit of using step-down methods is that the tests are made more powerful (smaller adjusted p-values) while, in most cases, maintaining strong control of the familywise error rate. The step-down method was pioneered

by Holm (1979) and further developed by Shaffer (1986), Holland and Copenhaver (1987), and Hochberg and Tamhane (1987).

The Bonferroni step-down (Holm) p-values $\tilde{p}_{(1)}, \ldots, \tilde{p}_{(m)}$ are obtained from

$$\tilde{p}_{(i)} = \begin{cases} mp_{(1)} & \text{for } i = 1 \\ \max\left(\tilde{p}_{(i-1)}, (m-i+1)p_{(i)}\right) & \text{for } i = 2, \ldots, m \end{cases}$$

As always, if any adjusted p-value exceeds 1, it is set to 1.

The Šidák step-down p-values are determined similarly:

$$\tilde{p}_{(i)} = \begin{cases} 1-(1-p_{(1)})^m & \text{for } i = 1 \\ \max\left(\tilde{p}_{(i-1)}, 1-(1-p_{(i)})^{m-i+1}\right) & \text{for } i = 2, \ldots, m \end{cases}$$

Step-down Bonferroni adjustments that use exact tests are defined as

$$\tilde{p}_{(i)} = \begin{cases} p^*_{(1)} + \cdots + p^*_{(m)} & \text{for } i = 1 \\ \max\left(\tilde{p}_{(i-1)}, p^*_{(i)} + \cdots + p^*_{(m)},\right) & \text{for } i = 2, \ldots, m \end{cases}$$

where the p^*_j are defined as before. Note that p^*_j is taken from the permutation distribution corresponding to the jth-smallest unadjusted p-value. Also, any $\tilde{p}_j$ greater than 1.0 is reduced to 1.0.

Step-down Šidák adjustments for exact tests are defined analogously by substituting $1-(1-p^*_{(j)})\cdots(1-p^*_{(m)})$ for $p^*_{(j)} + \cdots + p^*_{(m)}$.

The resampling-style step-down methods are analogous to the preceding step-down methods; the most extreme p-value is adjusted according to all m tests, the second-most extreme p-value is adjusted according to $(m-1)$ tests, and so on. The difference is that all correlational and distributional characteristics are incorporated when you use resampling methods. More specifically, assuming the same ordering of p-values as discussed previously, the resampling-style step-down-adjusted p-value for test i is the probability that the minimum pseudo-p-value of tests $i, \ldots, m$ is less than or equal to p_i.

This probability is evaluated by using Monte Carlo simulation, as are the previously described resampling-style-adjusted p-values. In fact, the computations for step-down-adjusted p-values are essentially no more time-consuming than the computations for the non-step-down-adjusted p-values. After Monte Carlo, the step-down-adjusted p-values are corrected to ensure monotonicity; this correction leaves the first adjusted p-values alone, then corrects the remaining ones as needed. The step-down method approximately controls the familywise error rate, and it is described in more detail by Westfall and Young (1993), Westfall et al. (1999), and Westfall and Wolfinger (2000).

Hommel

Hommel's (1988) method is a closed testing procedure based on Simes' test (Simes 1986). The Simes p-value for a joint test of any set of S hypotheses with p-values $p_{(1)} \leq p_{(2)} \leq \ldots \leq p_{(S)}$ is $\min((S/1)p_{(1)}, (S/2)p_{(2)}, \ldots, (S/S)p_{(S)})$. The Hommel-adjusted p-value for test j is the maximum of all such Simes p-values, taken over all joint tests that include j as one of their components.

Hochberg-adjusted p-values are always as large or larger than Hommel-adjusted p-values. Sarkar and Chang (1997) shows that Simes' method is valid under independent or positively dependent p-values, so Hommel's and Hochberg's methods are also valid in such cases by the closure principle.

Hochberg

Assuming p-values are independent and uniformly distributed under their respective null hypotheses, Hochberg (1988) demonstrates that Holm's step-down adjustments control the familywise error rate even when calculated in *step-up* fashion. Since the adjusted p-values are uniformly smaller for Hochberg's method than for Holm's method, the Hochberg method is more powerful. However, this improved power comes at the cost of having to make the assumption of independence. Hochberg's method can be derived from Hommel's (Liu 1996), and is thus also derived from Simes' test (Simes 1986).

Hochberg-adjusted p-values are always as large or larger than Hommel-adjusted p-values. Sarkar and Chang (1997) showed that Simes' method is valid under independent or positively dependent p-values, so Hommel's and Hochberg's methods are also valid in such cases by the closure principle.

The Hochberg-adjusted p-values are defined in reverse order of the step-down Bonferroni:

$$\tilde{p}_{(i)} = \begin{cases} p_{(m)} & \text{for } i = m \\ \min\left(\tilde{p}_{(i+1)}, (m-i+1)\,p_{(i)}\right) & \text{for } i = m-1, \ldots, 1 \end{cases}$$

Fisher Combination

The FISHER_C option requests adjusted p-values by using closed tests, based on the idea of Fisher's combination test. The Fisher combination test for a joint test of any set of S hypotheses with p-values uses the chi-square statistic $\chi^2 = -2\sum \log(p_i)$, with $2S$ degrees of freedom. The FISHER_C adjusted p-value for test j is the maximum of all p-values for the combination tests, taken over all joint tests that include j as one of their components. Independence of p-values is required for the validity of this method.

Stouffer-Liptak Combination

The STOUFFER option requests adjusted p-values by using closed tests, based on the Stouffer-Liptak combination test. The Stouffer combination joint test of any set of S one-sided hypotheses with p-values, $p_1, \ldots, p_S$, yields the p-value, $1 - \Phi\left(\frac{1}{\sqrt{S}}\sum_i \Phi^{-1}(1-p_i)\right)$. The STOUFFER adjusted p-value for test j is the maximum of all p-values for the combination tests, taken over all joint tests that include j as one of their components.

Independence of the one-sided p-values is required for the validity of this method. Westfall (2005) shows that the Stouffer-Liptak adjustment might have more power than the Fisher combination and Simes' adjustments when the test results reinforce each other.

Adaptive Adjustments

Adaptive adjustments modify the FWE- and FDR-controlling procedures by taking an estimate of the number m_0 or proportion π_0 of true null hypotheses into account. The adjusted p-values for Holm's and Hochberg's methods involve the number of unadjusted p-values larger than (i), $m - i + 1$. So the minimal significance level at which the ith ordered p-value is rejected implies that the number of true null hypotheses is $m - i + 1$. However, if you know m_0, then you can replace $m - i + 1$ with $\min(m_0, m - i + 1)$, thereby obtaining more power while maintaining the original α-level significance.

Since m_0 is unknown, there are several methods used to estimate the value—see the NTRUENULL= option for more information. The estimation method described by Hochberg and Benjamini (1990) considers the

graph of $1 - p_{(i)}$ versus i, where the $p_{(i)}$ are the ordered p-values of your tests. See Output 60.6.4 for an example. If all null hypotheses are actually true ($m_0 = m$), then the p-values behave like a sample from a uniform distribution and this graph should be a straight line through the origin. However, if points in the upper-right corner of this plot do not follow the initial trend, then some of these null hypotheses are probably false and $0 < m_0 < m$.

The ADAPTIVEHOLM option uses this estimate of m_0 to adjust the step-up Bonferroni method while the ADAPTIVEHOCHBERG option adjusts the step-down Bonferroni method. Both of these methods are due to Hochberg and Benjamini (1990). When m_0 is known, these procedures control the familywise error rate in the same manner as their nonadaptive versions but with more power; however, since m_0 must be estimated, the FWE control is only approximate. The ADAPTIVEFDR and PFDR options also use $\hat{m}_0$, and are described in the following section.

The adjusted p-values for the ADAPTIVEHOLM method are computed by

$$\tilde{p}_{(i)} = \begin{cases} \min(m, \hat{m}_0)\, p_{(1)} & \text{for } i = 1 \\ \max\left[\tilde{p}_{(i-1)}, \min(m - i + 1, \hat{m}_0)\, p_{(i)}\right] & \text{for } i = 2, \ldots, m \end{cases}$$

The adjusted p-values for the ADAPTIVEHOCHBERG method are computed by

$$\tilde{p}_{(i)} = \begin{cases} \min(1, \hat{m}_0)\, p_{(m)} & \text{for } i = m \\ \min\left[\tilde{p}_{(i+1)}, \min(m - i + 1, \hat{m}_0)\, p_{(i)}\right] & \text{for } i = m - 1, \ldots, 1 \end{cases}$$

False Discovery Rate Controlling Adjustments

Methods that control the *false discovery rate* (FDR) were described by Benjamini and Hochberg (1995). These adjustments do not necessarily control the familywise error rate (FWE). However, FDR-controlling methods are more powerful and more liberal, and hence reject more null hypotheses, than adjustments protecting the FWE. FDR-controlling methods are often used when you have a large number of null hypotheses. To control the FDR, Benjamini and Hochberg's (1995) linear step-up method is provided, as well as an adaptive version, a dependence version, and bootstrap and permutation resampling versions. Storey's (2002) pFDR methods are also provided.

The FDR option requests p-values that control the "false discovery rate" described by Benjamini and Hochberg (1995). These *linear step-up* adjustments are potentially much less conservative than the Hochberg adjustments.

The FDR-adjusted p-values are defined in step-up fashion, like the Hochberg adjustments, but with less conservative multipliers:

$$\tilde{p}_{(i)} = \begin{cases} p_{(m)} & \text{for } i = m \\ \min\left(\tilde{p}_{(i+1)}, \frac{m}{i} p_{(i)}\right) & \text{for } i = m - 1, \ldots, 1 \end{cases}$$

The FDR method is guaranteed to control the false discovery rate at level $\leq \frac{m_0}{m}\alpha \leq \alpha$ when you have independent p-values that are uniformly distributed under their respective null hypotheses. Benjamini and Yekateuli (2001) show that the false discovery rate is also controlled at level $\leq \frac{m_0}{m}\alpha$ when the *positive regression dependent* condition holds on the set of the true null hypotheses, and they provide several examples where this condition is true.

NOTE: The positive regression dependent condition on the set of the true null hypotheses holds if the joint distribution of the test statistics $\mathbf{X} = (X_1, \ldots, X_m)$ for the null hypotheses $H_{01}, \ldots, H_{0m}$ satisfies: $\Pr(\mathbf{X} \in A | X_i = x)$ is nondecreasing in x for each X_i where H_{0i} is true, for any increasing set A. The set A is increasing if $\boldsymbol{x} \in A$ and $\boldsymbol{y} \geq \boldsymbol{x}$ implies $\boldsymbol{y} \in A$.

Dependent False Discovery Rate

The DEPENDENTFDR option requests a false discovery rate controlling method that is always valid for p-values under any kind of dependency (Benjamini and Yekateuli 2001), but is thus quite conservative. Let $\gamma = \sum_{i=1}^{m} \frac{1}{i}$. The DEPENDENTFDR procedure always controls the false discovery rate at level $\leq \frac{m_0}{m}\alpha\gamma$. The adjusted p-values are computed as

$$\tilde{p}_{(i)} = \begin{cases} \gamma p_{(m)} & \text{for } i = m \\ \min\left(\tilde{p}_{(i+1)}, \gamma \frac{m}{i} p_{(i)}\right) & \text{for } i = m-1, \ldots, 1 \end{cases}$$

False Discovery Rate Resampling Adjustments

Bootstrap and permutation resampling methods to control the false discovery rate are available with the FDRBOOT and FDRPERM options (Yekateuli and Benjamini 1999). These methods approximately control the false discovery rate when the *subset pivotality* condition holds, as discussed in the section "Bootstrap" on page 5036, and when the p-values corresponding to the true null hypotheses are independent of those for the false null hypotheses.

The resampling methodology for the BOOTSTRAP and PERMUTATION methods is used to create B resamples. For the bth resample, let $R^b(p)$ denote the number of p-values that are less than or equal to the observed p-value p. Let $r_\beta(p)$ be the $100(1-\beta)$th quantile of $\{R^1(p) \ldots R^b(p) \ldots R^B(p)\}$, and let $r(p)$ be the number of observed p-values less than or equal to p. Compute one of the following estimators:

$$\text{local estimator} \qquad Q_1(p) = \begin{cases} \frac{1}{B}\sum_{b=1}^{B} \frac{R^b(p)}{R^b(p) + r(p) - pm} & \text{if } r(p) - r_\beta(p) \geq pm \\ \#\{R^b(p) \geq 1\}/B & \text{otherwise} \end{cases}$$

$$\text{upper limit estimator} \qquad Q_\beta(p) = \begin{cases} \sup_{x \in [0,p]} \left(\frac{1}{B}\sum_{b=1}^{B} \frac{R^b(x)}{R^b(x) + r(x) - r_\beta(x)} \right) & \text{if } r(x) - r_\beta(x) \geq 0 \\ \#\{R^b(p) \geq 1\}/B & \text{otherwise} \end{cases}$$

where m is the number of tests and B is the number of resamples. Then for $Q = Q_1$ or Q_β, the adjusted p-values are computed as

$$\tilde{p}_{(i)} = \begin{cases} Q(p_{(m)}) & \text{for } i = m \\ \min\left(\tilde{p}_{(i+1)}, Q(p_{(i)})\right) & \text{for } i = m-1, \ldots, 1 \end{cases}$$

Adaptive False Discovery Rate

Since the FDR method controls the false discovery rate at $\leq \frac{m_0}{m}\alpha \leq \alpha$, knowledge of m_0 allows improvement of the power of the adjustment while still maintaining control of the false discovery rate. The ADAPTIVEFDR option requests adaptive adjusted p-values for approximate control of the false discovery

rate, as discussed in Benjamini and Hochberg (2000). See the section "Adaptive Adjustments" on page 5038 for more details. These adaptive adjustments are also defined in step-up fashion but use an estimate $\hat{m}_0$ of the number of true null hypotheses:

$$\tilde{p}_{(i)} = \begin{cases} \frac{\hat{m}_0}{m} p_{(m)} & \text{for } i = m \\ \min\left(\tilde{p}_{(i+1)}, \frac{\hat{m}_0}{i} p_{(i)}\right) & \text{for } i = m-1, \ldots, 1 \end{cases}$$

Since $\hat{m}_0 \leq m$, the larger p-values are adjusted down. This means that controlling the false discovery rate allows you to reject these tests at a level less than the observed p-value. You can modify these results by outputting the raw and adjusted p-values with the OUT= option, then use a DATA step to set $\tilde{p}_i = \max\{\tilde{p}_i, p_i\}$.

To use this adjustment, Benjamini and Hochberg (2000) suggest first specifying the FDR option—if at least one test is rejected at your level, then apply the ADAPTIVEFDR adjustment. Alternatively, Benjamini, Krieger, and Yekutieli (2006) apply the FDR adjustment at level $\frac{\alpha}{\alpha+1}$, then specify the resulting number of true hypotheses with the NTRUENULL= option and apply the ADAPTIVEFDR adjustment; they show that this *two-stage linear step-up* procedure controls the false discovery rate at level α for independent test statistics.

Positive False Discovery Rate

The PFDR option computes the "q-values" $\hat{q}_\lambda(p_i)$ (Storey 2002; Storey, Taylor, and Siegmund 2004), which are adaptive adjusted p-values for strong control of the false discovery rate when the p-values corresponding to the true null hypotheses are independent and uniformly distributed. There are four versions of the PFDR available. Let $N(\lambda)$ be the number of observed p-values that are less than or equal to λ; let m be the number of tests; let $f = 1$ if the FINITE option is specified, and otherwise set $f = 0$; and denote the estimated proportion of true null hypotheses by

$$\hat{\pi}_0(\lambda) = \frac{m - N(\lambda) + f}{(1-\lambda)m}$$

The default estimate of FDR is

$$\widehat{\mathrm{FDR}}_\lambda(p) = \frac{\hat{\pi}_0(\lambda) p}{\max(N(p), 1)/m}$$

If you set $\lambda = 0$, then this is identical to the FDR adjustment.

The positive FDR is estimated by

$$\widehat{\mathrm{pFDR}}_\lambda(p) = \frac{\widehat{\mathrm{FDR}}_\lambda(p)}{1 - (1-p)^m}$$

The finite-sample versions of these two estimators for independent null p-values are given by

$$\widehat{\mathrm{FDR}}^*_\lambda(p) = \begin{cases} \frac{\hat{\pi}^*_0(\lambda) p}{\max(N(p), 1)/m} & \text{if } p \leq \lambda \\ 1 & \text{if } p > \lambda \end{cases}$$

$$\widehat{\mathrm{pFDR}}^*_\lambda(p) = \frac{\widehat{\mathrm{FDR}}^*_\lambda(p)}{1 - (1-p)^m}$$

Finally, the adjusted p-values are computed as

$$\tilde{p}_i = \hat{q}_\lambda(p_i) = \inf_{p \geq p_i} \mathrm{FDR}_\lambda(p) \quad i = 1, \ldots, m$$

This method can produce adjusted p-values that are smaller than the raw p-values. This means that controlling the false discovery rate allows you to reject these tests at a level less than the observed p-value. You can modify these results by outputting the raw and adjusted p-values with the OUT= option, then use a DATA step to set $\tilde{p}_i = \max\{\tilde{p}_i, p_i\}$.

Missing Values

If a CLASS or STRATA variable has a missing value, then PROC MULTTEST removes that observation from the analysis.

When there are missing values for test variables, the within-group-and-stratum sample sizes can differ from variable to variable. In most cases this is not a problem; however, it is possible for all data to be missing for a particular group within a particular stratum. For continuous variables and Freeman-Tukey tests, PROC MULTTEST re-centers the contrast trend coefficients within strata where all data for a particular group are missing. Re-centering the MEAN tests could redefine your t tests in an undesirable fashion; for example, if you specify coefficients to contrast the first and third groups (`contrast -1 0 1`) but the third group is missing, then the re-centered coefficients become –0.5 and 0.5, thus contrasting the first and second groups. If this is the case, you can run your t tests in separate PROC MULTTEST invocations, then combine the data and adjust the p-values by using the INPVALUES= option. However, you might find this re-centering acceptable for the Freeman-Tukey trend tests, since the contrast still tests for an increasing trend. The Cochran-Armitage and Peto tests are unaffected by this situation.

PROC MULTTEST uses missing values for resampling if they exist in the original data set. If all variables have missing values for any observation, then PROC MULTTEST removes the observation prior to resampling. Otherwise, PROC MULTTEST treats all missing values as ordinary observations in the resampling. This means that different resampled data sets can have different group sizes. In some cases it means that a resampled data set can have all missing values for a particular variable in a particular group/stratum combination, even when values exist for that combination in the original data. For this reason, PROC MULTTEST recomputes all quantities within each pseudo-data set, including such items as centered scoring coefficients and degrees of freedom for p-values.

While PROC MULTTEST does provide analyses in missing value cases, you should not feel that it completely solves the missing-value problem. If you are concerned about the adverse effects of missing data on a particular analysis, you should consider using imputation and sensitivity analyses to assess the effects of the missing data.

Computational Resources

PROC MULTTEST keeps all of the data in memory to expedite resampling. A large portion of the memory requirement is thus 8*NOBS*NVAR bytes, where NOBS is the number of observations in the data set, and NVAR is the number of variables analyzed, including CLASS, FREQ, and STRATA variables.

If you specify PERMUTATION=*number* (for exact permutation distributions), then PROC MULTTEST requires additional memory. This requirement is approximately 4*NTEST*NSTRATA*CMAX**number**(*number*+1) bytes, where NTEST is the number of contrasts, NSTRATA is the number of STRATA levels, and CMAX is the maximum contrast coefficient.

If you specify the FDRBOOT or FDRPERM option, then saving all the resamples in memory requires 8*NSAMPLE*NOBS bytes, where NSAMPLE is the number of resamples used.

The execution time is linear in the number of resamples; that is, 10,000 resamples will take 10 times longer than 1,000 resamples. The execution time is also linear in the sample size; that is, 100 resamples of size N will take 10 times longer than 100 resamples of size $10N$.

Output Data Sets

OUT= Data Set

The OUT= data set contains contrast names (_test_), variable names (_var_), the contrast label (_contrast_), raw p-values (raw_p or the value specified in the INPVALUES= option), and all requested adjusted p-values (bon_p, sid_p, boot_p, perm_p, stpbon_p, stpsid_p, stpbootp, stppermp, hom_p, hoc_p, fic_p, stouffer_p, aholm_p, ahoc_p, fdr_p, dfdr_p, fdrbootp, ufdbootp, fdrpermp, ufdpermp, afdr_p, or pfdr_p).

If a resampling-based adjusted p-value is requested, then the simulation standard error is included as either sim_se, stpsimse, fdrsimse, or ufdsimse, depending on whether single-step, step-down, or FDR adjustments are requested. The simulation standard errors are used to bound the true resampling-based adjusted p-value. For example, if the resampling-based estimate is 0.0312 and the simulation standard error is 0.00123, then a 95% confidence interval for the true adjusted p-value is $0.0312 \pm 1.96(0.00123)$, or 0.0288 to 0.0336.

Intermediate statistics used to calculate the p-values are also written to the OUT= data set. The statistics are separated by the _strat_ level. When _strat_ is reported as missing, the statistics refer to the pooled analysis over all _strat_ levels. The p-values are provided only for the pooled analyses and are therefore reported as missing for the strata-specific statistics.

For the Peto test, an additional variable, _tstrat_, is included to indicate whether the stratum is an incidental occurrence stratum (_tstrat_=0) or a fatal occurrence stratum (_tstrat_=1).

The statistic _value_ is the per-strata contribution to the numerator of the overall test statistic. In the case of the MEAN test, this is the contrast function of the sample means multiplied by the total number of observations within the stratum. For the FT test, _value_ is the contrast function of the double-arcsine transformed proportions, again multiplied by the total number of observations within the stratum. For the CA and Peto tests, _value_ is the observed value of the trend statistic within that stratum.

When either PETO or CA is requested, the variable _exp_ is included; this variable contains the expected value of the trend statistic for the given stratum.

The statistic _se_ is the square root of the variance of the per-strata _value_ statistic for any of the tests.

For MEAN tests, the variable _nval_ is included. When reported with an individual stratum level (that is, when the _strat_ value is nonmissing), the value _nval_ refers to the within-stratum sample size. For the

combined analysis (that is, the value of the _strat_ is missing), the value _nval_ contains degrees of freedom of the *t* distribution used to compute the unadjusted *p*-value.

When the FISHER test is requested, the OUT= data set contains the variables _xval_, _mval_, _yval_, and _nval_, which define observations and sample sizes in the two groups defined by the CONTRAST statement.

For example, the OUT= data set from the drug example in the section "Getting Started: MULTTEST Procedure" on page 5007 is displayed in Figure 60.5.

Figure 60.5 Output Data for the MULTTEST Procedure

Obs	_test_	_var_	_contrast_	_value_	_exp_	_se_	raw_p	boot_p	sim_se

OUTPERM= Data Set

The OUTPERM= data set contains contrast names (_contrast_), variable names (_var_), and the associated permutation distributions (_value_ and upper_p). PROC MULTTEST computes the permutation distributions when you use the PERMUTATION= option with the CA or Peto test. The _value_ variable represents the support of the distributions, and upper_p represents their cumulative upper-tail probabilities. The size of this data set depends on the number of variables and the support of their permutation distributions.

For information about how this distribution is computed, see the section "Exact Permutation Test" on page 5027. For an illustration, see Example 60.1.

OUTSAMP= Data Set

The OUTSAMP= data set contains the data sets used in the resampling analysis, if such an analysis is requested. The variable _sample_ indicates the number of the resampled data set. This variable ranges from 1 to the value of the NSAMPLE= option. For each value of the _sample_ variable, an entire resampled data set is included, with _stratum_, _class_, and all other variables in the original data set. The values of the original variables are mean-centered for the mean test, if requested. The variable _obs_ indicates the observation's position in the original data set.

Each new data set is randomly drawn from the original data set, either with (bootstrap) or without (permutation) replacement. The size of this data set is, thus, the number of observations in the original data set times the number of samples.

Displayed Output

The output produced by PROC MULTTEST is divided into several tables. If the DATA= data set is specified, then the following tables are displayed:

- The "Model Information" table provides a list of the options and settings used for that particular invocation of the procedure. This table is not displayed if the INPVALUES= data set is specified. Included in this list are the following items:
  - statistical tests
  - support of the exact permutation distribution for the CA and Peto tests
  - continuity corrections used for the CA test
  - test tails
  - strata adjustment
  - *p*-value adjustments and specified suboptions
  - centering of continuous variables
  - number of samples and seed
- The "Contrast Coefficients" table lists the coefficients used in constructing the statistical tests. These coefficients are either specified in CONTRAST statements or generated by default. The coefficients apply to the levels of the CLASS statement variable. If a MEAN or FT test is specified in the TEST statement, the centered coefficients are displayed. Patterns of missing values in your data set might affect the coefficients used in your analysis; the displayed contrasts take missing value patterns into account. See the section "Missing Values" on page 5042 for more information.
- The "Variable Tabulations" tables provide summary statistics for each variable listed in the TEST statement. Included for discrete variables are the count, sample size, and percentage of occurrences. For continuous variables, the mean, sample standard deviation, and sample size are displayed. All of the previously mentioned statistics are computed for distinct combinations of the CLASS and STRATA statement variables.

If the INPVALUES= data set is specified, then the following tables are displayed:

- The "P-Value Adjustment Information" table provides a list of the specified *p*-value adjustments. If an adaptive adjustment is specified (see section "Adaptive Adjustments" on page 5038), then the following settings are also displayed when appropriate:
  - whether the finite-sample version of the PFDR is used (FINITE)
  - the number of tuning parameters to check (NLAMBDA=), the maximum tuning parameter (MAXLAMBDA=), or the specified tuning parameter (LAMBDA=)
  - the degrees of freedom of the spline (DF=) and the smoothing parameter
  - the number of bootstrap resamples (NBOOT=) and the seed (SEED=)

- If the bootstrap or spline method for estimating the number of true null hypotheses m_0 is used and the PLOTS= option is specified, the "Lambda Values" table displays the m_0 estimates as a function of the tuning parameter λ. If the bootstrap method is used, the table also displays the mean-squared errors, the minimum of which is used to select a specific λ. This table contains the values used in the "Lambda Functions" plot.
- The "Estimated Number of True Null Hypotheses" table displays the p-value adjustment, the method used to estimate the number of true nulls, and an estimate of the number and proportion of true null hypotheses in the data set.

The following table is displayed unless the NOPVALUE option is specified:

- The "p-Values" table is a collection of the raw and adjusted p-values from the run of PROC MULTTEST. The p-values are identified by variable and test.

ODS Table Names

PROC MULTTEST assigns a name to each table it creates, and you must use this name to reference the table when using the Output Delivery System (ODS). These names are listed in the following table. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 60.2 ODS Tables Produced by PROC MULTTEST

ODS Table Name	Description	Statement or Option
Continuous	Continuous variable tabulations	TEST with MEAN
Contrasts	Contrast coefficients	default
Discrete	Discrete variable tabulations	TEST with CA, FT, PETO, or FISHER
LambdaValues	True null estimates	AHOLM, AHOC, AFDR, or PFDR
ModelInfo	Model information	default
NumTrueNull	Estimates of number of true nulls	AHOLM, AHOC, AFDR, or PFDR
pValues	p-values from the tests	default
pValueInfo	p-value adjustment information	INPVALUES=

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, "Statistical Graphics Using ODS."

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section "Enabling and Disabling ODS Graphics" on page 612 in Chapter 21, "Statistical Graphics Using ODS."

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section "A Primer on ODS Statistical Graphics" on page 611 in Chapter 21, "Statistical Graphics Using ODS."

You must also specify the options in the PROC MULTTEST statement that are indicated in Table 60.3.

PROC MULTTEST assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in Table 60.3.

Table 60.3 Graphs Produced by PROC MULTTEST

ODS Graph Name	Plot Description	Option
AdjPlots	Panel of adjusted *p*-value plots	PLOTS=ADJUSTED
AdjByRawRank	Adjusted by rank of raw *p*-values	PLOTS=ADJUSTED(UNPACK)
AdjbyRawP	Adjusted by raw *p*-values	PLOTS=ADJUSTED(UNPACK)

Examples: MULTTEST Procedure

Example 60.1: Cochran-Armitage Test with Permutation Resampling

This example, from Keith Soper at Merck, illustrates the exact permutation Cochran-Armitage test carried out on permutation resamples. In the following data set, each observation represents an animal. The binary variables S1 and S2 indicate two tumor types, with 0s indicating no tumor (failure) and 1 indicating a tumor (success); note that they have perfect negative association. The grouping variable is Dose.

```
data a;
   input S1 S2 Dose @@;
   datalines;
0 1 1   1 0 1   0 1 1
0 1 1   0 1 1   1 0 1
1 0 2   1 0 2   0 1 2
1 0 2   0 1 2   1 0 2
1 0 3   1 0 3   1 0 3
0 1 3   0 1 3   1 0 3
;

proc multtest data=a permutation nsample=10000 seed=36607 outperm=pmt;
   test ca(S1 S2 / permutation=10 uppertailed);
   class Dose;
   contrast 'CA Linear Trend' 0 1 2;
run;
proc print data=pmt;
run;
```

The PROC MULTTEST statement requests 10,000 permutation resamples. The OUTPERM= option creates an output SAS data set pmt used for the exact permutation distribution computed for the CA test.

The TEST statement specifies an upper-tailed Cochran-Armitage linear trend test for S1 and S2. The cutoff for exact permutation calculations is 10, as specified with the PERMUTATION= option in the TEST statement. Since S1 and S2 have 10 and 8 successes, respectively, PROC MULTTEST uses exact permutation distributions to compute the *p*-values for both variables.

The groups for the CA test are the levels of Dose from the CLASS statement. The trend coefficients applied to these groups are 0, 1, and 2, respectively, as specified in the CONTRAST statement.

Finally, the PROC PRINT statement displays the SAS data set pmt, which contains the permutation distributions.

The results from this analysis are displayed in Output 60.1.1 through Output 60.1.5. You should check the "Model Information" table to verify that the analysis specifications are correct.

Output 60.1.1 Cochran-Armitage Test with Permutation Resampling

The Multtest Procedure

Model Information

Test for discrete variables	Cochran-Armitage
Exact permutation distribution used	Everywhere
Tails for discrete tests	Upper-tailed
Strata weights	None
P-value adjustment	Permutation
Number of resamples	10000
Seed	36607

The label and coefficients from the CONTRAST statement are shown in Output 60.1.2.

Output 60.1.2 Contrast Coefficients

Contrast Coefficients

	Dose		
Contrast	1	2	3
CA Linear Trend	0	1	2

Output 60.1.3 displays summary statistics for the two test variables, S1 and S2. The Count column lists the number of successes for each level of the CLASS variable, Dose. The NumObs column lists the sample size, and the Percent column lists the percentage of successes in the sample.

Output 60.1.3 Summary Statistics

Discrete Variable Tabulations

Variable	Dose	Count	NumObs	Percent
S1	1	2	6	33.33
S1	2	4	6	66.67
S1	3	4	6	66.67
S2	1	4	6	66.67
S2	2	2	6	33.33
S2	3	2	6	33.33

The Raw column in Output 60.1.4 contains the p-values from the CA test, and the Permutation column contains the permutation-adjusted p-values.

Output 60.1.4 Resulting *p*-Values

p-Values

Variable	Contrast	Raw	Permutation
S1	CA Linear Trend	0.1993	0.4009
S2	CA Linear Trend	0.9220	1.0000

This table shows that, for S1, the adjusted *p*-value is approximately twice the raw *p*-value. In fact, resamples with small (large) *p*-values for S1 have large (small) *p*-values for S2 due to the perfect negative association of the variables, and hence the permutation-adjusted *p*-value for S1 should be $2 \times 0.1993 = 0.3986$; the difference is due to resampling error. For the same reason, since the raw *p*-value for S2 is 0.9220, the adjusted *p*-value equals 1. The permutation *p*-values for S1 and S2 also happen to be the Bonferroni-adjusted *p*-values for this example.

The OUTPERM= data set is displayed in Output 60.1.5, which contains the exact permutation distributions for S1 and S2 in terms of cumulative probabilities.

Output 60.1.5 Exact Permutation Distribution

Example 60.2: Freeman-Tukey and *t* Tests with Bootstrap Resampling

The data for this example are the same as for Example 60.1, except that a continuous variable T, which indicates the time of death of the animal, has been added.

```
data a;
   input S1 S2 T Dose @@;
   datalines;
0 1 104 1   1 0  80 1   0 1 104 1
0 1 104 1   0 1 100 1   1 0 104 1
1 0  85 2   1 0  60 2   0 1  89 2
1 0  96 2   0 1  96 2   1 0  99 2
1 0  60 3   1 0  50 3   1 0  80 3
0 1  98 3   0 1  99 3   1 0  50 3
;

proc multtest data=a bootstrap nsample=10000 seed=37081 outsamp=res;
   test ft(S1 S2 / lowertailed) mean(T / lowertailed);
   class Dose;
   contrast 'Linear Trend' 0 1 2;
run;

proc print data=res(obs=36);
run;
```

The BOOTSTRAP option in the PROC MULTTEST statement requests bootstrap resampling, and NSAMPLE=10000 requests 10,000 bootstrap samples. The SEED=37081 option provides a starting value for the random number generator. The OUTSAMP=res option creates an output SAS data set res containing the 10,000 bootstrap samples.

The TEST statement specifies the Freeman-Tukey test for S1 and S2 and specifies the *t* test for T. Both tests are lower-tailed. The grouping variable in the CLASS statement is Dose, and the coefficients across the levels of Dose are 0, 1, and 2, as specified in the CONTRAST statement. The PROC PRINT statement displays the first 36 observations of the res data set containing the bootstrap samples.

The results from this analysis are listed in Output 60.2.1 through Output 60.2.5.

The "Model Information" table in Output 60.2.1 corresponds to the specifications in the invocation of PROC MULTTEST.

Output 60.2.1 FT and *t* tests with Bootstrap Resampling

The Multtest Procedure

Model Information

Test for discrete variables	Freeman-Tukey
Test for continuous variables	Mean t-test
Degrees of Freedom Method	Pooled
Tails for discrete tests	Lower-tailed
Tails for continuous tests	Lower-tailed
Strata weights	None
P-value adjustment	Bootstrap
Center continuous variables	Yes
Number of resamples	10000
Seed	37081

The "Contrast Coefficients" table in Output 60.2.2 shows the coefficients from the CONTRAST statement after centering, and they model a linear trend.

Output 60.2.2 Contrast Coefficients

Contrast Coefficients

		Dose		
Contrast		1	2	3
Linear Trend	Centered	-1	0	1

The summary statistics are displayed in Output 60.2.3. The values for the discrete variables S1 and S2 are the same as those from Example 60.1. The mean, standard deviation, and sample size for the continuous variable T at each level of Dose are displayed in the "Continuous Variable Tabulations" table.

Output 60.2.3 Summary Statistics

Discrete Variable Tabulations

Variable	Dose	Count	NumObs	Percent
S1	1	2	6	33.33
S1	2	4	6	66.67
S1	3	4	6	66.67
S2	1	4	6	66.67
S2	2	2	6	33.33
S2	3	2	6	33.33

Output 60.2.3 *continued*

Continuous Variable Tabulations

Variable	Dose	NumObs	Mean	Standard Deviation
T	1	6	99.3333	9.6056
T	2	6	87.5000	14.4326
T	3	6	72.8333	22.7017

The *p*-values, displayed in Output 60.2.4, are from the Freeman-Tukey test for S1 and S2, and are from the *t* test for T.

Output 60.2.4 *p*-Values

p-Values

Variable	Contrast	Raw	Bootstrap
S1	Linear Trend	0.8547	1.0000
S2	Linear Trend	0.1453	0.4605
T	Linear Trend	0.0070	0.0281

The Raw column in Output 60.2.4 contains the results from the tests on the original data, while the Bootstrap column contains the bootstrap resampled adjustment to raw_p. Note that the adjusted *p*-values are larger than the raw *p*-values for all three variables. The adjusted *p*-values more accurately reflect the correlation of the raw *p*-values, the small size of the data, and the multiple testing.

Output 60.2.5 displays the first 36 observations of the SAS data set resulting from the OUTSAMP=RES option in the PROC MULTTEST statement. The entire data set has 180,000 observations, which is 10,000 times the number of observations in the data set.

Output 60.2.5 Resampling Data Set

35	2	3	18	1	0	-22.8333
36	2	3	10	1	0	8.5000

The _sample_ variable is the sample indicator and _class_ indicates the resampling group—that is, the level of the CLASS variable Dose assigned to the new observation. The number of the observation in the original data set is represented by _obs_. Also listed are the values of the original test variables, S1 and S2, and the mean-centered values of T.

Example 60.3: Peto Mortality-Prevalence Test

This example illustrates the use of the Peto mortality-prevalence test. The test is a combination of analyses about the prevalence of incidental tumors in the population and mortality due to fatal tumors.

In the following data set, each observation represents an animal. The variables S1−S3 are three tumor types, with a value of 0 indicating no tumor, 1 indicating an incidental (nonlethal) tumor, and 2 indicating a lethal tumor. The time variable T indicates the time of death of the animal, a strata variable B is constructed from T, and the grouping variable Dose is drug dosage.

```
data a;
   input S1-S3 T Dose @@;
   if T<=90 then B=1; else B=2;
   datalines;
0 0 0 104 0   2 0 1  80 0   0 0 1 104 0
0 0 0 104 0   0 2 0 100 0   1 0 0 104 0
2 0 0  85 1   2 1 0  60 1   0 1 0  89 1
2 0 1  96 1   0 0 0  96 1   2 0 1  99 1
2 1 1  60 2   2 0 0  50 2   2 0 1  80 2
0 0 2  98 2   0 0 1  99 2   2 1 1  50 2
;

proc multtest data=a notables out=p stepsid;
   test peto(S1-S3 / permutation=20 time=T uppertailed);
   class Dose;
   strata B;
   contrast 'mort-prev' 0  1  2;
run;
proc print data=p;
run;
```

The NOTABLES option in the PROC MULTTEST statement suppresses the display of the summary statistics for each variable. The OUT= option creates an output SAS data set p containing all *p*-values and intermediate statistics. The STEPSID option is used to adjust the *p*-values.

The TEST statement specifies an upper-tailed Peto test for S1−S3. The mortality strata are defined by TIME=T, the death times. The CLASS statement contains the grouping variable Dose. The prevalence strata are defined by the STRATA statement as the blocking variable B. The CONTRAST statement lists the default linear trend coefficients. The PROC PRINT statement displays the requested *p*-value data set.

The results from this analysis are listed in Output 60.3.1 through Output 60.3.4.

The "Model Information" table in Output 60.3.1 displays information corresponding to the PROC MULTTEST invocation. In this case the totals for all prevalence and fatality strata are less than 20, so exact permutation tests are used everywhere, and the STEPSID adjustments are computed from these permutation distributions.

Output 60.3.1 Peto Test

The Multtest Procedure

Model Information

Test for discrete variables	Peto
Exact permutation distribution used	Everywhere
Tails for discrete tests	Upper-tailed
Strata weights	Sample size
P-value adjustment	Stepdown Sidak

The contrast trend coefficients are listed in Output 60.3.2. They happen to be the same as the levels of the Dose variable.

Output 60.3.2 Contrast Coefficients

Contrast Coefficients

	Dose		
Contrast	0	1	2
mort-prev	0	1	2

In the "*p*-Values" table in Output 60.3.3, the *p*-values for the Peto tests are listed in the Raw column, and the step-down Šidák adjusted *p*-values are in the Stepdown Šidák column.

Output 60.3.3 *p*-Values

p-Values

Variable	Contrast	Raw	Stepdown Sidak
S1	mort-prev	0.0681	0.0814
S2	mort-prev	0.5000	0.5000
S3	mort-prev	0.0363	0.0781

Significant *p*-values in the preceding table support the claim that higher dosage levels lead to higher mortality and prevalence. The raw Peto test is significant at the 5% level for S3, but the adjusted S3 test is no longer significant at 5%. The raw and adjusted *p*-values for S2 are the same because of the step-down technique.

The OUT= data set is displayed in Output 60.3.4.

Output 60.3.4 OUT= Data Set

The first 30 observations correspond to intermediate statistics used to compute the Peto *p*-values. The _test_ variable lists the name of the test, the _var_ variable lists the name of the TEST variables, and the _contrast_ variable lists the CONTRAST label. The _strat_ variable lists the level of the STRATA variable, and the _tstrat_ variable indicates whether or not the stratum corresponds to values of the TIME= variable. The _value_ variable is the observed contrast for a stratum, and the _exp_ variable is its expected value. The variable _se_ contains the square root of the variance terms summed to form the denominator of the Peto statistics.

The final three observations correspond to the three Peto tests, with their *p*-values listed under the raw_p variable. The stpsid_p variable contains the step-down Šidák-adjusted *p*-values.

Example 60.4: Fisher Test with Permutation Resampling

The following data, from Brown and Fears (1981), are the results of an 80-week carcinogenesis bioassay with female mice. Six tissue sites are examined at necropsy; 1 indicates the presence of a tumor and 0 the absence. A frequency variable Freq is included. A control and four different doses of a drug (in parts per milliliter) make up the levels of the grouping variable Dose.

```

proc multtest data=a order=data notables out=p
              permutation nsample=1000 seed=764511;
   test fisher(Liver Lung Lymph Cardio Pitui Ovary /
               lowertailed);
   class Dose;
   freq Freq;
run;
proc print data=p;
run;
```

In the PROC MULTTEST statement, the ORDER=DATA option is required to keep the levels of Dose in the order in which they appear in the data set. Without this option, the levels are sorted by their formatted value, resulting in an alphabetic ordering. The NOTABLES option suppresses the display of summary statistics, and the OUT= option produces an output data set p containing the *p*-values. The PERMUTATION option specifies permutation resampling, NSAMPLE=1000 requests 1000 samples, and SEED=764511 option provides a starting value for the random number generator. You should specify a seed if you need to duplicate resampling results.

To test for higher rates of tumor occurrence in the treatment groups compared to the control group, the LOWERTAILED option is specified in the FISHER option of the TEST statement to produce a lower-tailed Fisher exact test for the six tissue sites. The Fisher test is appropriate for comparing a treatment and a control, but multiple testing can be a problem. Brown and Fears (1981) use a multivariate permutation to evaluate the entire collection of tests. PROC MULTTEST adjusts the *p*-values by simulation.

The treatments make up the levels of the grouping variable Dose, listed in the CLASS statement. Since no CONTRAST statement is specified, PROC MULTTEST uses the default pairwise contrasts with the first level of Dose. The FREQ statement is used since these are summary data containing frequency counts of occurrences.

The results from this analysis are listed in Output 60.4.1 through Output 60.4.4. First, the PROC MULTTEST specifications are displayed in Output 60.4.1.

Output 60.4.1 Fisher Test with Permutation Resampling

The Multtest Procedure

Model Information

Test for discrete variables	Fisher
Tails for discrete tests	Lower-tailed
Strata weights	None
P-value adjustment	Permutation
Number of resamples	1000
Seed	764511

The default contrasts for the Fisher test are displayed in Output 60.4.2. Note that each dose is compared with the control.

Output 60.4.2 Default Contrast Coefficients

Contrast Coefficients

	Dose				
Contrast	CTRL	4PPM	8PPM	16PPM	50PPM
CTRL vs. 4PPM	1	-1	0	0	0
CTRL vs. 8PPM	1	0	-1	0	0
CTRL vs. 16PPM	1	0	0	-1	0
CTRL vs. 50PPM	1	0	0	0	-1

The "p-Values" table in Output 60.4.3 displays *p*-values for the Fisher exact tests and their permutation-based adjustments.

Output 60.4.3 *p*-Values

p-Values

Ovary	CTRL vs. 16PPM	0.7760	1.0000
Ovary	CTRL vs. 50PPM	0.3689	0.9930

As noted by Brown and Fears, only one of the 24 tests is significant at the 5% level (Lymph, CTRL vs. 16PPM). Brown and Fears report a 12% chance of observing at least one significant raw *p*-value for 16PPM and a 9% chance of observing at least one significant raw *p*-value for Lymph (both at the 5% level). Adjusted *p*-values exhibit much lower chances of false significances. For this example, none of the adjusted *p*-values are close to significant.

The OUT= data set is displayed in Output 60.4.4.

Output 60.4.4 OUT= Data Set

The _test_, _var_, and _contrast_ variables provide the TEST name, TEST variable, and CONTRAST label, respectively. The _xval_, _mval_, _yval_, and _nval_ variables contain the components used to compute the Fisher exact tests from the hypergeometric distribution. The raw_p variable contains the *p*-values from the Fisher exact tests, and the perm_p variable contains their permutation-based adjustments. The variable sim_se is the simulation standard error from the permutation resampling.

Example 60.5: Inputting Raw *p*-Values

This example illustrates how to use PROC MULTTEST to multiplicity-adjust a collection of raw *p*-values obtained from some other source. This is a valuable option for those cases where PROC MULTTEST cannot compute the raw *p*-values directly. The data set a, which follows, contains the unadjusted *p*-values computed in Example 60.4. Note that the data set needs to have one variable containing the *p*-values, but the data set can contain other variables as well.

```
data a;
   input Test$ Raw_P @@;
   datalines;
test01  0.28282    test02  0.30688    test03  0.71022
test04  0.77175    test05  0.78180    test06  0.88581
test07  0.54685    test08  0.84978    test09  0.24228

;

proc multtest inpvalues=a holm hoc fdr;
run;
```

Note that the PROC MULTTEST statement is the only statement that can be specified with the *p*-value input mode. In this example, the raw *p*-values are adjusted by the Holm, Hochberg, and FDR methods.

The "P-Value Adjustment Information" table, displayed in Output 60.5.1, provides information about the requested adjustments and replaces the usual "Model Information" table. The adjusted *p*-values are displayed in Output 60.5.2

Output 60.5.1 Inputting Raw *p*-Values

20	0.5051	1.0000	0.9437	0.9243
21	0.9437	1.0000	0.9437	0.9437
22	0.8126	1.0000	0.9437	0.9243
23	0.7760	1.0000	0.9437	0.9243
24	0.3689	1.0000	0.9437	0.9243

Note that the adjusted *p*-values for the Hochberg method are less than or equal to those for the Holm (Stepdown Bonferroni) method. In turn, the adjusted *p*-values for the FDR method (False Discovery Rate) are less than or equal to those for the Hochberg method. These comparisons hold generally for all *p*-value configurations. The FDR method controls the false discovery rate and not the familywise error rate. The Hochberg method controls the familywise error rate under independence. The Holm method controls the familywise error rate without assuming independence.

Example 60.6: Adaptive Adjustments and ODS Graphics

An experiment was performed using Affymetrix® gene chips on the CD4 lymphocyte white blood cells of patients with and without a hereditary allergy (atopy) and possibly with asthma. The Asthma-Atopy microarray data set and analysis are discussed in Gibson and Wolfinger (2004): a one-way ANOVA model of the log2mas5 variable ($\log_2$(MAS 5.0 summary statistics) is fit against a classification variable trt describing different asthma-atopy combinations in the patients, and the least squares means of the trt variable are computed.

For this example, a 1% random sample of least squares means having p-values exceeding 1E–6 is taken. The resulting data are recorded in the test data set, where the Probe_Set_ID variable identifies the probe and the Probt variable contains the p-values for the $m = 121$ tests, as follows:

```
data test;
   length Probe_Set_ID $9.;
   input Probe_Set_ID $ Probt @@;
   datalines;

The following statements adjust the p-values in the test data set by using the adaptive adjustments (ADAPTIVEHOLM, ADAPTIVEHOCHBERG, ADAPTIVEFDR, and PFDR), which require an estimate of the number of true null hypotheses ($\hat{m}_0$) or proportion of true null hypotheses ($\hat{\pi}_0$). This example illustrates some of the features and graphics for computing and evaluating these estimates. The NOPVALUE option is specified to suppress the display of the "p-Values" table.

ods graphics on;
proc multtest inpvalues(Probt)=test plots=all seed=518498000
              aholm ahoc afdr pfdr(positive) nopvalue;
run;
ods graphics off;
```

Output 60.6.1 lists the requested *p*-value adjustments, along with the selected value of the "Lambda" tuning parameter and the seed (specified with the SEED= option) used in the bootstrap method of estimating the number of true null hypotheses. The "Lambda Values" table lists the estimated number of true nulls for each value of λ, where you can see that the minimum MSE (0.002315) occurs at $\lambda = 0.4$. Output 60.6.2 shows that the SPLINE method failed due to a large slope at $\lambda = 0.95$, so the bootstrap method is used and the MSE plot is displayed.

Output 60.6.1 *p* and Lambda Values

The Multtest Procedure

P-Value Adjustment Information

P-Value Adjustment	Adaptive Holm
P-Value Adjustment	Adaptive Hochberg
P-Value Adjustment	Adaptive FDR
P-Value Adjustment	pFDR Q-Value
Lambda	0.4
Seed	518498000

Lambda Values

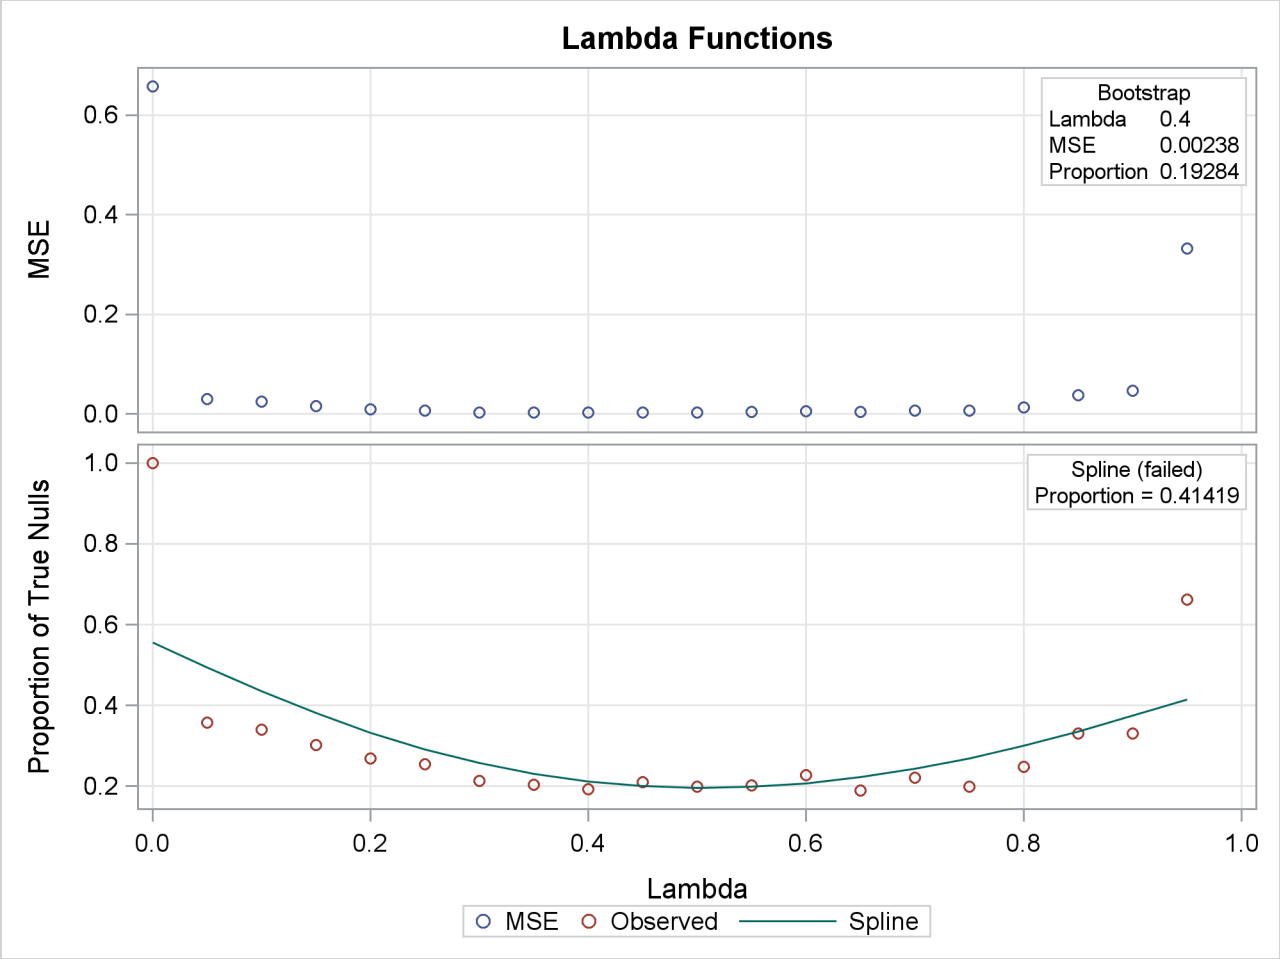
0.950000	0.332183	80.000000	50.117369

Output 60.6.2 Tuning Parameter Plots



Output 60.6.3 also shows that the bootstrap estimate is used for the PFDR adjustment. The other adjustments have different default methods for estimating the number of true nulls.

Output 60.6.3 Adjustments and Their Default Estimation Method

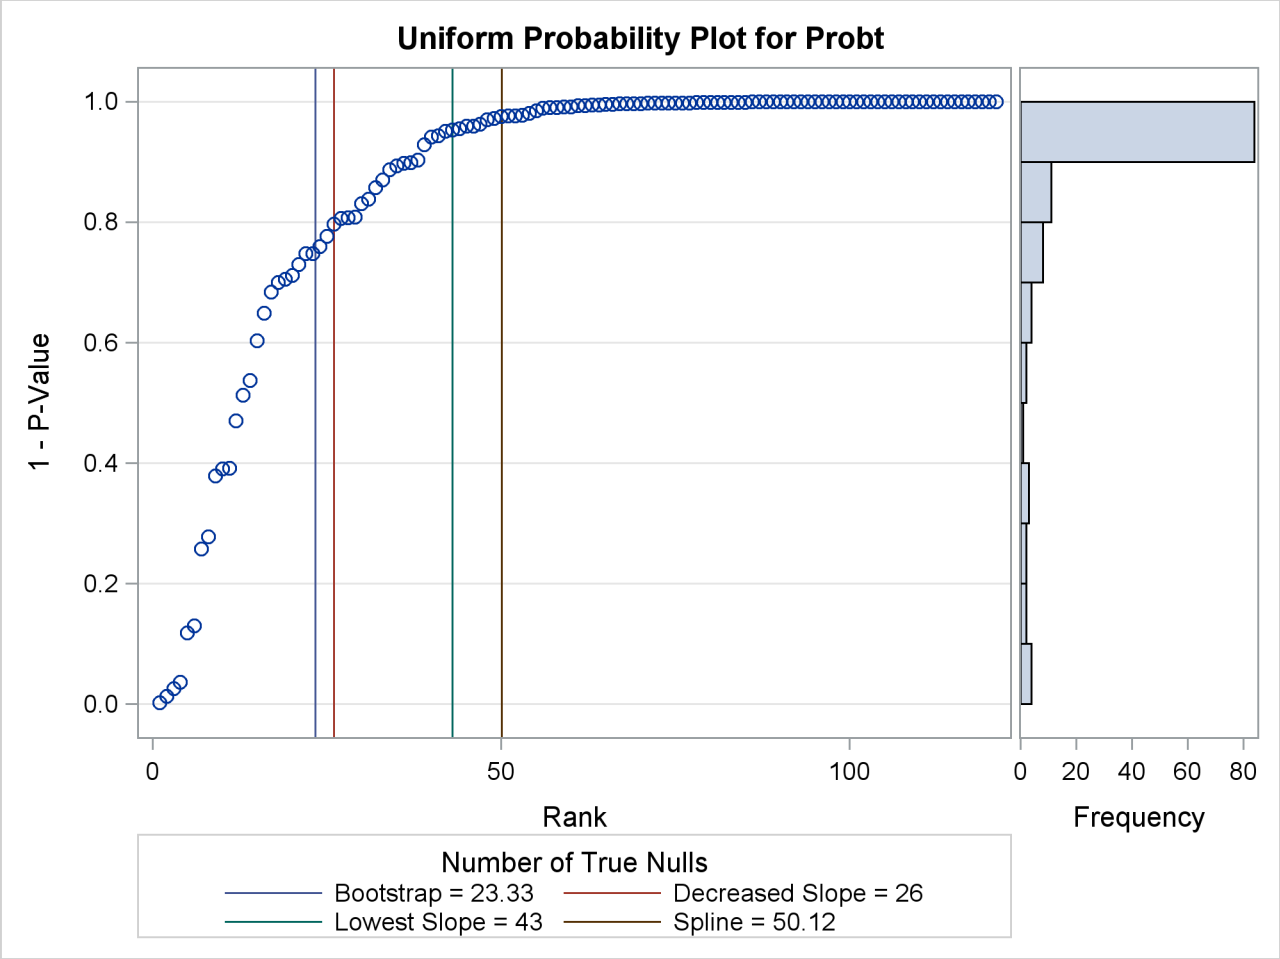
Estimated Number of True Null Hypotheses

P-Value Adjustment	Method	Estimate	Proportion
Adaptive Holm	Decreased Slope	26	0.21488
Adaptive Hochberg	Decreased Slope	26	0.21488
Adaptive FDR	Lowest Slope	43	0.35537
Positive FDR	Bootstrap	23.3333	0.19284

Output 60.6.4 displays the estimated number of true nulls $\hat{m}_0$ against a uniform probability plot of the unadjusted p-values (if the p-values are distributed uniformly, the points on the plot will all lie on a straight line). According to Schweder and Spjøtvoll (1982) and Hochberg and Benjamini (1990), the points on the

left side of the plot should be approximately linear with slope $\frac{1}{m_0+1}$, so you can use this plot to evaluate whether your estimate of $\hat{m}_0$ seems reasonable.

Output 60.6.4 *p*-Value Distribution



The NTRUENULL= option provides several methods for estimating the number of true null hypotheses; the following table displays each method and its estimate for this example:

NTRUENULL=	Estimate
BOOTSTRAP	23.3
DECREASESLOPE	26
KSTEST	35
LEASTSQUARES	28
LOWESTSLOPE	43
MEANDIFF	42
SPLINE	50.1

Another method of estimating the number of true null hypotheses fits a finite mixture model (mixing a uniform with a beta) to the distribution of the unadjusted *p*-values (Allison et al. 2002). Osborne (2006) provides the following PROC NLMIXED statements to fit this model:

```
proc nlmixed data=test;
   parameters pi0=0.5 a=.1 b=.1;
   pi1= 1-pi0;
   bounds 0 <= pi0 <= 1;
   loglikelihood= log(pi0+pi1*pdf('beta',Probt,a,b));
   model Probt ~ general(loglikelihood);
run;
```

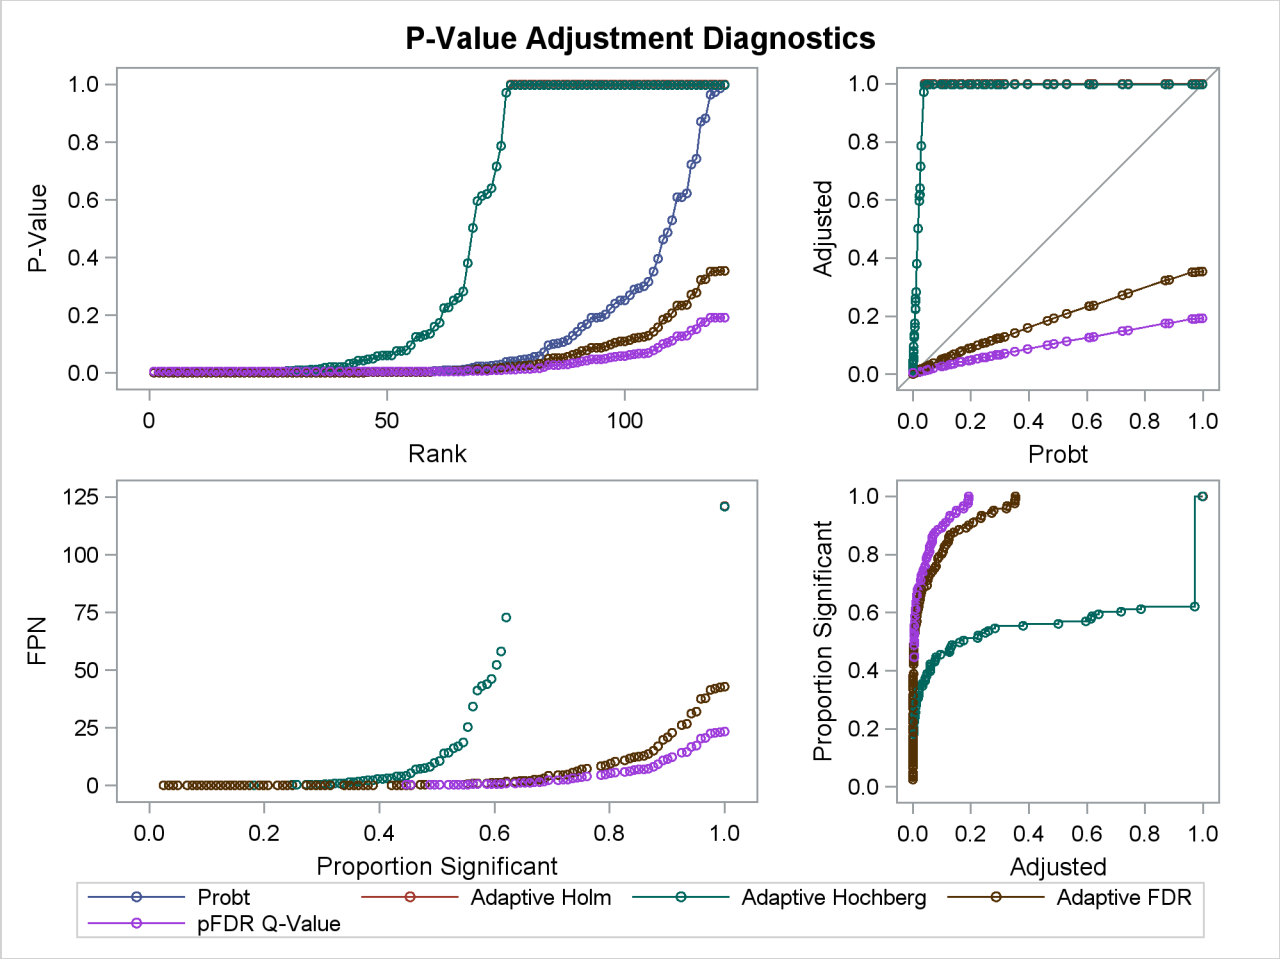
You might have to change the initial parameter values in the PARAMETERS statement to achieve convergence; see Chapter 63, "The NLMIXED Procedure," for more information. This mixture model estimates $\hat{\pi}_0 = 0$, meaning that the distribution of *p*-values is completely specified by a single beta distribution. If the estimate were, say, $\hat{\pi}_0 = 0.10$, you could then specify it as follows:

```
proc multtest inpvalues(Probt)=test ptruenull=0.10
              aholm ahoc afdr pfdr(positive) nopvalue;
run;
```

A plot of the unadjusted and adjusted *p*-values for each test is also produced. Due to the large number of tests and adjustments, the plot is not very informative and is not displayed here.

The top two plots in Output 60.6.5 show how the adjusted values compare with each other and the unadjusted *p*-values. The PFDR and AFDR adjustments are eventually smaller than the unadjusted *p*-values since they control the false discovery rate. The adaptive Holm and Hochberg adjustments are almost identical, so the adaptive Holm values are mostly obscured in all four plots. The plot of the Proportion Significant versus the Adjusted *p*-values tells you how many of the tests are significant for each cutoff, while the plot of the number of false positives (FPN) versus the Proportion Significant tells you how many false positives you can expect for that cutoff.

Output 60.6.5 Adjustment Diagnostics



If you have a lot of tests, the "Raw and Adjusted *p*-Values" and "P-Value Adjustment Diagnostics" plots can be more informative if you suppress some of the tests. In the following statements, the SIGONLY=0.001 option selects tests with adjusted *p*-values < 0.001 for display. Output 60.6.6 displays tests with their "significant" adjusted *p*-values:

```
ods graphics on;
proc multtest inpvalues(Probt)=test plots(sigonly=0.001)=PByTest
              aholm ahoc afdr pfdr(positive) nopvalue;
run;
ods graphics off;
```

Output 60.6.6 Raw and Adjusted *p*-Values

Chapter 61

The NESTED Procedure

Contents

Overview: NESTED Procedure

The NESTED procedure performs random-effects analysis of variance for data from an experiment with a nested (hierarchical) structure.[1] A random-effects model for data from a completely nested design with two factors has the form

$$y_{ijr} = \mu + \alpha_i + \beta_{ij} + \epsilon_{ijr}$$

where

[1] PROC NESTED is modeled after the General Purpose Nested Analysis of Variance program of the Dairy Cattle Research Branch of the United States Department of Agriculture. That program was originally written by M. R. Swanson, Statistical Reporting Service, United States Department of Agriculture.

y_{ijr} is the value of the dependent variable observed at the rth replication with the first factor at its ith level and the second factor at its jth level.

μ is the overall (fixed) mean of the sampling population.

$\alpha_i, \beta_{ij}, \epsilon_{ijr}$ are mutually uncorrelated random effects with zero means and respective variances σ_α^2, σ_β^2, and σ_ϵ^2 (the variance components).

This model is appropriate for an experiment with a multistage nested sampling design. An example of this is given in Example 61.1, where four turnip plants are randomly chosen (the first factor), then three leaves are randomly chosen from each plant (the second factor nested within the first), and then two samples are taken from each leaf (the different replications at fixed levels of the two factors).

Note that PROC NESTED is appropriate for models with only classification effects; it does not handle models that contain continuous covariates. For random effects models with covariates, use either the GLM or MIXED procedure.

Contrasted with Other SAS Procedures

The NESTED procedure performs a computationally efficient analysis of variance for data with a nested design, estimating the different components of variance and also testing for their significance if the design is balanced (see the section "Unbalanced Data" on page 5081). Although other procedures (such as GLM and MIXED) provide similar analyzes, PROC NESTED is both easier to use and computationally more efficient for this special type of design. This is especially true when the design involves a large number of factors, levels, or observations.

For example, to specify a four-factor completely nested design in the GLM procedure, you use the following form:

```
class a b c d;
model y=a b(a) c(a b) d(a b c);
```

However, to specify the same design in PROC NESTED, you simply use the following form:

```
class a b c d;
var y;
```

In addition, other procedures require TEST statements to perform appropriate tests, whereas the NESTED procedure produces the appropriate tests automatically. However, PROC NESTED makes one assumption about the input data that the other procedures do not: **PROC NESTED assumes that the input data set is sorted by the classification (CLASS) variables defining the effects.** If you use PROC NESTED on data that are not sorted by the CLASS variables, then the results might not be valid.

Getting Started: NESTED Procedure

Reliability of Automobile Models

A study is performed to compare the reliability of several models of automobiles. Three different automobile models (Model) from each of four U.S. automobile manufacturers (Make) are tested. Three different cars of each make and model are subjected to a reliability test and given a score between 1 and 100 (Score), where higher scores indicate greater reliability.

The following statements create the SAS data set auto.

```
title1 'Reliability of Automobile Models';
data auto;
   input Make $ Model Score @@;
   datalines;
a 1 62  a 2 77  a 3 59
a 1 67  a 2 73  a 3 64
a 1 60  a 2 79  a 3 60
b 1 72  b 2 58  b 3 80
b 1 75  b 2 63  b 3 84
b 1 69  b 2 57  b 3 89
c 1 94  c 2 76  c 3 81
c 1 90  c 2 75  c 3 85
c 1 88  c 2 78  c 3 85
d 1 69  d 2 73  d 3 90
d 1 72  d 2 88  d 3 87
d 1 76  d 2 87  d 3 92
;
```

The Make variable contains the make of the automobile, represented here by ‘a’, ‘b’, ‘c’, or ‘d’, while the Model variable represents the automobile model with a ‘1’, ‘2’, or ‘3’. The Score variable contains the reliability scores given to the three sampled cars from each Make-Model group. Since the automobile models are nested within their makes, the NESTED procedure is used to analyze these data. The NESTED procedure requires the data to be sorted by Make and, within Make, by Model, so the following statements execute a PROC SORT before completing the analysis.

```
proc sort data=auto;
   by Make Model;
run;

title1 'Reliability of Automobile Models';
proc nested data=auto;
   classes Make Model;
   var Score;
run;
```

The Model variable appears after the Make variable in the CLASS statement because it is nested within Make. The VAR statement specifies the response variable. The output is displayed in Figure 61.1.

Figure 61.1 Output from PROC NESTED

Reliability of Automobile Models

The NESTED Procedure

Coefficients of Expected Mean Squares

Source	Make	Model	Error
Make	9	3	1
Model	0	3	1
Error	0	0	1

Nested Random Effects Analysis of Variance for Variable Score

Variance Source	DF	Sum of Squares	F Value	Pr > F	Error Term	Mean Square	Variance Component	Percent of Total
Total	35	4177.888889				119.368254	131.876543	100.0000
Make	3	1709.000000	2.15	0.1719	Model	569.666667	33.867284	25.6811
Model	8	2118.888889	18.16	<.0001	Error	264.861111	83.425926	63.2606
Error	24	350.000000				14.583333	14.583333	11.0583

Score Mean	75.94444444
Standard Error of Score Mean	3.97794848

Figure 61.1 first displays the coefficients of the variance components that make up each of the expected mean squares, and then it displays the ANOVA table. The results do not indicate significant variation between the different automobile makes ($F = 2.15$, $p = 0.1719$). However, they do suggest that there is significant variation between the different models within the makes ($F = 18.16$, $p < 0.0001$). This is evident in the fact that the make of car accounts for only 25.7% of the total variation in the data, while the car model accounts for 63.3% (as shown in the Percent of Total column). The estimated variance components are shown in the Variance Component column.

Syntax: NESTED Procedure

The following statements are available in PROC NESTED:

PROC NESTED < *options* > ;
CLASS *variables* < / *option* > ;
VAR *variables* ;
BY *variables* ;

The PROC NESTED and CLASS statements are required. The BY, CLASS, and VAR statements are described after the PROC NESTED statement.

PROC NESTED Statement

PROC NESTED < *options* > **;**

The PROC NESTED statement has the following options:

AOV
displays only the analysis of variance statistics when there is more than one dependent variable. The "analysis of covariation" statistics are suppressed (see the section "Analysis of Covariation" on page 5082).

DATA=*SAS-data-set*
names the SAS data set to be used by PROC NESTED. By default, the procedure uses the most recently created SAS data set.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC NESTED to obtain separate analyses on observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the NESTED procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variables* < / *option* > **;**

You must include a CLASS statement with PROC NESTED specifying the classification variables for the analysis.

Values of a variable in the CLASS statement denote the levels of an effect. The name of that variable is also the name of the corresponding effect. The second effect is assumed to be nested within the first effect, the third effect is assumed to be nested within the second effect, and so on.

By default, class levels are determined from the entire formatted values of the CLASS variables. Note that this represents a slight change from previous releases in the way in which class levels are determined. Prior to SAS 9, class levels were determined using no more than the first eight characters of the formatted values, except for numeric variables with no explicit format, for which class levels were determined from the raw numeric values. If you want to revert to this previous behavior, you can use the TRUNCATE option in the CLASS statement. In any case, you can use formats to group values into levels. Refer to the discussion of the FORMAT procedure in the *Base SAS Procedures Guide*, and the discussions for the FORMAT statement and SAS formats in *SAS Language Reference: Dictionary*.

NOTE: The data set must be sorted by the classification variables in the order in which they are given in the CLASS statement. Use PROC SORT to sort the data if they are not already sorted.

You can specify the following option in the CLASS statement after a slash (/):

TRUNCATE
specifies that class levels should be determined by using only up to the first 16 characters of the formatted values of CLASS variables. When formatted values are longer than 16 characters, you can use this option to revert to the levels as determined in releases prior to SAS 9.

VAR Statement

VAR *variables* **;**

The VAR statement lists the dependent variables for the analysis. The dependent variables must be numeric variables. If you do not specify a VAR statement, PROC NESTED performs an analysis of variance for all numeric variables in the data set, except those already specified in the CLASS statement.

Details: NESTED Procedure

Missing Values

An observation with missing values for any of the variables used by PROC NESTED is omitted from the analysis. Blank values of CLASS character variables are treated as missing values.

Unbalanced Data

A completely nested design is defined to be unbalanced if the groups corresponding to the levels of some classification variable are not all of the same size. The NESTED procedure can compute unbiased estimates for the variance components in an unbalanced design, but because the sums of squares on which these estimates are based no longer have χ^2 distributions under a Gaussian model for the data, F tests for the significance of the variance components cannot be computed. PROC NESTED checks to see that the design is balanced. If it is not, a warning to that effect appears in the log, and the columns corresponding to the F tests in the analysis of variance are left blank.

General Random-Effects Model

A random-effects model for data from a completely nested design with n factors has the general form

$$y_{i_1 i_2 \cdots i_n r} = \mu + \alpha_{i_1} + \beta_{i_1 i_2} + \cdots + \epsilon_{i_1 i_2 \cdots i_n r}$$

where

$y_{i_1 i_2 \cdots i_n r}$	is the value of the dependent variable observed at the rth replication with factor j at level i_j, for $j = 1, \ldots, n$.
μ	is the overall (fixed) mean of the sampled population.
$\alpha_{i_1}, \beta_{i_1 i_2}, \ldots, \epsilon_{i_1 i_2 \cdots i_n r}$	are mutually uncorrelated random effects with zero means and respective variances $\sigma^2_\alpha, \sigma^2_\beta, \ldots, \sigma^2_\epsilon$.

Analysis of Covariation

When you specify more than one dependent variable, the NESTED procedure produces a descriptive analysis of the covariance between each pair of dependent variables in addition to a separate analysis of variance for each variable. The analysis of covariation is computed under the basic random-effects model for each pair of dependent variables:

$$\begin{aligned} y_{i_1 i_2 \cdots i_n r} &= \mu + \alpha_{i_1} + \beta_{i_1 i_2} + \cdots + \epsilon_{i_1 i_2 \cdots i_n r} \\ y'_{i_1 i_2 \cdots i_n r} &= \mu' + \alpha'_{i_1} + \beta'_{i_1 i_2} + \cdots + \epsilon'_{i_1 i_2 \cdots i_n r} \end{aligned}$$

where the notation is the same as that used in the preceding general random-effects model.

There is an additional assumption that all the random effects in the two models are mutually uncorrelated except for corresponding effects, for which

$$\begin{aligned} \mathrm{Corr}(\alpha_{i_1}, \alpha'_{i_1}) &= \rho_\alpha \\ \mathrm{Corr}(\beta_{i_1 i_2}, \beta'_{i_1 i_2}) &= \rho_\beta \\ &\vdots \\ \mathrm{Corr}(\epsilon_{i_1 i_2 \cdots i_n r}, \epsilon'_{i_1 i_2 \cdots i_n r}) &= \rho_\epsilon \end{aligned}$$

Error Terms in *F* Tests

Random-effects ANOVAs are distinguished from fixed-effects ANOVAs by which error mean squares are used as the denominator for *F* tests. Under a fixed-effects model, there is only one true error term in the model, and the corresponding mean square is used as the denominator for all tests. This is how the usual analysis is computed in PROC ANOVA, for example. However, in a random-effects model for a nested experiment, mean squares are compared sequentially. The correct denominator in the test for the first factor is the mean square due to the second factor; the correct denominator in the test for the second factor is the mean square due to the third factor; and so on. Only the mean square due to the last factor, the one at the bottom of the nesting order, should be compared to the error mean square.

Computational Method

The building blocks of the analysis are the sums of squares for the dependent variables for each classification variable within the factors that precede it in the model, corrected for the factors that follow it. For example, for a two-factor nested design, PROC NESTED computes the following sums of squares:

$$\text{Total SS} \qquad \sum_{ijr}(y_{ijr} - y_{...})^2$$

$$\text{SS for Factor 1} \qquad \sum_{i} n_{i\cdot}\left(\frac{y_{i\cdot\cdot}}{n_{i\cdot}} - \frac{y_{...}}{n_{\cdot\cdot}}\right)^2$$

$$\text{SS for Factor 2 within Factor 1} \qquad \sum_{ij} n_{ij}\left(\frac{y_{ij\cdot}}{n_{ij}} - \frac{y_{i\cdot\cdot}}{n_{i\cdot}}\right)^2$$

$$\text{Error SS} \qquad \sum_{ijr}\left(y_{ijr} - \frac{y_{ij\cdot}}{n_{ij}}\right)^2$$

where y_{ijr} is the rth replication, n_{ij} is the number of replications at level i of the first factor and level j of the second, and a dot as a subscript indicates summation over the corresponding index. If there is more than one dependent variable, PROC NESTED also computes the corresponding sums of crossproducts for each pair. The expected value of the sum of squares for a given classification factor is a linear combination of the variance components corresponding to this factor and to the factors that are nested within it. For each factor, the coefficients of this linear combination are computed. (The efficiency of PROC NESTED is partly due to the fact that these various sums can be accumulated with just one pass through the data, assuming that the data have been sorted by the classification variables.) Finally, estimates of the variance components are derived as the solution to the set of linear equations that arise from equating the mean squares to their expected values.

Displayed Output

PROC NESTED displays the following items for each dependent variable:

- Coefficients of Expected Mean Squares, which are the coefficients of the $n + 1$ variance components making up the expected mean square. Denoting the element in the ith row and jth column of this matrix by C_{ij}, the expected value of the mean square due to the ith classification factor is

  $$C_{i1}\sigma_1^2 + \cdots + C_{in}\sigma_n^2 + C_{i,n+1}\sigma_\epsilon^2$$

  C_{ij} is always zero for $i > j$, and if the design is balanced, C_{ij} is equal to the common size of all classification groups of the jth factor for $i \leq j$. Finally, the mean square for error is always an unbiased estimate of σ_ϵ^2. In other words, $C_{n+1,n+1} = 1$.

For every dependent variable, PROC NESTED displays an analysis of variance table. Each table contains the following:

- each Variance Source in the model (the different components of variance) and the total variance
- degrees of freedom (DF) for the corresponding sum of squares
- Sum of Squares for each classification factor. The sum of squares for a given classification factor is the sum of squares in the dependent variable within the factors that precede it in the model, corrected for the factors that follow it. (See the section "Computational Method" on page 5083.)
- F Value for a factor, which is the ratio of its mean square to the appropriate error mean square. The next column, labeled PR > F, gives the significance levels that result from testing the hypothesis that each variance component equals zero.
- the appropriate Error Term for an F test, which is the mean square due to the next classification factor in the nesting order. (See the section "Error Terms in F Tests" on page 5082.)
- Mean Square due to a factor, which is the corresponding sum of squares divided by the degrees of freedom
- estimates of the Variance Components. These are computed by equating the mean squares to their expected values and solving for the variance terms. (See the section "Computational Method" on page 5083.)
- Percent of Total, the proportion of variance due to each source. For the ith factor, the value is

$$100 \times \frac{\text{source variance component}}{\text{total variance component}}$$

- Mean, the overall average of the dependent variable. This gives an unbiased estimate of the mean of the population. Its variance is estimated by a certain linear combination of the estimated variance components, which is identical to the mean square due to the first factor in the model divided by the total number of observations when the design is balanced.

If there is more than one dependent variable, then the NESTED procedure displays an "analysis of covariation" table for each pair of dependent variables (unless the AOV option is specified in the PROC NESTED statement). See the section "Analysis of Covariation" on page 5082 for details. For each source of variation, this table includes the following:

- Degrees of Freedom
- Sum of Products
- Mean Products
- Covariance Component, the estimate of the covariance component

Items in the analysis of covariation table are computed analogously to their counterparts in the analysis of variance table. The analysis of covariation table also includes the following:

- Variance Component Correlation for a given factor. This is an estimate of the correlation between corresponding effects due to this factor. This correlation is the ratio of the covariance component for this factor to the square root of the product of the variance components for the factor for the two different dependent variables. (See the section "Analysis of Covariation" on page 5082.)
- Mean Square Correlation for a given classification factor. This is the ratio of the Mean Products for this factor to the square root of the product of the Mean Squares for the factor for the two different dependent variables.

ODS Table Names

PROC NESTED assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 61.1 ODS Tables Produced by PROC NESTED

ODS Table Name	Description	Statement
ANCOVA	Analysis of covariance	default with more than one dependent variable
ANOVA	Analysis of variance	default
EMSCoef	Coefficients of expected mean squares	default
Statistics	Overall statistics for fit	default

Example: NESTED Procedure

Example 61.1: Variability of Calcium Concentration in Turnip Greens

In the following example from Snedecor and Cochran (1976), an experiment is conducted to study the variability of calcium concentration in turnip greens. Four plants are selected at random; then three leaves are randomly selected from each plant. Two 100-mg samples are taken from each leaf. The amount of calcium is determined by microchemical methods.

Because the data are read in sorted order, it is not necessary to use PROC SORT on the CLASS variables. Leaf is nested in Plant; Sample is nested in Leaf and is left for the residual term. All the effects are random effects. The following statements read the data and invoke PROC NESTED. These statements produce Output 61.1.1.

```
title 'Calcium Concentration in Turnip Leaves--Nested Random Model';
title2 'Snedecor and Cochran, ''Statistical Methods'', 1976, p. 286';
data Turnip;
   do Plant=1 to 4;
      do Leaf=1 to 3;
         do Sample=1 to 2;
            input Calcium @@;
            output;
         end;
      end;
   end;
   datalines;
3.28 3.09 3.52 3.48 2.88 2.80 2.46 2.44
1.87 1.92 2.19 2.19 2.77 2.66 3.74 3.44
2.55 2.55 3.78 3.87 4.07 4.12 3.31 3.31
;

proc nested data=Turnip;
   classes plant leaf;
   var calcium;
run;
```

Output 61.1.1 Analysis of Calcium Concentration in Turnip Greens Using PROC NESTED

Calcium Concentration in Turnip Leaves--Nested Random Model
Snedecor and Cochran, 'Statistical Methods', 1976, p. 286

The NESTED Procedure

Coefficients of Expected Mean Squares

Source	Plant	Leaf	Error
Plant	6	2	1
Leaf	0	2	1
Error	0	0	1

Nested Random Effects Analysis of Variance for Variable Calcium

Variance Source	DF	Sum of Squares	F Value	Pr > F	Error Term	Mean Square	Variance Component	Percent of Total
Total	23	10.270396				0.446539	0.532938	100.0000
Plant	3	7.560346	7.67	0.0097	Leaf	2.520115	0.365223	68.5302
Leaf	8	2.630200	49.41	<.0001	Error	0.328775	0.161060	30.2212
Error	12	0.079850				0.006654	0.006654	1.2486

Calcium Mean	3.01208333
Standard Error of Calcium Mean	0.32404445

The results indicate that there is significant (nonzero) variation from plant to plant (Pr > F is 0.0097) and from leaf to leaf within a plant (Pr > F is less than 0.0001). Notice that the variance component for Plant uses the Leaf mean square as an error term in the model rather than the error mean square.

Chapter 62

The NLIN Procedure

Contents

Overview: NLIN Procedure

The NLIN procedure fits nonlinear regression models and estimates the parameters by nonlinear least squares or weighted nonlinear least squares. You specify the model with programming statements. This gives you great flexibility in modeling the relationship between the response variable and independent (regressor) variables. It does, however, require additional coding compared to model specifications in linear modeling procedures such as the REG, GLM, and MIXED procedures.

Estimating parameters in a nonlinear model is an iterative process that commences from starting values. You need to declare the parameters in your model and supply their initial values for the NLIN procedure. You do not need to specify derivatives of the model equation with respect to the parameters. Although facilities for specifying first and second derivatives exist in the NLIN procedure, it is not recommended that you specify derivatives this way. Obtaining derivatives from user-specified expressions predates the high-quality automatic differentiator that is now used by the NLIN procedure.

Nonlinear least-squares estimation involves finding those values in the parameter space that minimize the (weighted) residual sum of squares. In a sense, this is a "distribution-free" estimation criterion since the distribution of the data does not need to be fully specified. Instead, the assumption of homoscedastic and uncorrelated model errors with zero mean is sufficient. You can relax the homoscedasticity assumption by using a weighted residual sum of squares criterion. The assumption of uncorrelated errors (independent observations) cannot be relaxed in the NLIN procedure. In summary, the primary assumptions for analyses with the NLIN procedure are as follows:

- The structure in the response variable can be decomposed additively into a mean function and an error component.
- The model errors are uncorrelated and have zero mean. Unless a weighted analysis is performed, the errors are also assumed to be homoscedastic (have equal variance).
- The mean function consists of known regressor (independent) variables and unknown constants (the parameters).

Fitting nonlinear models can be a difficult undertaking. There is no closed-form solution for the parameter estimates, and the process is iterative. There can be one or more local minima in the residual sum of squares surface, and the process depends on the starting values supplied by the user. You can reduce the dependence on the starting values and reduce the chance to arrive at a local minimum by specifying a grid of starting values. The NLIN procedure then computes the residual sum of squares at each point on the grid and

starts the iterative process from the point that yields the lowest sum of squares. Even in this case, however, convergence does not guarantee that a global minimum has been found.

The numerical behavior of a model and a model–data combination can depend on the way in which you parameterize the model—for example, whether parameters are expressed on the logarithmic scale or not. Parameterization also has bearing on the interpretation of the estimated quantities and the statistical properties of the parameter estimators. Inferential procedures in nonlinear regression models are typically approximate in that they rely on the asymptotic properties of the parameter estimators that are obtained as the sample size grows without bound. Such asymptotic inference can be questionable in small samples, especially if the behavior of the parameter estimators is "far-from-linear." Reparameterization of the model can yield parameters whose behavior is akin to that of estimators in linear models. These parameters exhibit close-to-linear behavior.

The NLIN procedure solves the nonlinear least squares problem by one of the following four algorithms (methods):

- steepest-descent or gradient method
- Newton method
- modified Gauss-Newton method
- Marquardt method

These methods use derivatives or approximations to derivatives of the SSE with respect to the parameters to guide the search for the parameters producing the smallest SSE. Derivatives computed automatically by the NLIN procedure are analytic, unless the model contains functions for which an analytic derivative is not available.

Using PROC NLIN, you can also do the following:

- confine the estimation procedure to a certain range of values of the parameters by imposing bounds on the estimates
- produce new SAS data sets containing predicted values, parameter estimates, residuals and other model diagnostics, estimates at each iteration, and so forth.

You can use the NLIN procedure for segmented models (see Example 62.1) or robust regression (see Example 62.2). You can also use it to compute maximum-likelihood estimates for certain models (see Jennrich and Moore 1975; Charnes, Frome, and Yu 1976). For maximum likelihood estimation in a model with a linear predictor and binomial error distribution, see the LOGISTIC, PROBIT, GENMOD, GLIMMIX, and CATMOD procedures. For a linear model with a Poisson, gamma, or inverse gaussian error distribution, see the GENMOD and GLIMMIX procedures. For likelihood estimation in a linear model with a normal error distribution, see the MIXED, GENMOD, and GLIMMIX procedures. The PHREG and LIFEREG procedures fit survival models by maximum likelihood. For general maximum likelihood estimation, see the NLP procedure in the *SAS/OR User's Guide* and the NLMIXED procedure in the *SAS/STAT User's Guide*. These procedures are recommended over the NLIN procedure for solving maximum likelihood problems.

PROC NLIN uses the Output Delivery System (ODS). ODS enables you to convert any of the output from PROC NLIN into a SAS data set. See the section "ODS Table Names" on page 5143 for a listing of the ODS tables that are produced by the NLIN procedure.

In addition, PROC NLIN can produce graphs (experimental in this release) when ODS Graphics is enabled. For more information, see the PLOTS option and the section "ODS Graphics (Experimental)" on page 5144 for a listing of the ODS graphs.

Getting Started: NLIN Procedure

Nonlinear or Linear Model

The NLIN procedure performs univariate nonlinear regression by using the least squares method. Nonlinear regression analysis is indicated when the functional relationship between the response variable and the predictor variables is nonlinear. Nonlinearity in this context refers to a nonlinear relationship in the *parameters*. Many linear regression models exhibit a relationship in the regressor (predictor) variables that is not simply a straight line. This does not make the models nonlinear. A model is nonlinear in the parameters if the derivative of the model with respect to a parameter depends on this or other parameters.

Consider, for example the models

$$\mathrm{E}[Y|x] = \beta_0 + \beta_1 x$$
$$\mathrm{E}[Y|x] = \beta_0 + \beta_1 x + \beta_2 x^2$$
$$\mathrm{E}[Y|x] = \beta + x/\alpha$$

In these expressions, $\mathrm{E}[Y|x]$ denotes the expected value of the response variable Y at the fixed value of x. (The conditioning on x simply indicates that the predictor variables are assumed to be non-random in models fit by the NLIN procedure. Conditioning is often omitted for brevity in this chapter.)

Only the third model is a nonlinear model. The first model is a simple linear regression. It is linear in the parameters β_0 and β_1 since the model derivatives do not depend on unknowns:

$$\frac{\partial}{\beta_0}(\beta_0 + \beta_1 x) = 1$$
$$\frac{\partial}{\beta_1}(\beta_0 + \beta_1 x) = x$$

The model is also linear in its relationship with x (a straight line). The second model is also linear in the parameters, since

$$\frac{\partial}{\beta_0}\left(\beta_0 + \beta_1 x + \beta_2 x^2\right) = 1$$
$$\frac{\partial}{\beta_1}\left(\beta_0 + \beta_1 x + \beta_2 x^2\right) = x$$
$$\frac{\partial}{\beta_2}\left(\beta_0 + \beta_1 x + \beta_2 x^2\right) = x^2$$

It is a *curvilinear* model since it exhibits a curved relationship when plotted against x. The third model, finally, is a nonlinear model since

$$\frac{\partial}{\beta}\left(\beta + x/\alpha\right) = 1$$
$$\frac{\partial}{\alpha}\left(\beta + x/\alpha\right) = -\frac{x}{\alpha^2}$$

The second of these derivatives depends on a parameter α. A model is nonlinear if it is not linear in at least one parameter.

Notation for Nonlinear Regression Models

This section briefly introduces the basic notation for nonlinear regression models that applies in this chapter. Additional notation is introduced throughout as needed.

The $(n \times 1)$ vector of observed responses is denoted as $\mathbf{y}$. This vector is the realization of an $(n \times 1)$ random vector $\mathbf{Y}$. The NLIN procedure assumes that the variance matrix of this random vector is $\sigma^2\mathbf{I}$. In other words, the observations have equal variance (are homoscedastic) and are uncorrelated. By defining the special variable _WEIGHT_ in your NLIN programming statements, you can introduce heterogeneous variances. If a _WEIGHT_ variable is present, then $\mathrm{Var}[\mathbf{Y}] = \sigma^2\mathbf{W}^{-1}$, where $\mathbf{W}$ is a diagonal matrix containing the values of the _WEIGHT_ variable.

The mean of the random vector is represented by a nonlinear model that depends on parameters $\beta_1, \cdots, \beta_p$ and regressor (independent) variables $z_1, \cdots, z_k$:

$$\mathrm{E}[Y_i] = f\left(\beta_1, \beta_2, \cdots, \beta_p; z_{i1}, \cdots, z_{ik}\right)$$

In contrast to linear models, the number of regressor variables (k) does not necessarily equal the number of parameters (p) in the mean function $f(\,)$. For example, the model fitted in the next subsection contains a single regressor and two parameters.

To represent the mean of the vector of observations, boldface notation is used in an obvious extension of the previous equation:

$$\mathrm{E}[\mathbf{Y}] = \mathbf{f}(\boldsymbol{\beta}; \mathbf{z}_1, \cdots, \mathbf{z}_k)$$

The vector $\mathbf{z}_1$, for example, is an $(n \times 1)$ vector of the values for the first regressor variables. The explicit dependence of the mean function on $\boldsymbol{\beta}$ and/or the $\mathbf{z}$ vectors is often omitted for brevity.

In summary, the stochastic structure of models fit with the NLIN procedure is mathematically captured by

$$\begin{aligned} \mathbf{Y} &= \mathbf{f}(\boldsymbol{\beta}; \mathbf{z}_1, \cdots, \mathbf{z}_k) + \boldsymbol{\epsilon} \\ \mathrm{E}[\boldsymbol{\epsilon}] &= \mathbf{0} \\ \mathrm{Var}[\boldsymbol{\epsilon}] &= \sigma^2 \mathbf{I} \end{aligned}$$

Note that the residual variance σ^2 is typically also unknown. Since it is not estimated in the same fashion as the other p parameters, it is often not counted in the number of parameters of the nonlinear regression. An estimate of σ^2 is obtained after the model fit by the method of moments based on the residual sum of squares.

A matrix that plays an important role in fitting nonlinear regression models is the $(n \times p)$ matrix of the first partial derivatives of the mean function $\mathbf{f}$ with respect to the p model parameters. It is frequently denoted as

$$\mathbf{X} = \frac{\partial \mathbf{f}(\boldsymbol{\beta}; \mathbf{z}_1, \cdots, \mathbf{z}_k)}{\partial \boldsymbol{\beta}}$$

The use of the symbol $\mathbf{X}$—common in linear statistical modeling—is no accident here. The first derivative matrix plays a similar role in nonlinear regression to that of the $\mathbf{X}$ matrix in a linear model. For example, the asymptotic variance of the nonlinear least-squares estimators is proportional to $(\mathbf{X}'\mathbf{X})^{-1}$, and projection-type matrices in nonlinear regressions are based on $\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'$. Also, fitting a nonlinear regression model can be cast as an iterative process where a nonlinear model is approximated by a series of linear models in which the derivative matrix is the regressor matrix. An important difference between linear and nonlinear models is that the derivatives in a linear model do not depend on any parameters (see previous subsection). In contrast, the derivative matrix $\partial \mathbf{f}(\boldsymbol{\beta})/\partial \boldsymbol{\beta}$ is a function of at least one element of $\boldsymbol{\beta}$. It is this dependence that lies at the core of the fact that estimating the parameters in a nonlinear model cannot be accomplished in closed form, but it is an iterative process that commences with user-supplied starting values and attempts to continually improve on the parameter estimates.

Estimating the Parameters in the Nonlinear Model

As an example of a nonlinear regression analysis, consider the following theoretical model of enzyme kinetics. The model relates the initial velocity of an enzymatic reaction to the substrate concentration.

$$f(\mathbf{x}, \boldsymbol{\theta}) = \frac{\theta_1 x_i}{\theta_2 + x_i}, \quad \text{for } i = 1, 2, \ldots, n$$

where x_i represents the amount of substrate for n trials and $f(\mathbf{x}, \boldsymbol{\theta})$ is the velocity of the reaction. The vector $\boldsymbol{\theta}$ contains the rate parameters. This model is known as the Michaelis-Menten model in biochemistry (Ratkowsky, 1990, p. 59). The model exists in many parameterizations. In the form shown here, θ_1 is the maximum velocity of the reaction that is theoretically attainable. The parameter θ_2 is the substrate concentration at which the velocity is 50% of the maximum.

Suppose that you want to study the relationship between concentration and velocity for a particular enzyme/substrate pair. You record the reaction rate (velocity) observed at different substrate concentrations.

A SAS data set is created for this experiment in the following DATA step:

```
data Enzyme;
   input Concentration Velocity @@;
   datalines;
0.26 124.7   0.30 126.9
0.48 135.9   0.50 137.6
0.54 139.6   0.68 141.1
0.82 142.8   1.14 147.6
1.28 149.8   1.38 149.4
1.80 153.9   2.30 152.5
2.44 154.5   2.48 154.7
;
```

The SAS data set Enzyme contains the two variables Concentration (substrate concentration) and Velocity (reaction rate). The following statements fit the Michaelis-Menten model by nonlinear least squares:

```
proc nlin data=Enzyme method=marquardt hougaard;
   parms theta1=155
         theta2=0 to 0.07 by 0.01;
   model Velocity = theta1*Concentration / (theta2 + Concentration);
run;
```

The DATA= option specifies that the SAS data set Enzyme be used in the analysis. The METHOD= option directs PROC NLIN to use the MARQUARDT iterative method. The HOUGAARD option requests that a skewness measure be calculated for the parameters.

The PARMS statement declares the parameters and specifies their initial values. Suppose that V represents the velocity and C represents the substrate concentration. In this example, the initial estimates listed in the PARMS statement for θ_1 and θ_2 are obtained as follows:

θ_1: Because the model is a monotonic increasing function in C, and because

$$\lim_{C \to \infty} \left(\frac{\theta_1 C}{\theta_2 + C} \right) = \theta_1$$

you can take the largest observed value of the variable Velocity (154.7) as the initial value for the parameter Theta1. Thus, the PARMS statement specifies 155 as the initial value for Theta1, which is approximately equal to the maximum observed velocity.

θ_2: To obtain an initial value for the parameter θ_2, first rearrange the model equation to solve for θ_2:

$$\theta_2 = \frac{\theta_1 C}{V} - C$$

By substituting the initial value of Theta1 for θ_1 and taking each pair of observed values of Concentration and Velocity for C and V, respectively, you obtain a set of possible starting values for Theta2 ranging from about 0.01 to 0.07.

You can choose any value within this range as a starting value for Theta2, or you can direct PROC NLIN to perform a preliminary search for the best initial Theta2 value within that range of values. The PARMS statement specifies a range of values for Theta2, resulting in a search over the grid points from 0 to 0.07 in increments of 0.01.

The MODEL statement specifies the enzymatic reaction model

$$V = \frac{\theta_1 C}{\theta_2 + C}$$

in terms of the data set variables Velocity and Concentration and in terms of the parameters in the PARMS statement.

The results from this PROC NLIN invocation are displayed in the following figures.

PROC NLIN evaluates the model at each point on the specified grid for the Theta2 parameter. Figure 62.1 displays the calculations resulting from the grid search.

Figure 62.1 Nonlinear Least-Squares Grid Search

The NLIN Procedure
Dependent Variable Velocity

Grid Search

theta1	theta2	Sum of Squares
155.0	0	3075.4
155.0	0.0100	2074.1
155.0	0.0200	1310.3
155.0	0.0300	752.0
155.0	0.0400	371.9
155.0	0.0500	147.2
155.0	0.0600	58.1130
155.0	0.0700	87.9662

The parameter Theta1 is held constant at its specified initial value of 155, the grid is traversed, and the residual sum of squares is computed at each point. The "best" starting value is the point that corresponds to the smallest value of the residual sum of squares. The best set of starting values is obtained for $\theta_1 = 155, \theta_2 = 0.06$ (Figure 62.1). PROC NLIN uses this point from which to start the following, iterative phase of nonlinear least-squares estimation.

Figure 62.2 displays the iteration history. Note that the first entry in the "Iterative Phase" table echoes the starting values and the residual sum of squares for the best value combination in Figure 62.1. The subsequent rows of the table show the updates of the parameter estimates and the improvement (decrease) in the residual sum of squares. For this data-and-model combination, the first iteration yielded a large improvement in the sum of squares (from 58.113 to 19.7017). Further steps were necessary to improve the estimates in order to achieve the convergence criterion. The NLIN procedure by default determines convergence by using R, the relative offset measure of Bates and Watts (1981). Convergence is declared when this measure is less than 10^{-5}—in this example, after three iterations.

Figure 62.2 Iteration History and Convergence Status

The NLIN Procedure
Dependent Variable Velocity
Method: Marquardt

Iterative Phase

0	155.0	0.0600	58.1130
1	158.0	0.0736	19.7017
2	158.1	0.0741	19.6606
3	158.1	0.0741	19.6606

NOTE: Convergence criterion met.

Figure 62.3 Estimation Summary

Estimation Summary

Method	Marquardt
Iterations	3
R	5.861E-6
PPC(theta2)	8.569E-7
RPC(theta2)	0.000078
Object	2.902E-7
Objective	19.66059
Observations Read	14
Observations Used	14
Observations Missing	0

A summary of the estimation including several convergence measures (R, PPC, RPC, and Object) is displayed in Figure 62.3.

The "R" measure in Figure 62.3 is the relative offset convergence measure of Bates and Watts. A "PPC" value of $8.569\text{E}-7$ indicates that the parameter Theta2 (which has the largest PPC value of the parameters) would change by that relative amount, if PROC NLIN were to take an additional iteration step. The "RPC" value indicates that Theta2 changed by 0.000078, relative to its value in the last iteration. These changes are measured before step length adjustments are made. The "Object" measure indicates that the objective function changed by $2.902\text{E}-7$ in relative value from the last iteration.

Figure 62.4 displays the analysis of variance table for the model. The table displays the degrees of freedom, sums of squares, and mean squares along with the model F test.

Figure 62.4 Nonlinear Least-Squares Analysis of Variance

NOTE: An intercept was not specified for this model.

Source	DF	Sum of Squares	Mean Square	F Value	Approx Pr > F
Model	2	290116	145058	88537.2	<.0001
Error	12	19.6606	1.6384		
Uncorrected Total	14	290135			

Figure 62.5 Parameter Estimates and Approximate 95% Confidence Intervals

Parameter	Estimate	Approx Std Error	Approximate 95% Confidence Limits		Skewness
theta1	158.1	0.6737	156.6	159.6	0.0152
theta2	0.0741	0.00313	0.0673	0.0809	0.0362

Figure 62.5 displays the estimates for each parameter, the associated asymptotic standard error, and the upper and lower values for the asymptotic 95% confidence interval. PROC NLIN also displays the asymptotic correlations between the estimated parameters (not shown).

The skewness measures of 0.0152 and 0.0362 indicate that the parameter estimators exhibit close-to-linear behavior and that their standard errors and confidence intervals can be safely used for inferences.

Thus, the estimated nonlinear model relating reaction velocity and substrate concentration can be written as

$$\widehat{V} = \frac{158.1C}{0.0741 + C}$$

where $\widehat{V}$ represents the predicted velocity or rate of the reaction, and C represents the substrate concentration.

Syntax: NLIN Procedure

PROC NLIN < *options* > **;**
BOUNDS *inequality* < *, . . . , inequality* > **;**
BY *variables* **;**
CONTROL *variable* < *=values* > < *. . . variable* < *=values* > > **;**
DER. *parameter=expression* **;**
DER. *parameter.parameter=expression* **;**
ID *variables* **;**
MODEL *dependent=expression* **;**
OUTPUT OUT=*SAS-data-set keyword=names* < *. . . keyword=names* > **;**
PARAMETERS < *parameter-specification* > < *,. . . , parameter-specification* >
< */* **PDATA=***SAS-data-set* > **;**
RETAIN *variable* < *=values* > < *. . . variable* < *=values* > > **;**
Programming Statements **;**

The statements in the NLIN procedure, in addition to the PROC NLIN statement, are as follows:

BOUNDS	constrains the parameter estimates within specified bounds
BY	specifies variables to define subgroups for the analysis
DER	specifies the first or second partial derivatives
ID	specifies additional variables to add to the output data set
MODEL	defines the relationship between the dependent and independent variables (the mean function)
OUTPUT	creates an output data set containing observation-wise statistics
PARAMETERS	identifies parameters to be estimated and their starting values
Programming Statements	includes, for example, assignment statements, ARRAY statements, DO loops, and other program control statements. These are valid SAS expressions that can appear in the DATA step. PROC NLIN enables you to create new variables within the procedure and use them in the nonlinear analysis. These programming statements can appear anywhere in the PROC NLIN code, but new variables must be created before they appear in other statements. The NLIN procedure automatically creates several variables that are also available for use in the analysis. See the section "Special Variables" on page 5128 for more information.

The PROC NLIN, PARAMETERS, and MODEL statements are required.

PROC NLIN Statement

PROC NLIN < *options* > **;**

The PROC NLIN statement invokes the procedure.

The following table lists important options available in the PROC NLIN statement. All options are subsequently discussed in alphabetical order.

Table 62.1 Summary of Important Options in PROC NLIN Statement

Option	Description
Options Related to Data Sets	
DATA=	Specifies the input data set
OUTEST=	Specifies the output data set for parameter estimates, covariance matrix, and so on
SAVE	Requests that final estimates be added to the OUTEST= data set
Optimization Options	
BEST=	Limits display of grid search
METHOD=	Chooses the optimization method
MAXITER=	Specifies the maximum number of iterations
MAXSUBIT=	Specifies the maximum number of step halvings
NOHALVE	Allows the objective function to increase between iterations
RHO=	Controls the step-size search
SMETHOD=	Specifies the step-size search method
TAU=	Controls the step-size search
G4	Uses the Moore-Penrose inverse
UNCORRECTEDDF	Does not expense degrees of freedom when bounds are active
SIGSQ=	Specifies the fixed value for residual variance
Singularity and Convergence Criteria	
CONVERGE=	Tunes the convergence criterion
CONVERGEOBJ=	Uses the change in loss function as the convergence criterion and tunes its value
CONVERGEPARM=	Uses the maximum change in parameter estimates as the convergence criterion and tunes its value
SINGULAR=	Tunes the singularity criterion used in matrix inversions
ODS Graphics Options	
PLOTS=	Produces ODS graphical displays
Displayed Output	
HOUGAARD	Adds Hougaard's skewness measure to the "Parameter Estimates" table
BIAS	Adds Box's bias measure to the "Parameter Estimates" table
NOITPRINT	Suppresses the "Iteration History" table
NOPRINT	Suppresses displayed output

Table 62.1 *continued*

Option	Description
LIST	Displays the model program and variable list
LISTALL	Selects the LIST, LISTDEP, LISTDER, and LISTCODE options
LISTCODE	Displays the model program code
LISTDEP	Displays dependencies of model variables
LISTDER	Displays the derivative table
NLINMEASURES	Displays the global nonlinearity measures table
TOTALSS	Adds the uncorrected or corrected total sum of squares to the analysis of variance table
XREF	Displays the cross-reference of variables
Trace Model Execution	
FLOW	Displays execution messages for program statements
PRINT	Displays results of statements in model program
TRACE	Displays results of operations in model program

ALPHA=α

specifies the level of significance α used in the construction of $100(1-\alpha)\%$ confidence intervals. The value must be strictly between 0 and 1; the default value of $\alpha = 0.05$ results in 95% intervals. This value is used as the default confidence level for limits computed in the "Parameter Estimates" table and with the LCLM, LCL, UCLM, and UCL options in the OUTPUT statement.

BEST=*n*

requests that PROC NLIN display the residual sums of squares only for the best n combinations of possible starting values from the grid. If you do not specify the BEST= option, PROC NLIN displays the residual sum of squares for every combination of possible parameter starting values.

BIAS

Experimental

adds Box's bias and percentage bias measures to the "Parameter Estimates" table (Box 1971). Box's bias measure, along with Hougaard's measure of skweness, is used for assessing a parameter estimator's close-to-linear behavior (Ratkowsky 1983, 1990). Hence, it is useful for identifying problematic parameters (Seber and Wild 1989, sec. 4.7.1). When you specify the BIAS option, Box's bias measure (Box 1971) and the percentage bias (the bias expressed as a percentage of the least-squares estimator) are added for each parameter to the "Parameter Estimates" table. Ratkowsky (1983, p. 21) takes a percentage bias in excess of 1% to be a good rule of thumb for indicating nonlinear behavior.

See the section "Box's Measure of Bias" on page 5124 for further details. Example 62.4 shows how to use this measure, along with Hougaard's measure of skewness, to evaluate changes in the parameterization of a nonlinear model. Computation of the Box's bias measure requires first and second derivatives. If you do not provide derivatives with the DER statement—and it is recommended that you do not—the analytic derivatives are computed for you.

CONVERGE=*c*

specifies the convergence criterion for PROC NLIN. For all iterative methods the relative offset convergence measure of Bates and Watts is used by default to determine convergence. This measure

is labeled "R" in the "Estimation Summary" table. The iterations are said to have converged for CONVERGE=c if

$$\sqrt{\frac{\mathbf{r}'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{r}}{\mathrm{LOSS}^{(i)}}} < c$$

where $\mathbf{r}$ is the residual vector and $\mathbf{X}$ is the $(n \times p)$ matrix of first derivatives with respect to the parameters. The default LOSS function is the sum of squared errors (SSE), and $\mathrm{LOSS}^{(i)}$ denotes the value of the loss function at the ith iteration. By default, CONVERGE=10^{-5}. The R convergence measure cannot be computed accurately in the special case of a perfect fit (residuals close to zero). When the SSE is less than the value of the SINGULAR= criterion, convergence is assumed.

CONVERGEOBJ=*c*

uses the change in the LOSS function as the convergence criterion and tunes the criterion. The iterations are said to have converged for CONVERGEOBJ=c if

$$\frac{|\mathrm{LOSS}^{(i-1)} - \mathrm{LOSS}^{(i)}|}{|\mathrm{LOSS}^{(i-1)} + 10^{-6}|} < c$$

where $\mathrm{LOSS}^{(i)}$ is the LOSS for the ith iteration. The default LOSS function is the sum of squared errors (SSE), the residual sum of squares. The constant c should be a small positive number. For more details about the LOSS function, see the section "Special Variable Used to Determine Convergence Criteria" on page 5129. For more details about the computational methods in the NIN procedure, see the section "Computational Methods" on page 5133.

Note that in SAS 6 the CONVERGE= and CONVERGEOBJ= options both requested that convergence be tracked by the relative change in the loss function. If you specify the CONVERGEOBJ= option in newer releases, the CONVERGE= option is disabled. This enables you to track convergence as in SAS 6.

CONVERGEPARM=*c*

uses the maximum change among parameter estimates as the convergence criterion and tunes the criterion. The iterations are said to have converged for CONVERGEPARM=c if

$$\max_j \left(\frac{|\beta_j^{(i-1)} - \beta_j^{(i)}|}{|\beta_j^{(i-1)}|} \right) < c$$

where $\beta_j^{(i)}$ is the value of the jth parameter at the ith iteration.

The default convergence criterion is CONVERGE. If you specify CONVERGEPARM=c, the maximum change in parameters is used as the convergence criterion. If you specify both the CONVERGEOBJ= and CONVERGEPARM= options, PROC NLIN continues to iterate until the decrease in LOSS is sufficiently small (as determined by the CONVERGEOBJ= option) and the maximum change among the parameters is sufficiently small (as determined by the CONVERGEPARM= option).

DATA=*SAS-data-set*

specifies the input SAS data set to be analyzed by PROC NLIN. If you omit the DATA= option, the most recently created SAS data set is used.

FLOW

displays a message for each statement in the model program as it is executed. This debugging option is rarely needed, and it produces large amounts of output.

G4

uses a Moore-Penrose inverse (g_4-inverse) in parameter estimation. See Kennedy and Gentle (1980) for details.

HOUGAARD

adds Hougaard's measure of skewness to the "Parameter Estimates" table (Hougaard 1982, 1985). The skewness measure is one method of assessing a parameter estimator's close-to-linear behavior in the sense of Ratkowsky (1983, 1990). The behavior of estimators that are close to linear approaches that of least squares estimators in linear models, which are unbiased and have minimum variance. When you specify the HOUGAARD option, the standardized skewness measure of Hougaard (1985) is added for each parameter to the "Parameter Estimates" table. Because of the linkage between nonlinear behavior of a parameter estimator in nonlinear regression and the nonnormality of the estimator's sampling distribution, Ratkowsky (1990, p. 28) provides the following rules to interpret the (standardized) Hougaard skewness measure:

- Values less than 0.1 in absolute value indicate very close-to-linear behavior.
- Values between 0.1 and 0.25 in absolute value indicate reasonably close-to-linear behavior.
- The nonlinear behavior is apparent for absolute values above 0.25 and is considerable for absolute values above 1.

See the section "Hougaard's Measure of Skewness" on page 5124 for further details. Example 62.4 shows how to use this measure to evaluate changes in the parameterization of a nonlinear model. Computation of the Hougaard skewness measure requires first and second derivatives. If you do not provide derivatives with the DER statement—and it is recommended that you do not—the analytic derivatives are computed for you.

LIST

displays the model program and variable lists, including the statements added by macros. Note that the expressions displayed by the LIST option do not necessarily represent the way the expression is actually calculated—because intermediate results for common subexpressions can be reused—but are shown in expanded form. To see how the expression is actually evaluated, use the LISTCODE option.

LISTALL

selects the LIST, LISTDEP, LISTDER, and LISTCODE options.

LISTCODE

displays the derivative tables and the compiled model program code. The LISTCODE option is a debugging feature and is not normally needed.

LISTDEP

produces a report that lists, for each variable in the model program, the variables that depend on it and the variables on which it depends.

LISTDER

displays a table of derivatives. The derivatives table lists each nonzero derivative computed for the problem. The derivative listed can be a constant, a variable in the model program, or a special derivative variable created to hold the result of an expression.

MAXITER=*n*

specifies the maximum number n of iterations in the optimization process. The default is $n = 100$.

MAXSUBIT=*n*

places a limit on the number of step halvings. The value of MAXSUBIT must be a positive integer and the default value is $n = 30$.

METHOD=GAUSS

METHOD=MARQUARDT

METHOD=NEWTON

METHOD=GRADIENT

specifies the iterative method employed by the NLIN procedure in solving the nonlinear least squares problem. The GAUSS, MARQUARDT, and NEWTON methods are more robust than the GRADIENT method. If you omit the METHOD= option, METHOD=GAUSS is used. See the section "Computational Methods" on page 5133 for more information.

NLINMEASURES

Experimental

displays the global nonlinearity measures table. These measures include the maximum intrinsic and parameter-effects curvatures (Bates and Watts 1980), the root mean square (RMS) intrinsic and parameter-effects curvatures and the critical curvature value (Bates and Watts 1980). In addition, the variances of the ordinary and projected residuals are included. According to Bates and Watts (1980), both intrinisic and parameter-effects curvatures are deemed negligible if they are less than the critical curvature value. This critical value is given by $1/(\sqrt{F})$ where $F = F(p, n-p; \alpha)$. The value $1/\sqrt{F}$ can be considered as the radius of curvature of the $100(1-\alpha)$ percent confidence region (Bates and Watts 1980).

NOITPRINT

suppresses the display of the "Iteration History" table.

NOHALVE

removes the restriction that the objective value must decrease at every iteration. Step halving is still used to satisfy BOUNDS and to ensure that the number of observations that can be evaluated does not decrease. The NOHALVE option can be useful in weighted nonlinear least squares problems where the weights depend on the parameters, such as in iteratively reweighted least squares (IRLS) fitting. See Example 62.2 for an application of IRLS fitting.

NOPRINT

suppresses the display of the output. Note that this option temporarily disables the Output Delivery System (ODS). For more information, see Chapter 20, "Using the Output Delivery System."

OUTEST=*SAS-data-set*

specifies an output data set that contains the parameter estimates produced at each iteration. See the section "Output Data Sets" for details. If you want to create a permanent SAS data set, you must specify a two-level name. See the chapter "SAS Files" in *SAS Language Reference: Concepts* for more information about permanent SAS data sets.

PLOTS <(*global-plot-option***)> <= *plot-request* <(***options***)>>**

PLOTS <(*global-plot-option***)> <= (***plot-request* <(***options***)>** **<... *plot-request* <(***options***)>>)>**

Experimental

controls the plots produced through ODS Graphics. When you specify only one plot request, you can omit the parentheses around the plot request. Here are some examples:

```
plots
plots         = none
plots         = diagnostics(unpack)
plots         = fit(stats=none)
plots         = residuals(residualtype=proj unpack smooth)
plots(stats=all)  = (diagnostics(stats=(maxincurv maxpecurv)) fit)
```

ODS Graphics must be enabled before requesting plots. For example:

```
ods graphics on;

proc nlin plots=diagnostics(stats=all);
   model y = alpha - beta*(gamma**x);
run;

ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section "Enabling and Disabling ODS Graphics" on page 612 in Chapter 21, "Statistical Graphics Using ODS."

To produce graphs, ODS Graphics must be enabled. If you do not specify the PLOTS option, PROC NLIN produces no graphs. PROC NLIN produces the plots listed in Table 62.2 with the default set of statistics and options if you specify the PLOTS option simply as PLOTS.

Table 62.2 Graphs Produced When PLOTS Option Is Specified

Plot	Conditional On
FitDiagnosticsPanel	Unconditional
LeveragePlot	Unconditional
LocalInfluencePlot	Unconditional
ResidualPanel	Unconditional
FitPlot	Model with one regressor
ContourFitPlot	Model with two regressors

You can request additional graphs by specifying the PLOTS=*plot-request* option. For a listing of all the plots that PROC NLIN produces, see the section "ODS Graphics (Experimental)" on page 5144. Each *global-plot-option* applies to all plots generated by the NLIN procedure, unless it is altered by a specific *option* after a *plot-request*.

The following *global-plot-options* are available:

RESIDUALTYPE=RAW | PROJ | BOTH
specifies the residual type to be plotted in the fit diagnostics and residual plots. RESIDUALTYPE=RAW requests that only the ordinary residuals be included in the plots; RESIDUALTYPE=PROJ sets the choice to projected residuals. By default, both residual types are included, which can also be effected by setting RESIDUALTYPE=BOTH. See the section "Residuals in Nonlinear Regression" on page 5127 for details about the properties of ordinary and projected residuals in nonlinear regression.

STATS=ALL | DEFAULT | NONE | (*plot-statistics*)
requests the statistics to be included in all plots, except the ResidualPlots and the unpacked diagnostics plots. Table 62.3 lists the statistics that you can request. STATS=ALL requests all these statistics, STATS=NONE suppresses all statistics, and STATS=DEFAULT selects the default statistics. You request statistics in addition to the default set by including the keyword DEFAULT in the *plot-statistics* list.

Table 62.3 Statistics Available in Plots

Keyword	Default	Description
DEFAULT		All default statistics
MAXINCURV		Maximum intrinsic curvature
MAXPECURV		Maximum parameter-effects curvature
MSE	x	Mean squared error, estimated or set by the SIGSQ option
NOBS	x	Number of observations used
NPARM	x	Number of parameters in the model
PVAR	x	Estimated variance of the projected residuals
RMSNINCURV		Root mean square intrinsic curvature
RMSPECURV		Root mean square parameter-effects curvature
VAR	x	Estimated variance of the ordinary residuals

Along with the maximum intrinisic and parameter-effects curvatures, the critical curvature (CURVCRIT) value, $1/\sqrt{F}$ where $F = F(p, n-p; \alpha)$, is also displayed. You do not need to specify any option for it. See the section "Relative Curvature Measures of Nonlinearity" on page 5125 for details about curvature measures of nonlinearity.

UNPACK
suppresses paneling.

You can specify the following *plot-requests* in the PLOTS= option:

ALL
produces all appropriate plots.

NONE
suppresses all plots.

DIAGNOSTICS <(*diagnostics-options*)>

produces a summary panel of fit diagnostics, leverage plots, and local-influence plots. The fit diagnostics panel includes:

- histogram of the ordinary residuals
- histogram of the projected residuals
- response variable values versus the predicted values
- expectation or mean of the ordinary residuals versus the predicted values
- ordinary and projected residuals versus the predicted values
- standardized ordinary and projected residuals versus the predicted values
- standardized ordinary and projected residuals versus the tangential leverage
- standardized ordinary and projected residuals versus the Jacobian leverage
- box plot of the ordinary and projected residuals if you specify the STATS=NONE suboption

The leverage and local influence plots are produced separately. The leverage plot is an index plot of the tangential and Jacobian leverages (by observation), and the local-influence plot contains the local influence by observation for a perturbation of the response variable. See the sections "Leverage in Nonlinear Regression" on page 5126 and "Local Influence in Nonlinear Regression" on page 5127 for a some details about leverages and local-influence in nonlinear regression.

You can specify the following *diagnostics-options*:

RESIDUALTYPE=RAW | PROJ | BOTH

specifies the residual type to be plotted in the panel. See the RESIDUALTYPE= *global-plot-option* for details. This *diagnostics-option* overrides the PLOTS RESIDUALTYPE *global-plot-option*. Only the plots that overlay both ordinary and projected residuals in the same plot are affected by this option.

LEVERAGETYPE=TAN | JAC | BOTH

specifies the leverage type to be plotted in the leverage plot. LEVERAGETYPE=TAN specifies that only the tangential leverage be included in the leverage plot, and LEVERAGETYPE=JAC specifies that only the Jacobian leverage be included. By default, both are displayed in the leverage plot. The same result can be effected by setting LEVERAGETYPE=BOTH. Only the leverage plot is affected by this option.

LABELOBS

specifies that the leverage and local-infuence plots be labeled with the observation number. Only these two plots are affected by this option.

STATS=*stats-options*

determines which statistics are included in the panel. See the STATS= *global-plot-option* for details. This *diagnostics-option* overrides the PLOTS STATS *global-plot-option*.

UNPACK

produces the plots in the diagnostics panel as individual plots. The statistics panel is not included in the individual plots, even if STATS= *global-plot-option* or STATS= *diagnostics-option* or both are specified.

FITPLOT | FIT < (*fit-options*) >

produces, depending on the number of regressors, a scatter or contour fit plot. For a single-regressor model, a scatter plot of the data overlaid with the regression curve, confidence, and prediction bands is produced. For two-regressor models, a contour fit plot of the model with overlaid data is produced. If the model contains more than two regressors, no fit plot is produced.

You can specify the following *fit-options*:

NOCLI

suppresses the prediction limits for single-regressor models.

NOCLM

suppresses the confidence limits for single-regressor models.

NOLIMITS

suppresses the confidence and prediction limits for single-regressor models.

OBS=GRADIENT | NONE | OUTLINE | OUTLINEGRADIENT

controls how the observations are displayed. The suboptions are as follows:

OBS=GRADIENT specifies that observations be displayed as circles colored by the observed response. The same color gradient is used to display the fitted surface and the observations. Observations for which the predicted response is close to the observed response have similar colors—the greater the contrast between the color of an observation and the surface, the larger the residual is at that point. OBS=GRADIENT is the default.

OBS=NONE suppresses the observations.

OBS=OUTLINE specifies that observations be displayed as circles with a border but with a completely transparent fill.

OBS=OUTLINEGRADIENT is the same as OBS=GRADIENT except that a border is shown around each observation. This option is useful for identifying the location observations for which the residuals are small, because at these points the color of the observations and the color of the surface are indistinguishable.

CONTLEG

specifies that a continous legend be included in the contour fit plot of a two-regressor model.

STATS=*stats-options*

determines which model fit statistics are included in the panel. See the STATS= *global-plot-option* for details. This *fit-option* overrides the PLOTS STATS *global-plot-option*.

RESIDUALS < *residual-options*) >

produces panels of the ordinary and projected residuals versus the regressors in the model. Each panel contains at most six plots, and multiple panels are used in the case where there are more than six regressors in the model.

The following *residual-options* are available:

RESIDUALTYPE=RAW | PROJ | BOTH
specifies the residual type to be plotted in the panel. See the RESIDUALTYPE= *global-plot-option* for details. This *residual-option* overrides the PLOTS RESIDUALTYPE *global-plot-option*.

SMOOTH
requests a nonparametric smooth of the residuals for each regressor. Each nonparametric fit is a loess fit that uses local linear polynomials, linear interpolation, and a smoothing parameter selected that yields a local minimum of the corrected Akaike information criterion (AICC). See Chapter 52, "The LOESS Procedure," for details.

UNPACK
suppresses paneling.

PRINT
displays the result of each statement in the program as it is executed. This option is a debugging feature that produces large amounts of output and is normally not needed.

RHO=*value*
specifies a value that controls the step-size search. By default RHO=0.1, except when METHOD=MARQUARDT. In that case, RHO=10. See the section "Step-Size Search" on page 5138 for more details.

SAVE
specifies that, when the iteration limit is exceeded, the parameter estimates from the final iteration be output to the OUTEST= data set. These parameter estimates are associated with the observation for which _TYPE_="FINAL". If you omit the SAVE option, the parameter estimates from the final iteration are not output to the data set unless convergence has been attained.

SIGSQ=*value*
specifies a value to use as the estimate of the residual variance in lieu of the estimated mean-squared error. This value is used in computing the standard errors of the estimates. Fixing the value of the residual variance can be useful, for example, in maximum likelihood estimation.

SINGULAR=*s*
specifies the singularity criterion, s, which is the absolute magnitude of the smallest pivot value allowed when inverting the Hessian or the approximation to the Hessian. The default value is 1E4 times the machine epsilon; this product is approximately $1E-12$ on most computers.

SMETHOD=HALVE
SMETHOD=GOLDEN
SMETHOD=CUBIC
specifies the step-size search method. The default is SMETHOD=HALVE. See the section "Step-Size Search" on page 5138 for details.

TAU=*value*

specifies a value that is used to control the step-size search. The default is TAU=1, except when METHOD=MARQUARDT. In that case the default is TAU=0.01. See the section "Step-Size Search" on page 5138 for details.

TOTALSS

adds to the analysis of variance table the uncorrected total sum of squares in models that have an (implied) intercept, and adds the corrected total sum of squares in models that do not have an (implied) intercept.

TRACE

displays the result of each operation in each statement in the model program as it is executed, in addition to the information displayed by the FLOW and PRINT options. This debugging option is needed very rarely, and it produces even more output than the FLOW and PRINT options.

XREF

displays a cross-reference of the variables in the model program showing where each variable is referenced or given a value. The XREF listing does not include derivative variables.

UNCORRECTEDDF

specifies that no degrees of freedom be lost when a bound is active. When the UNCORRECTEDDF option is not specified, an active bound is treated as if a restriction were applied to the set of parameters, so one parameter degree of freedom is deducted.

BOUNDS Statement

BOUNDS *inequality* < , . . . , *inequality* > **;**

The BOUNDS statement restricts the parameter estimates so that they lie within specified regions. In each BOUNDS statement, you can specify a series of boundary values separated by commas. The series of bounds is applied simultaneously. Each boundary specification consists of a list of parameters, an inequality comparison operator, and a value. In a single-bounded expression, these three elements follow one another in the order described. The following are examples of valid single-bounded expressions:

```
bounds a1-a10 <= 20;
bounds c > 30;
bounds a b c > 0;
```

Multiple-bounded expressions are also permitted. For example:

```
bounds 0 <= B<= 10;
bounds 15 < x1 <= 30;
bounds r <= s <= p < q;
```

If you need to restrict an expression involving several parameters (for example, $\alpha + \beta < 1$), you can reparameterize the model so that the expression becomes a parameter or so that the boundary constraint can be expressed as a simple relationship between two parameters. For example, the boundary constraint $\alpha + \beta < 1$ in the model

```
model y = alpha + beta*x;
```

can be achieved by parameterizing $\theta = 1 - \beta$ as follows:

```
bounds alpha < theta;
model y = alpha + (1-theta)*x;
```

Starting with SAS 7.01, Lagrange multipliers are reported for all bounds that are enforced (active) when the estimation terminates. In the "Parameter Estimates" table, the Lagrange multiplier estimates are identified with names *Bound1*, *Bound2*, and so forth. An active bound is treated as if a restriction were applied to the set of parameters so that one parameter degree of freedom is deducted. You can use the UNCORRECTEDDF option to prevent the loss of degrees of freedom when bounds are active.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC NLIN to obtain separate analyses for observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the NLIN procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about the BY statement, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the *Base SAS Procedures Guide*.

CONTROL Statement

CONTROL *variable* <**=***values*> <*. . . variable* <**=***values*>> **;**

The CONTROL statement declares control variables and specifies their values. A control variable is like a retained variable (see the section "RETAIN Statement" on page 5119) except that it is retained *across* iterations, and the derivative of the model with respect to a control variable is always zero.

DER Statements

DER. *parameter***=***expression* **;**

DER. *parameter.parameter***=***expression* **;**

The DER statement specifies first or second partial derivatives. By default, analytical derivatives are automatically computed. However, you can specify the derivatives yourself by using the DER.parm syntax. Use the first form shown to specify first partial derivatives, and use the second form to specify second partial derivatives. Note that the DER.parm syntax is retained for backward compatibility. The automatic analytical derivatives are, in general, a better choice. For additional information about automatic analytical derivatives, see the section "Automatic Derivatives" on page 5122.

For most of the computational methods, you need only specify the first partial derivative with respect to each parameter to be estimated. For the NEWTON method, specify both the first and the second derivatives. If any needed derivatives are not specified, they are automatically computed.

The expression can be an algebraic representation of the partial derivative of the expression in the MODEL statement with respect to the parameter or parameters that appear on the left side of the DER statement. Numerical derivatives can also be used. The expression in the DER statement must conform to the rules for a valid SAS expression, and it can include any quantities that the MODEL statement expression contains.

ID Statement

ID *variables* **;**

The ID statement specifies additional variables to place in the output data set created by the OUTPUT statement. Any variable on the left side of any assignment statement is eligible. Also, the special variables created by the procedure can be specified. Variables in the input data set do not need to be specified in the ID statement since they are automatically included in the output data set.

MODEL Statement

MODEL *dependent*=*expression* **;**

The MODEL statement defines the prediction equation by declaring the dependent variable and defining an expression that evaluates predicted values. The expression can be any valid SAS expression that yields a numeric result. The expression can include parameter names, variables in the data set, and variables created by programming statements in the NLIN procedure. Any operators or functions that can be used in a DATA step can also be used in the MODEL statement.

A statement such as

```
model y=expression;
```

is translated into the form

```
model.y=expression;
```

using the compound variable name model.y to hold the predicted value. You can use this assignment directly as an alternative to the MODEL statement. Either a MODEL statement or an assignment to a compound variable such as model.y must appear.

OUTPUT Statement

OUTPUT OUT= *SAS-data-set keyword*=*names* < *. . . keyword*=*names* > < / *options* > **;**

The OUTPUT statement specifies an output data set to contain statistics calculated for each observation. For each statistic, specify the keyword, an equal sign, and a variable name for the statistic in the output data set. All of the names appearing in the OUTPUT statement must be valid SAS names, and none of the new variable names can match a variable already existing in the data set to which PROC NLIN is applied.

If an observation includes a missing value for one of the independent variables, both the predicted value and the residual value are missing for that observation. If the iterations fail to converge, all the values of all the variables named in the OUTPUT statement are missing values.

You can specify the following options in the OUTPUT statement. For a description of computational formulas, see Chapter 4, "Introduction to Regression Procedures."

OUT=*SAS-data-set*
specifies the SAS data set to be created by PROC NLIN when an OUTPUT statement is included. The new data set includes the variables in the input data set. Also included are any ID variables specified in the ID statement, plus new variables with names that are specified in the OUTPUT statement.

The following values can be calculated and output to the new data set.

H=*name*

specifies a variable that contains the tangential leverage. See the section "Leverage in Nonlinear Regression" on page 5126 for details.

J=*name*

Experimental

specifies a variable that contains the Jacobian leverage. See the section "Leverage in Nonlinear Regression" on page 5126 for details.

L95=*name*

specifies a variable that contains the lower bound of an approximate 95% confidence interval for an individual prediction. This includes the variance of the error as well as the variance of the parameter estimates. See also the description for the U95= option later in this section.

L95M=*name*

specifies a variable that contains the lower bound of an approximate 95% confidence interval for the expected value (mean). See also the description for the U95M= option later in this section.

LCL=*name*

specifies a variable that contains the lower bound of an approximate $100(1-\alpha)\%$ confidence interval for an individual prediction. The α level is equal to the value of the ALPHA= option in the OUTPUT statement or, if this option is not specified, to the value of the ALPHA= option in the PROC NLIN statement. If neither of these options is specified, then $\alpha = 0.05$ by default, resulting in a lower bound for an approximate 95% confidence interval. For the corresponding upper bound, see the UCL keyword.

LCLM=*name*

specifies a variable that contains the lower bound of an approximate $100(1-\alpha)\%$ confidence interval for the expected value (mean). The α level is equal to the value of the ALPHA= option in the OUTPUT statement or, if this option is not specified, to the value of the ALPHA= option in the PROC NLIN statement. If neither of these options is specified, then $\alpha = 0.05$ by default, resulting in a lower bound for an approximate 95% confidence interval. For the corresponding lower bound, see the UCLM keyword.

LMAX=*name*

Experimental

specifies a variable that contains the direction of maximum local influence of an additive perturbation of the response variable. See the section "Local Influence in Nonlinear Regression" on page 5127 for details.

PARMS=*names*

specifies variables in the output data set that contains parameter estimates. These can be the same variable names that are listed in the PARAMETERS statement; however, you can choose new names for the parameters identified in the sequence from the parameter estimates table. A note in the log indicates which variable in the output data set is associated with which parameter name. Note that, for each of these new variables, the values are the same for every observation in the new data set.

PREDICTED=*name*

P=*name*

specifies a variable in the output data set that contains the predicted values of the dependent variable.

PROJRES=*name*

Experimental

specifies a variable that contains the projected residuals obtained by projecting the residuals (ordinary residuals) into the null space of $(X|H)$. For the ordinary residuals, see the RESIDUAL= option later in this section. The section "Residuals in Nonlinear Regression" on page 5127 describes the statistical properties of projected residuals in nonlinear regression.

PROJSTUDENT=*name*

Experimental

specifies a variable that contains the standardized projected residuals. See the section "Residuals in Nonlinear Regression" on page 5127 for details and the STUDENT= option later in this section.

RESEXPEC=*name*

Experimental

specifies a variable that contains the mean of the residuals. In contrast to linear regressions where the mean of the residuals is zero, in nonlinear regression the residuals have a nonzero mean value and show a negative covarience with the mean response. See the section "Residuals in Nonlinear Regression" on page 5127 for details.

RESIDUAL=*name*

R=*name*

specifies a variable in the output data set that contains the residuals. See also the description of PROJRES= option stated previously in this section and the section "Residuals in Nonlinear Regression" on page 5127 for the statistical properties of residuals and projected residuals.

SSE=*name*

ESS=*name*

specifies a variable in the output data set that contains the residual sum of squares finally determined by the procedure. The value of the variable is the same for every observation in the new data set.

STDI=*name*

specifies a variable that contains the standard error of the individual predicted value.

STDP=*name*

specifies a variable that contains the standard error of the mean predicted value.

STDR=*name*

specifies a variable that contains the standard error of the residual.

STUDENT=*name*

specifies a variable that contains the standardized residuals. These are residuals divided by their estimated standard deviation. See the PROJSTUDENT= option defined previously in this section and the section "Residuals in Nonlinear Regression" on page 5127 for the statistical properties of residuals and projected residuals.

U95=*name*

specifies a variable that contains the upper bound of an approximate 95% confidence interval for an individual prediction. See also the description for the L95= option.

U95M=*name*

specifies a variable that contains the upper bound of an approximate 95% confidence interval for the expected value (mean). See also the description for the L95M= option.

UCL=*name*

specifies a variable that contains the upper bound of an approximate $100(1-\alpha)\%$ confidence interval an individual prediction. The α level is equal to the value of the ALPHA= option in the OUTPUT statement or, if this option is not specified, to the value of the ALPHA= option in the PROC NLIN statement. If neither of these options is specified, then $\alpha = 0.05$ by default, resulting in an upper bound for an approximate 95% confidence interval. For the corresponding lower bound, see the LCL keyword.

UCLM=*name*

specifies a variable that contains the upper bound of an approximate $100(1-\alpha)\%$ confidence interval for the expected value (mean). The α level is equal to the value of the ALPHA= option in the OUTPUT statement or, if this option is not specified, to the value of the ALPHA= option in the PROC NLIN statement. If neither of these options is specified, then $\alpha = 0.05$ by default, resulting in an upper bound for an approximate 95% confidence interval. For the corresponding lower bound, see the LCLM keyword.

WEIGHT=*name*

specifies a variable in the output data set that contains values of the special variable _WEIGHT_.

You can specify the following options in the OUTPUT statement after a slash (/) :

ALPHA=α

specifies the level of significance α for $100(1-\alpha)\%$ confidence intervals. By default, α is equal to the value of the ALPHA= option in the PROC NLIN statement or 0.05 if that option is not specified. You can supply values that are strictly between 0 and 1.

DER

saves the first derivatives of the model with respect to the parameters to the OUTPUT data set. The derivatives are named DER_parmname, where "parmname" is the name of the model parameter in your NLIN statements. You can use the DER option to extract the $\mathbf{X} = \partial \mathbf{f}/\partial \boldsymbol{\beta}$ matrix into a SAS data set. For example, the following statements create the data set nlinX, which contains the $\mathbf{X}$ matrix:

```
proc nlin;
   parms theta1=155 theta3=0.04;
   model V = theta1*c / (theta3 + c);
   output out=nlinout / der;
run;

data nlinX;
   set nlinout(keep=DER_:);
run;
```

The derivatives are evaluated at the final parameter estimates.

PARAMETERS Statement

PARAMETERS < *parameter-specification* > < *, . . . , parameter-specification* >
< / **PDATA=***SAS-data-set* > **;**

PARMS < *parameter-specification* > < *, . . . , parameter-specification* >
< / **PDATA=***SAS-data-set* > **;**

A PARAMETERS (or PARMS) statement is required. The purpose of this statement is to provide starting values for the NLIN procedure. You can provide values that define a point in the parameter space or a set of points.

All parameters must be assigned starting values through the PARAMETERS statement. The NLIN procedure does not assign default starting values to parameters in your model that do not appear in the PARAMETERS statement. However, it is not necessary to supply parameters and starting values explicitly through a *parameter-specification*. Starting values can also be provided through a data set. The names assigned to parameters must be valid SAS names and must not coincide with names of variables in the input data set (see the DATA= option in the PROC NLIN statement). Parameters that are assigned starting values through the PARAMETERS statement can be omitted from the estimation, for example, if the expression in the MODEL statement does not depend on them.

Assigning Starting Values with Parameter-Specification

A *parameter-specification* has the general form

name **=** *value-list*

where *name* identifies the parameter and *value-list* provides the set of starting values for the parameter.

Very often, the *value-list* contains only a single value, but more general and flexible list specifications are possible:

m	a single value
$m1, m2, \ldots, mn$	several values
m TO n	a sequence where m equals the starting value, n equals the ending value, and the increment equals 1
m TO n BY i	a sequence where m equals the starting value, n equals the ending value, and the increment is i
$m1, m2$ TO $m3$	mixed values and sequences

When you specify more than one value for a parameter, PROC NLIN sorts the values in ascending sequence and removes duplicate values from the parameter list before forming the grid for the parameter search. If you specify several values for each parameter, PROC NLIN evaluates the model at each point on the grid. The iterations then commence from the point on the grid that yields the smallest objective function value.

For example, the following PARMS statement specifies five parameters and sets their possible starting values as shown in the table:

```
parms  b0 = 0
       b1 = 4 to 8
       b2 = 0 to .6 by .2
       b3 = 1, 10, 100
       b4 = 0, .5, 1 to 4;
```

Possible starting values				
B0	B1	B2	B3	B4
0	4	0.0	1	0.0
	5	0.2	10	0.5
	6	0.4	100	1.0
	7	0.6		2.0
	8			3.0
				4.0

Residual sums of squares are calculated for each of the $1 \times 5 \times 4 \times 3 \times 6 = 360$ combinations of possible starting values. (Specifying a large grid of values can take considerable computing time.)

If you specify a starting value with a *parameter-specification*, any starting values provided for this parameter through the PDATA= data set are ignored. The *parameter-specification* overrides the information in the PDATA= data set. When you specify a BY statement, the same *parameter-specification* is applied in each BY group. To vary starting values with BY groups, use the PDATA= option in the PARAMETERS statement as described in the following paragraphs.

Assigning Starting Values from a SAS Data Set

The PDATA= option in the PARAMETERS statement enables you to assign starting values for parameters through a SAS data set. The data set must contain at least two variables that identify the parameter and contain starting values, respectively. The *character* variable identifying the parameters must be named Parameter or Parm. The *numeric* variable containing the starting value must be named Estimate or Est. This enables you, for example, to use the contents of the "ParameterEstimates" table from one PROC NLIN run to supply starting values for a subsequent run, as in the following example:

```
proc nlin data=FirstData;
   parameters alpha=100 beta=3 gamma=4;
   < other NLIN statements >
   model y = ... ;
   ods output ParameterEstimates=pest;
run;

proc nlin data=SecondData;
   parameters / pdata=pest;
   Switch = 1/(1+gamma*exp(beta*log(dose)));
   model y = alpha*Switch;
run;
```

You can specify multiple values for a parameter in the PDATA= data set, and the parameters can appear in any order. The starting values are collected by parameter and arranged in ascending order, and duplicate values are removed. The parameter names in the PDATA= data set are not case sensitive. For example, the following DATA step defines starting values for three parameters and a starting grid with $1 \times 3 \times 1 = 3$ points:

```
data test;
   input Parameter $ Estimate;
   datalines;
alpha  100
 BETA   4
 beta   4.1
beta    4.2
beta    4.1
 gamma 30
;
```

If starting values for a parameter are provided through the PDATA= data set and through an explicit *parameter-specification*, the latter takes precedence.

When you specify a BY statement, you can control whether the same starting values are applied to each BY group or whether the starting values are varied. If the BY variables are not present in the PDATA= data set, the entire contents of the PDATA= data set are applied in each BY group. If the BY variables are present in the PDATA= data set, then BY-group-specific starting values are assigned.

RETAIN Statement

RETAIN *variable* < **=***values* > < *. . . variable* < **=***values* > > **;**

The RETAIN statement declares retained variables and specifies their values. A retained variable is like a control variable (see the section "CONTROL Statement" on page 5112) except that it is retained only *within* iterations. An iteration involves a single pass through the data set.

Other Programming Statements

PROC NLIN supports many statements that are similar to SAS programming statements used in a DATA step. However, there are some differences in capabilities; for additional information, see also the section "Incompatibilities with SAS 6.11 and Earlier Versions of PROC NLIN" on page 5142.

Several SAS programming statements can be used after the PROC NLIN statement. These statements can appear anywhere in the PROC NLIN code, but new variables must be created before they appear in other statements. For example, the following statements are valid since they create the variable temp before it is used in the MODEL statement:

```
proc nlin;
   parms b0=0 to 2 by 0.5 b1=0.01 to 0.09 by 0.01;
   temp = exp(-b1*x);
   model y=b0*(1-temp);
run;
```

The following statements result in missing values for y because the variable temp is undefined before it is used:

```
proc nlin;
   parms b0=0 to 2 by 0.5 b1=0.01 to 0.09 by 0.01;
   model y = b0*(1-temp);
   temp = exp(-b1*x);
run;
```

PROC NLIN can process assignment statements, explicitly or implicitly subscripted ARRAY statements, explicitly or implicitly subscripted array references, IF statements, SAS functions, and program control statements. You can use programming statements to create new SAS variables for the duration of the procedure. These variables are not included in the data set to which PROC NLIN is applied. Program statements can include variables in the DATA= data set, parameter names, variables created by preceding programming statements within PROC NLIN, and special variables used by PROC NLIN. The following SAS programming statements can be used in PROC NLIN:

ARRAY;
variable = expression;
variable + expression;
CALL *name [(expression [, expression . . .])]*;
DO *[variable = expression*
*[***TO** *expression] [***BY** *expression]*
[, expression [**TO** *expression] [* **BY** *expression] . . .]*
]
[**WHILE** *expression] [* **UNTIL** *expression]*;
END;
FILE;
GOTO *statement_label*;
IF *expression*;
IF *expression* **THEN** *program_statement*;
ELSE *program_statement*;
variable = expression;
variable + expression;
LINK *statement_label*;
PUT *[variable] [=] [...]*;
RETURN;
SELECT[(*expression* **)];**

These statements can use the special variables created by PROC NLIN. See the section "Special Variables" on page 5128 for more information.

Details: NLIN Procedure

Automatic Derivatives

Depending on the optimization method you select, analytical first- and second-order derivatives are computed automatically. Derivatives can still be supplied using the DER.parm syntax. These DER.parm derivatives are not verified by the differentiator. If any needed derivatives are not supplied, they are computed and added to the programming statements. To view the computed derivatives, use the LISTDER or LIST option.

The following model is solved using Newton's method. Analytical first- and second-order derivatives are automatically computed. The compiled program code is shown in Figure 62.6.

```
proc nlin data=Enzyme method=newton list;
   parms x1=4 x2=2;
   model Velocity = x1 * exp (x2 * Concentration);
run;
```

Figure 62.6 Model and Derivative Code Output

```
                          The NLIN Procedure

                 Listing of Compiled Program Code

Measures of Nonlinearity and Diagnostics

A "close-to-linear" nonlinear regression model, in the sense of Ratkowsky (1983, 1990), is a model in which parameter estimators have properties similar to those in a linear regression model. That is, the least squares estimators of the parameters are close to being unbiased and normally distributed, and they have minimum variance.

A nonlinear regression model sometimes fails to be close to linear due to the properties of one or several parameters. When this occurs, bias in the parameter estimates can render inferences that use the reported standard errors and confidence limits invalid.

PROC NLIN provides various measures of nonlinearity. To assess the nonlinearity of a model-data combination, you can use both of the following complementary sets of measures:

- Box's bias (Box 1971) and Hougaard's skewness (Hougaard 1982, 1985) of the least squares parameter estimates
- curvature measures of nonlinearity (Bates and Watts 1980).

Furthermore, PROC NLIN provides residual, leverage, and local-influence diagnostics (St. Laurent and Cook 1993).

In the following several sections, these nonlinearity measures and diagnostics are discussed. For this material, several basic definitions are required. Let $\mathbf{X}$ be the Jacobian matrix for the model, $\mathbf{X} = \frac{\partial \mathbf{f}}{\partial \boldsymbol{\beta}}$, and let $\mathbf{Q}$ and $\mathbf{R}$ be the components of the QR decomposition of $\mathbf{X} = \mathbf{QR}$ of $\mathbf{X}$, where $\mathbf{Q}$ is an $(n \times n)$ orthogonal matrix. Finally, let $\mathbf{B}$ be the inverse of the matrix constructed from the first p rows of the $(n \times p)$ dimensional matrix $\mathbf{R}$ (that is, $\mathbf{B} = \mathbf{R}_p^{-1}$). Next define

$$\begin{aligned}
\left[\mathbf{H}_j\right]_{kl} &= \frac{\partial^2 \mathbf{f}_j}{\partial \boldsymbol{\beta}_k \partial \boldsymbol{\beta}_l} \\
\left[\mathbf{U}_j\right]_{kl} &= \sum_{mn} \mathbf{B}'_{km} \left[\mathbf{H}_j\right]_{mn} \mathbf{B}_{nl} \\
\left[\mathbf{A}_j\right]_{kl} &= \sqrt{p \times mse} \sum_m \mathbf{Q}'_{jm} \left[\mathbf{U}_m\right]_{kl} \ ,
\end{aligned}$$

where $\mathbf{H}$, $\mathbf{U}$ and the acceleration array $\mathbf{A}$ are three-dimensional $(n \times p \times p)$ matrices. The first p faces of the acceleration array constitute a $(p \times p \times p)$ parameteter-effects array and the last $(n - p)$ faces constitute the $(n - p \times p \times p)$ intrinsic curvature array (Bates and Watts 1980). The previous and subsequent quantities are computed at the least squares parameter estimators.

Box's Measure of Bias

The degree to which parameter estimators exhibit close-to-linear behavior can be assessed with Box's bias (Box 1971) and Hougaard's measure of skewness (Hougaard 1982, 1985). The bias and percentage bias measures are available through the BIAS option in the PROC NLIN statement. Box's bias measure is defined as

$$\widehat{\mathrm{E}}\left[\widehat{\theta} - \theta\right] = -\frac{\sigma^2}{2} \left(\mathbf{X}'W\mathbf{X}\right)^{-1} \sum_{i=1}^{n} w_i \mathbf{x}'_i \operatorname{Tr}\left(\left(\mathbf{X}'W\mathbf{X}\right)^{-1} \left[\mathbf{H}_i\right]\right)$$

where $\sigma^2 = \text{mse}$ if the SIGSQ option is not set. Otherwise, σ^2 is the value you set with the SIGSQ option. $\mathbf{W}$ is the diagonal weight matrix specified with the _WEIGHT_ variable (or the identity matrix if _WEIGHT_ is not defined) and $[\mathbf{H}_i]$ is the $(p \times p)$ Hessian matrix at the ith observation. In the case of unweighted least squares, the bias formula can be expressed in terms of the acceleration array $\mathbf{A}$,

$$\widehat{\mathrm{E}}\left[\widehat{\theta}_i - \theta_i\right] = -\frac{\sigma^2}{2p \times \text{mse}} \sum_{j,k=1}^{p} \mathbf{B}_{ij} \left[\mathbf{A}_j\right]_{kk}$$

As the preceeding formulas illustrate, the bias depends solely on the parameter-effects array, thereby permitting its reduction through reparameterization. Example 62.4 shows how changing the parameterization of a four-parameter logistic model can reduce the bias. Ratkowsky (1983, p. 21) recommends that you consider reparameterization if the percentage bias exceeds 1%.

Hougaard's Measure of Skewness

In addition to Box's bias, Hougaard's measure of skewness, g_{1i} (Hougaard 1982, 1985), is also provided in PROC NLIN to assess the close-to-linear behavior of parameter estimators. This measure is available

through the HOUGAARD option in the PROC NLIN statement. Hougaard's skewness measure for the ith parameter is based on the third central moment, defined as

$$\mathrm{E}\left[\widehat{\theta}_i - \mathrm{E}\left(\widehat{\theta}_i\right)\right]^3 = -\left(\sigma^2\right)^2 \sum_{jkl} [\mathbf{L}]_{ij}[\mathbf{L}]_{ik}[\mathbf{L}]_{il}\left(\left[\mathbf{V}_j\right]_{kl} + [\mathbf{V}_k]_{jl} + [\mathbf{V}_l]_{jk}\right)$$

where the sum is a triple sum over the number of parameters and

$$\mathbf{L} = \left(\mathbf{X}'\mathbf{X}\right)^{-1} = \left(\frac{\partial \mathbf{f}}{\partial \boldsymbol{\beta}'}\frac{\partial \mathbf{f}}{\partial \boldsymbol{\beta}}\right)^{-1}$$

The term $[\mathbf{L}]_{ij}$ denotes the value in row i, column j of the matrix $\mathbf{L}$. (Hougaard (1985) uses superscript notation to denote elements in this inverse.) The matrix $\mathbf{V}$ is a three-dimensional $(p \times p \times p)$ array

$$\left[\mathbf{V}_j\right]_{kl} = \sum_{m=1}^{n} \frac{\partial F_m}{\partial \beta_j}\frac{\partial^2 F_m}{\partial \beta_k \partial \beta_l}$$

The third central moment is then normalized using the standard error as

$$G_{1i} = \mathrm{E}\left[\widehat{\theta}_i - E(\widehat{\theta}_i)\right]^3 / \left(\sigma^2 \times [\mathbf{L}]_{ii}\right)^{3/2}$$

The previous expressions depend on the unknown values of the parameters and on the residual variance σ^2. In order to evaluate the Hougaard measure in a particular data set, the NLIN procedure computes

$$g_{1i} = \widehat{\mathrm{E}}\left[\widehat{\theta}_i - \mathrm{E}(\widehat{\theta}_i)\right]^3 / \left(\mathrm{mse} \times [\widehat{\mathbf{L}}]_{ii}\right)^{3/2}$$

$$\widehat{\mathrm{E}}\left[\widehat{\theta}_i - \mathrm{E}(\widehat{\theta}_i)\right]^3 = -\mathrm{mse}^2 \sum_{jkl} [\widehat{\mathbf{L}}]_{ij}[\widehat{\mathbf{L}}]_{ik}[\widehat{\mathbf{L}}]_{il}\left([\widehat{\mathbf{V}}_j]_{kl} + [\widehat{\mathbf{V}}_k]_{jl} + [\widehat{\mathbf{V}}_l]_{jk}\right)$$

Following Ratkowsky (1990, p. 28), the parameter θ_i is considered to be very close to linear, reasonably close, skewed, or quite nonlinear according to the absolute value of the Hougaard measure $|g_{1i}|$ being less than 0.1, between 0.1 and 0.25, between 0.25 and 1, or greater than 1, respectively.

Relative Curvature Measures of Nonlinearity

Bates and Watts (1980) formulated the maximum parameter-effects and maximum intrinsic curvature measures of nonlinearity to assess the close-to-linear behavior of nonlinear models. Ratkowsky (1990) notes that of the two curvature components in a nonlinear model, the parameter-effects curvature is typically larger. It is this component that you can affect by changing the parameterization of a model. PROC NLIN provides these two measures of curvature both through the STATS *plot-option* and through the NLINMEASURES option in the PROC NLIN statement.

The maximum parameter-effects and intrinsic curvatures are defined, in a compact form, as

$$\mathbf{T}^{\tau} = \max_{\theta}\left|\left|\theta' \mathbf{A}^{\tau} \theta\right|\right|$$

$$\mathbf{T}^{\eta} = \max_{\theta}\left|\left|\theta' \mathbf{A}^{\eta} \theta\right|\right|$$

where $\mathbf{T}^{\tau}$ and $\mathbf{T}^{\eta}$ denote the maximum parameter-effects and intrinsic curvatures, while $\mathbf{A}^{\tau}$ and $\mathbf{A}^{\eta}$ stand for the parameter-effects and intrinsic curvature arrays. The maximization is carried out over a unit-vector of the parameter values (Bates and Watts 1980). In line with Bates and Watts (1980), PROC NLIN takes 10^{-4} as the convergence tolerance for the maximum intrinsic and parameter-effects curvatures. Note that the preceeding matrix products involve contraction of the faces of the three-dimensional acceleration arrays with the normalized parameter vector, θ. The corresponding expressions for the RMS (root mean square) parameter-effects and intrinsic curvatures can be found in Bates and Watts (1980).

The statistical significance of $\mathbf{T}^{\tau}$ and $\mathbf{T}^{\eta}$ and the corresponding RMS values can be assessed by comparing these values with $1/\sqrt{F}$, where F is the upper $\alpha \times 100\%$ quantile of an F distribution with p and $n - p$ degrees of freedom (Bates and Watts 1980).

One motivation for fitting a nonlinear model in a different parameterization is to obtain a particular interpretation and to give parameter estimators more close-to-linear behavior. Example 62.4 shows how changing the parameterization of a four-parameter logistic model can reduce the parameter-effects curvature and can yield a useful parameter interpretation at the same time. In addition, Example 62.6 shows a nonlinear model with a high intrinsic curvature and the corresponding diagnostics.

Leverage in Nonlinear Regression

In contrast to linear regression, there are several measures of leverage in nonlinear regression. Furthermore, in nonlinear regression, the effect of a change in the ith response on the ith predicted value might depend on both the size of the change and the ith response itself (St. Laurent and Cook 1992). As a result, some observations might show superleverage —namely, leverages in excess of one (St. Laurent and Cook 1992).

PROC NLIN provides two measures of leverages: tangential and Jacobian leverages through the PLOTS option in the PROC NLIN statement and the H= and J= options of OUTPUT statement. Tangential leverage, $\mathbf{H}_i$, is based on approximating the nonlinear model with a linear model that parameterizes the tangent plane at the least squares parameter estimators. In contrast, Jacobian leverage, $\mathbf{J}_i$, is simply defined as the instantaneous rate of change in the ith predicted value with respect to the ith response (St. Laurent and Cook 1992).

The mathematical formulas for tangential and Jacobian leverages are

$$\mathbf{H}_i = w_i \mathbf{x}_i (\mathbf{X}'\mathbf{W}\mathbf{X})^{-1} \mathbf{x}_i'$$
$$\mathbf{J}_i = w_i \mathbf{x}_i (\mathbf{X}'\mathbf{W}\mathbf{X} - [\mathbf{W}\,\mathbf{e}][\mathbf{H}])^{-1} \mathbf{x}_i' \,,$$

where $\mathbf{e}$ is the vector of residuals, $\mathbf{W}$ is the diagonal weight matrix if you specify the special variable _WEIGHT_ and otherwise the identity matrix, and i indexes the corresponding quantities for the ith observation. The brackets [.][.] indicate column multiplication as defined in Bates and Watts (1980). The preceeding formula for tangential leverage holds if the gradient, Marquardt, or Gauss methods are used. For the Newton method, the tangential leverage is set equal to the Jacobian leverage.

In a model with a large intrinsic curvature, the Jacobian and tangential leverages can be very different. In fact, the two leverages are identical only if the model provides an exact fit to the data ($\mathbf{e} = 0$) or the model is intrinsically linear (St. Laurent and Cook 1993). This is also illustrated by the leverage plot and nonlinearity measures provided in Example 62.6.

Local Influence in Nonlinear Regression

St. Laurent and Cook (1993) suggest using $l_{\max}$, the direction that yields the maximum normal curvature, to assess the local influence of an additive perturbation to the response variable on the estimation of the parameters and variance of a nonlinear model. Defining the normal curvature components

$$\mathbf{C}_\theta = \max_l \frac{2}{\sigma^2} l'\mathbf{J}l$$
$$\mathbf{C}_\sigma = \max_l \frac{4}{\sigma^2} l'\mathbf{P}_e l$$

where $\mathbf{J}$ is the Jacobian leverage matrix and $\mathbf{P}_e = \mathbf{e}\mathbf{e}'/(\mathbf{e}'\mathbf{e})$, you choose the $l_{\max}$ that results in the maximum of the two curvature components (St. Laurent and Cook 1993). PROC NLIN provides $l_{\max}$ through the PLOTS option in the PROC NLIN statement and the LMAX= option in the OUTPUT statement. Example 62.6 shows a plot of $l_{\max}$ for a model with high intrinsic curvature.

Residuals in Nonlinear Regression

If a nonlinear model is intrinsically nonlinear, using the residuals $\mathbf{e} = \mathbf{y} - \hat{\mathbf{y}}$ for diagnostics can be misleading (Cook and Tsai 1985). This is due to the fact that in correctly specified intrinsically nonlinear models, the residuals have nonzero means and different variances, even when the original error terms have identical variances. Furthermore, the covariance between the residuals and the predicted values tends to be negative semidefinite, complicating the interpretation of plots based on $\mathbf{e}$ (Cook and Tsai 1985).

Projected residuals are proposed by Cook and Tsai (1985) to overcome these shortcomings of residuals, which are henceforth called raw (ordinary) residuals to differentiate them from their projected counterparts. Projected residuals have zero means and are uncorrelated with the predicted values. In fact, projected residuals are identical to the raw residuals in intrinsically linear models.

PROC NLIN provides raw and projected residuals, along with their standardized forms. In addition, the mean or expectation of the raw residuals is available. These can be accessed with the PLOTS option in the PROC NLIN statement and the OUTPUT statement options PROJRES=, PROJSTUDENT=, RESEXPEC=, RESIDUAL= and STUDENT=.

Denote the projected residuals by $\mathbf{e}_p$ and the expectation of the raw residuals by E[$\mathbf{e}$]. Then

$$\mathbf{e}_p = (I_n - \mathbf{P}_{xh})\,\mathbf{e}$$
$$\mathrm{E}[\mathbf{e}_i] = -\frac{\sigma^2}{2} \sum_{j=1}^{n} \tilde{\mathbf{P}}_{x,ij} \mathrm{Tr}\left([\mathbf{H}_j] \left(\mathbf{X}'\mathbf{X}\right)^{-1} \right)$$

where $\mathbf{e}_i$ is the ith observation raw residual, I_n is an n-dimensional identity matrix, $\mathbf{P}_{xh}$ is the projector onto the column space of $(\mathbf{X}|\mathbf{H})$, and $\tilde{\mathbf{P}}_x = I_n - \mathbf{P}_x$. The preceeding formulas are general with the projectors defined accordingly to take the weighting into consideration. In unweighted least squares, E[$\mathbf{e}$] reduces to

$$\mathrm{E}[\mathbf{e}] = -\frac{1}{2}\sigma^2 \tilde{\mathbf{Q}}\,\mathbf{a}$$

with $\tilde{\mathbf{Q}}$ being the last $n - p$ columns of the $\mathbf{Q}$ matrix in the QR decomposition of X and the $(n - p)$ dimensional vector $\mathbf{a}$ being defined in terms of the intrinsic acceleration array

$$\mathbf{a}_i = \sum_{j=1}^{p} \left[\mathbf{A}_{i+p}\right]_{jj}$$

Standardization of the projected residuals requires the variance of the projected residuals. This is estimated using the formula (Cook and Tsai 1985)

$$\sigma_p^2 = \frac{\mathbf{e}_p' \mathbf{e}_p}{\mathrm{Tr}\left(I_n - \mathbf{P}_{xh}\right)}$$

The standardized raw and projected residuals, denoted by $\tilde{\mathbf{e}}$ and $\tilde{\mathbf{e}}_p$ respectively, are given by

$$\tilde{\mathbf{e}} = \frac{\sqrt{w_i}\,\mathbf{e}}{\sigma\sqrt{1 - \mathbf{P}_{x,ii}}}$$
$$\tilde{\mathbf{e}}_p = \frac{\sqrt{w_i}\,\mathbf{e}_p}{\sigma\sqrt{1 - \mathbf{P}_{xh,ii}}}$$

The use of raw and projected residuals for diagnostics in nonlinear regression is illustrated in Example 62.6.

Missing Values

If the value of any one of the SAS variables involved in the model is missing from an observation, that observation is omitted from the analysis. If only the value of the dependent variable is missing, that observation has a predicted value calculated for it when you use an OUTPUT statement and specify the PREDICTED= option.

If an observation includes a missing value for one of the independent variables, both the predicted value and the residual value are missing for that observation. If the iterations fail to converge, the values for all variables named in the OUTPUT statement are set to missing.

Special Variables

Several special variables are created automatically and can be used in PROC NLIN programming statements.

Special Variables with Values That Are Set by PROC NLIN

The values of the following six special variables are set by PROC NLIN and should not be reset to a different value by programming statements:

ERROR is set to 1 if a numerical error or invalid argument to a function occurs during the current execution of the program. It is reset to 0 before each new execution.

ITER represents the current iteration number. The variable _ITER_ is set to −1 during the grid search phase.

MODEL is set to 1 for passes through the data when only the predicted values are needed, and not the derivatives. It is 0 when both predicted values and derivatives are needed. If your derivative calculations consume a lot of time, you can save resources by using the following statement after your MODEL statement but before your derivative calculations:

```
if _model_ then return;
```

The derivatives generated by PROC NLIN do this automatically.

_N_ indicates the number of times the PROC NLIN step has been executed. It is never reset for successive passes through the data set.

OBS indicates the observation number in the data set for the current program execution. It is reset to 1 to start each pass through the data set (unlike the _N_ variable).

SSE has the error sum of squares of the last iteration. During the grid search phase, the _SSE_ variable is set to 0. For iteration 0, the _SSE_ variable is set to the SSE associated with the point chosen from the grid search.

Special Variable Used to Determine Convergence Criteria

The special variable _LOSS_ can be used to determine the criterion function for convergence and step shortening. PROC NLIN looks for the variable _LOSS_ in the programming statements and, if it is defined, uses the (weighted) sum of this value instead of the residual sum of squares to determine the criterion function for convergence and step shortening. This feature is useful in certain types of maximum-likelihood estimation.

CAUTION: Even if you specify the _LOSS_ variable in your programming statements, the NLIN procedure continues to solve a least squares problem. The specified _LOSS_ function does **not** define or alter the objective function for parameter estimation.

Weighted Regression with the Special Variable _WEIGHT_

To obtain weighted nonlinear least squares estimates of parameters, make an assignment to the _WEIGHT_ variable as in the following statement:

```
_weight_ = expression;
```

When this statement is included, the expression on the right side of the assignment statement is evaluated for each observation in the data set. The values multiplied by $1/\sigma^2$ are then taken as inverse elements of the diagonal variance-covariance matrix of the dependent variable.

When a variable name is given after the equal sign, the values of the variable are taken as the inverse elements of the variance-covariance matrix. The larger the _WEIGHT_ value, the more importance the observation is given.

The _WEIGHT_ variable can be a function of the estimated parameters. For estimation purposes, the derivative of the _WEIGHT_ variable with respect to the parameters is not included in the gradient and the Hessian of the loss function. This is normally the desired approach for iteratively reweighted least squares estimation. When the _WEIGHT_ variable is a function of the parameters, the gradient and the Hessian used can lead to poor convergence or nonconvergence of the requested estimation. To have the derivative of the _WEIGHT_ variable with respect to the parameters included in the gradient and the Hessian of the loss function, do not use the _WEIGHT_ variable. Instead, redefine the model as

$$(y - f(x, \beta)) \times \sqrt{wgt(\beta)}$$

where y is the original dependent variable, $f(x, \beta)$ is the nonlinear model, and $wgt(\beta)$ is the weight that is a function of the parameters.

If the _WEIGHT_= statement is not used, the default value of 1 is used, and regular least squares estimates are obtained.

Troubleshooting

This section describes a number of problems that might occur in your analysis with PROC NLIN.

Excessive Computing Time

If you specify a grid of starting values that contains many points, the analysis might take excessive time since the procedure must go through the entire data set for each point on the grid.

The analysis might also take excessive time if your problem takes many iterations to converge, since each iteration requires as much time as a linear regression with predicted values and residuals calculated.

Dependencies

The matrix of partial derivatives can be singular, possibly indicating an overparameterized model. For example, if b0 starts at zero in the following model, the derivatives for b1 are all zero for the first iteration:

```
parms b0=0 b1=.022;
model pop=b0*exp(b1*(year-1790));
der.b0=exp(b1*(year-1790));
der.b1=(year-1790)*b0*exp(b1*(year-1790));
```

The first iteration changes a subset of the parameters; then the procedure can make progress in succeeding iterations. This singularity problem is local. The next example displays a global problem. The term b2 in the exponent is not identifiable since it trades roles with b0.

```
parms b0=3.9 b1=.022 b2=0;
model pop=b0*exp(b1*(year-1790)+b2);
der.b0 = exp(b1*(year-1790)+b2);
der.b1 = (year-1790)*b0*exp(b1*(year-1790)+b2);
der.b2 = b0*exp(b1*(year-1790)+b2);
```

Unable to Improve

The method can lead to steps that do not improve the estimates even after a series of step halvings. If this happens, the procedure issues a message stating that it is unable to make further progress, but it then displays the following warning message:

```
PROC NLIN failed to converge
```

Then it displays the results. This often means that the procedure has not converged at all. If you provided your own derivatives, check them carefully and then examine the residual sum of squares surface. If PROC NLIN has not converged, try a different set of starting values, a different METHOD= specification, the G4 option, or a different model.

Divergence

The iterative process might diverge, resulting in overflows in computations. It is also possible that parameters enter a space where arguments to such functions as LOG and SQRT become invalid. For example, consider the following model:

```
parms b=0;
model y = x / b;
```

Suppose that y contains only zeros, and suppose that the values for variable x are not zero. There is no least squares estimate for b since the SSE declines as b approaches infinity or minus infinity. To avoid the problem, the same model could be parameterized as `y = a*x`.

If you have divergence problems, try reparameterizing the model, selecting different starting values, increasing the maximum allowed number of iterations (the MAXITER= option), specifying an alternative METHOD= option, or including a BOUNDS statement.

Local Minimum

The program might converge to a local rather than a global minimum. For example, consider the following model:

```
parms a=1 b=-1;
model y=(1-a*x)*(1-b*x);
```

Once a solution is found, an equivalent solution with the same SSE can be obtained by swapping the values of a and b.

Discontinuities

The computational methods assume that the model is a continuous and smooth function of the parameters. If this is not true, the method does not work. For example, the following models do not work:

```
model y=a+int(b*x);

model y=a+b*x+4*(z>c);
```

Responding to Trouble

PROC NLIN does not necessarily produce a good solution the first time. Much depends on specifying good initial values for the parameters. You can specify a grid of values in the PARMS statement to search for good starting values. While most practical models should give you no trouble, other models can require switching to a different iteration method or a different computational method for matrix inversion. Specifying the option METHOD=MARQUARDT sometimes works when the default method (Gauss-Newton) does not work.

Computational Methods

Nonlinear Least Squares

Recall the basic notation for the nonlinear regression model from the section "Notation for Nonlinear Regression Models" on page 5093. The parameter vector $\boldsymbol{\beta}$ belongs to $\boldsymbol{\Omega}$, a subset of R^p. Two points of this set are of particular interest: the true value $\widetilde{\boldsymbol{\beta}}$ and the least squares estimate $\widehat{\boldsymbol{\beta}}$. The general nonlinear model fit with the NLIN procedure is represented by the equation

$$\mathbf{Y} = \mathbf{f}(\widetilde{\beta_0}, \widetilde{\beta_1}, \ldots, \widetilde{\beta_p}; \mathbf{z}_1, \mathbf{z}_2, \ldots, \mathbf{z}_k) + \boldsymbol{\epsilon} = \mathbf{f}(\widetilde{\boldsymbol{\beta}}; \mathbf{z}_1, \mathbf{z}_2, \ldots, \mathbf{z}_k) + \boldsymbol{\epsilon}$$

where $\mathbf{z}_j$ denotes the $(n \times 1)$ vector of the jth regressor (independent) variable, $\widetilde{\boldsymbol{\beta}}$ is the true value of the parameter vector, and $\boldsymbol{\epsilon}$ is the $(n \times 1)$ vector of homoscedastic and uncorrelated model errors with zero mean.

To write the model for the ith observation, the ith elements of $\mathbf{z}_1, \cdots, \mathbf{z}_k$ are collected in the row vector $\mathbf{z}_i'$, and the model equation becomes

$$Y_i = f(\boldsymbol{\beta}; \mathbf{z}_i') + \epsilon_i$$

The shorthand $f_i(\boldsymbol{\beta})$ will also be used throughout to denote the mean of the ith observation.

For any given value $\boldsymbol{\beta}$ we can compute the residual sum of squares

$$\begin{aligned} \text{SSE}(\boldsymbol{\beta}) &= \sum_{i=1}^{n} \left(y_i - f\left(\boldsymbol{\beta}; \mathbf{z}_i'\right)\right)^2 \\ &= \sum_{i=1}^{n} \left(y_i - f_i\left(\boldsymbol{\beta}\right)\right)^2 = \mathbf{r}(\boldsymbol{\beta})'\mathbf{r}(\boldsymbol{\beta}) \end{aligned}$$

The aim of nonlinear least squares estimation is to find the value $\widehat{\boldsymbol{\beta}}$ that minimizes $\text{SSE}(\boldsymbol{\beta})$. Because $\mathbf{f}$ is a nonlinear function of $\boldsymbol{\beta}$, a closed-form solution does not exist for this minimization problem. An iterative process is used instead. The iterative techniques that PROC NLIN uses are similar to a series of linear regressions involving the matrix $\mathbf{X}$ and the residual vector $\mathbf{r} = \mathbf{y} - \mathbf{f}(\boldsymbol{\beta})$, evaluated at the current values of $\boldsymbol{\beta}$.

It is more insightful, however, to describe the algorithms in terms of their approach to minimizing the residual sum of squares and in terms of their updating formulas. If $\widehat{\boldsymbol{\beta}}^{(u)}$ denotes the value of the parameter estimates at the uth iteration, and $\widehat{\boldsymbol{\beta}}^{(0)}$ are your starting values, then the NLIN procedure attempts to find values k and $\boldsymbol{\Delta}$ such that

$$\widehat{\boldsymbol{\beta}}^{(u+1)} = \widehat{\boldsymbol{\beta}}^{(u)} + k\boldsymbol{\Delta}$$

and

$$\text{SSE}\left(\widehat{\boldsymbol{\beta}}^{(u+1)}\right) < \text{SSE}\left(\widehat{\boldsymbol{\beta}}^{(u)}\right)$$

The various methods to fit a nonlinear regression model—which you can select with the METHOD= option in the PROC NLIN statement—differ in the calculation of the update vector $\boldsymbol{\Delta}$.

The gradient and Hessian of the residual sum of squares with respect to individual parameters and pairs of parameters are, respectively,

$$\mathbf{g}(\beta_j) = \frac{\partial \text{SSE}(\boldsymbol{\beta})}{\partial \beta_j} = -2\sum_{i=1}^{n}(y_i - f_i(\boldsymbol{\beta}))\,\frac{\partial f_i(\boldsymbol{\beta})}{\partial \beta_j}$$

$$[\mathbf{H}(\boldsymbol{\beta})]_{jk} = \frac{\partial \text{SSE}(\boldsymbol{\beta})}{\partial \beta_j \partial \beta_k} = 2\sum_{i=1}^{n}\frac{\partial f_i(\boldsymbol{\beta})}{\partial \beta_j}\frac{\partial f_i(\boldsymbol{\beta})}{\partial \beta_k} - (y_i - f_i(\boldsymbol{\beta}))\,\frac{\partial^2 f_i(\boldsymbol{\beta})}{\partial \beta_j \partial \beta_k}$$

Denote as $\mathbf{H}_i^*(\boldsymbol{\beta})$ the Hessian matrix of the mean function,

$$\left[\mathbf{H}_i^*(\boldsymbol{\beta})\right]_{jk} = \left[\frac{\partial^2 f_i(\boldsymbol{\beta})}{\partial \beta_j \partial \beta_k}\right]_{jk}$$

Collecting the derivatives across all parameters leads to the expressions

$$\mathbf{g}(\boldsymbol{\beta}) = \frac{\partial \text{SSE}(\boldsymbol{\beta})}{\partial \boldsymbol{\beta}} = -2\mathbf{X}'\mathbf{r}(\boldsymbol{\beta})$$

$$\mathbf{H}(\boldsymbol{\beta}) = \frac{\partial^2 \text{SSE}(\boldsymbol{\beta})}{\partial \boldsymbol{\beta}\partial \boldsymbol{\beta}'} = 2\left(\mathbf{X}'\mathbf{X} - \sum_{i=1}^{n} r_i(\boldsymbol{\beta})\mathbf{H}_i^*(\boldsymbol{\beta})\right)$$

The change in the vector of parameter estimates is computed as follows, depending on the estimation method:

$$\text{Gauss-Newton: } \boldsymbol{\Delta} = (-\text{E}[\mathbf{H}(\boldsymbol{\beta})])^{-}\,\mathbf{g}(\boldsymbol{\beta}) = (\mathbf{X}'\mathbf{X})^{-}\mathbf{X}'\mathbf{r}$$

$$\text{Marquardt: } \boldsymbol{\Delta} = \left(\mathbf{X}'\mathbf{X} + \lambda\,\text{diag}(\mathbf{X}'\mathbf{X})\right)^{-}\mathbf{X}'\mathbf{r}$$

$$\text{Newton: } \boldsymbol{\Delta} = -\mathbf{H}(\boldsymbol{\beta})^{-}\mathbf{g}(\boldsymbol{\beta}) = \mathbf{H}(\boldsymbol{\beta})^{-}\mathbf{X}'\mathbf{r}$$

$$\text{Steepest descent: } \boldsymbol{\Delta} = -\frac{1}{2}\frac{\partial \text{SSE}(\boldsymbol{\beta})}{\partial \boldsymbol{\beta}} = \mathbf{X}'\mathbf{r}$$

The Gauss-Newton and Marquardt iterative methods regress the residuals onto the partial derivatives of the model with respect to the parameters until the estimates converge. You can view the Marquardt algorithm as a Gauss-Newton algorithm with a ridging penalty. The Newton iterative method regresses the residuals onto a function of the first and second derivatives of the model with respect to the parameters until the estimates converge. Analytical first- and second-order derivatives are automatically computed as needed.

The default method used to compute $(\mathbf{X}'\mathbf{X})^{-}$ is the sweep (Goodnight 1979). It produces a reflexive generalized inverse (a g_2-inverse, Pringle and Rayner, 1971). In some cases it might be preferable to use a Moore-Penrose inverse (a g_4-inverse) instead. If you specify the G4 option in the PROC NLIN statement, a g_4-inverse is used to calculate $\boldsymbol{\Delta}$ on each iteration.

The four algorithms are now described in greater detail.

Algorithmic Details

Gauss-Newton and Newton Methods

From the preceding set of equations you can see that the Marquardt method is a ridged version of the Gauss-Newton method. If the ridge parameter λ equals zero, the Marquardt step is identical to the Gauss-Newton step. An important difference between the Newton methods and the Gauss-Newton-type algorithms lies in the use of second derivatives. To motivate this distinctive element between Gauss-Newton and the Newton method, focus first on the objective function in nonlinear least squares. To numerically find the minimum of

$$\text{SSE}(\boldsymbol{\beta}) = \mathbf{r}(\boldsymbol{\beta})'\mathbf{r}(\boldsymbol{\beta})$$

you can approach the problem by approximating the sum of squares criterion by a criterion for which you can compute a closed-form solution. Following Seber and Wild (1989, Sect. 2.1.3), we can achieve that by doing the following:

- approximating the model and substituting the approximation into $\text{SSE}(\boldsymbol{\beta})$
- approximating $\text{SSE}(\boldsymbol{\beta})$ directly

The first method, approximating the nonlinear model with a first-order Taylor series, is the purview of the Gauss-Newton method. Approximating the residual sum of squares directly is the realm of the Newton method.

The first-order Taylor series of the residual $\mathbf{r}(\boldsymbol{\beta})$ at the point $\widehat{\boldsymbol{\beta}}$ is

$$\mathbf{r}(\boldsymbol{\beta}) \approx \mathbf{r}(\widehat{\boldsymbol{\beta}}) - \widehat{\mathbf{X}}\left(\boldsymbol{\beta} - \widehat{\boldsymbol{\beta}}\right)$$

Substitution into $\text{SSE}(\boldsymbol{\beta})$ leads to the objective function for the Gauss-Newton step:

$$\text{SSE}\,(\boldsymbol{\beta}) \approx S_G(\boldsymbol{\beta}) = \mathbf{r}(\widehat{\boldsymbol{\beta}})' - 2\mathbf{r}'(\widehat{\boldsymbol{\beta}})\widehat{\mathbf{X}}\left(\boldsymbol{\beta} - \widehat{\boldsymbol{\beta}}\right) + \left(\boldsymbol{\beta} - \widehat{\boldsymbol{\beta}}\right)'\left(\widehat{\mathbf{X}}'\widehat{\mathbf{X}}\right)\left(\boldsymbol{\beta} - \widehat{\boldsymbol{\beta}}\right)$$

"Hat" notation is used here to indicate that the quantity in question is evaluated at $\widehat{\boldsymbol{\beta}}$.

To motivate the Newton method, take a second-order Taylor series of $\text{SSE}(\boldsymbol{\beta})$ around the value $\widehat{\boldsymbol{\beta}}$:

$$\text{SSE}\,(\boldsymbol{\beta}) \approx S_N(\boldsymbol{\beta}) = \text{SSE}\left(\widehat{\boldsymbol{\beta}}\right) + \mathbf{g}(\widehat{\boldsymbol{\beta}})'\left(\boldsymbol{\beta} - \widehat{\boldsymbol{\beta}}\right) + \frac{1}{2}\left(\boldsymbol{\beta} - \widehat{\boldsymbol{\beta}}\right)'\mathbf{H}(\widehat{\boldsymbol{\beta}})\left(\boldsymbol{\beta} - \widehat{\boldsymbol{\beta}}\right)$$

Both $S_G(\boldsymbol{\beta})$ and $S_N(\boldsymbol{\beta})$ are quadratic functions in $\boldsymbol{\beta}$ and are easily minimized. The minima occur when

$$\text{Gauss-Newton: } \boldsymbol{\beta} - \widehat{\boldsymbol{\beta}} = \left(\widehat{\mathbf{X}}'\widehat{\mathbf{X}}\right)^{-}\widehat{\mathbf{X}}'\mathbf{r}(\widehat{\boldsymbol{\beta}})$$

$$\text{Newton : } \boldsymbol{\beta} - \widehat{\boldsymbol{\beta}} = -\mathbf{H}(\widehat{\boldsymbol{\beta}})^{-}\mathbf{g}(\widehat{\boldsymbol{\beta}})$$

and these terms define the preceding $\boldsymbol{\Delta}$ update vectors.

Gauss-Newton Method

Since the Gauss-Newton method is based on an approximation of the model, you can also derive the update vector by first considering the "normal" equations of the nonlinear model

$$\mathbf{X}'\mathbf{f}(\boldsymbol{\beta}) = \mathbf{X}'\mathbf{Y}$$

and then substituting the Taylor approximation

$$\mathbf{f}(\boldsymbol{\beta}) \approx \mathbf{f}(\widehat{\boldsymbol{\beta}}) + \mathbf{X}\left(\boldsymbol{\beta} - \widehat{\boldsymbol{\beta}}\right)$$

for $\mathbf{f}(\boldsymbol{\beta})$. This leads to

$$\begin{aligned}
\mathbf{X}'\left(\mathbf{f}(\widehat{\boldsymbol{\beta}}) + \mathbf{X}(\boldsymbol{\beta} - \widehat{\boldsymbol{\beta}})\right) &= \mathbf{X}'\mathbf{Y} \\
(\mathbf{X}'\mathbf{X})(\boldsymbol{\beta} - \widehat{\boldsymbol{\beta}}) &= \mathbf{X}'\mathbf{Y} - \mathbf{X}'\mathbf{f}(\widehat{\boldsymbol{\beta}}) \\
(\mathbf{X}'\mathbf{X})\boldsymbol{\Delta} &= \mathbf{X}'\mathbf{r}(\widehat{\boldsymbol{\beta}})
\end{aligned}$$

and the update vector becomes

$$\boldsymbol{\Delta} = \left(\mathbf{X}'\mathbf{X}\right)^{-}\mathbf{X}'\mathbf{r}(\widehat{\boldsymbol{\beta}})$$

CAUTION: If $\mathbf{X}'\mathbf{X}$ is singular or becomes singular, PROC NLIN computes $\boldsymbol{\Delta}$ by using a generalized inverse for the iterations after singularity occurs. If $\mathbf{X}'\mathbf{X}$ is still singular for the last iteration, the solution should be examined.

Newton Method

The Newton method uses the second derivatives and solves the equation

$$\boldsymbol{\Delta} = \mathbf{H}^{-}\mathbf{X}'\mathbf{r}$$

If the automatic variables _WEIGHT_, _WGTJPJ_, and _RESID_ are used, then

$$\boldsymbol{\Delta} = \mathbf{H}^{-}\mathbf{X}'\mathbf{W}^{SSE}\mathbf{r}^{*}$$

is the direction, where

$$\mathbf{H} = \mathbf{X}'\mathbf{W}^{XPX}\mathbf{X} - \sum_{i=1}^{n}\mathbf{H}_i^{*}(\boldsymbol{\beta})w_i^{XPX}r_i^{*}$$

and

$\mathbf{W}^{SSE}$ is an $n \times n$ diagonal matrix with elements w_i^{SSE} of weights from the _WEIGHT_ variable. Each element w_i^{SSE} contains the value of _WEIGHT_ for the ith observation.

$\mathbf{W}^{XPX}$ is an $n \times n$ diagonal matrix with elements w_i^{XPX} of weights from the _WGTJPJ_ variable. Each element w_i^{XPX} contains the value of _WGTJPJ_ for the ith observation.

$\mathbf{r}^{*}$ is a vector with elements r_i^{*} from the _RESID_ variable. Each element r_i^{*} contains the value of _RESID_ evaluated for the ith observation.

Marquardt Method

The updating formula for the Marquardt method is as follows:

$$\mathbf{\Delta} = (\mathbf{X}'\mathbf{X} + \lambda \text{diag}(\mathbf{X}'\mathbf{X}))^{-}\mathbf{X}'\mathbf{e}$$

The Marquardt method is a compromise between the Gauss-Newton and steepest descent methods (Marquardt 1963). As $\lambda \to 0$, the direction approaches Gauss-Newton. As $\lambda \to \infty$, the direction approaches steepest descent.

Marquardt's studies indicate that the average angle between Gauss-Newton and steepest descent directions is about 90°. A choice of λ between 0 and infinity produces a compromise direction.

By default, PROC NLIN chooses $\lambda = 10^{-7}$ to start and computes $\mathbf{\Delta}$. If $\text{SSE}(\boldsymbol{\beta}_0 + \mathbf{\Delta}) < \text{SSE}(\boldsymbol{\beta}_0)$, then $\lambda = \lambda/10$ for the next iteration. Each time $\text{SSE}(\boldsymbol{\beta}_0 + \mathbf{\Delta}) > \text{SSE}(\boldsymbol{\beta}_0)$, then $\lambda = 10\lambda$.

NOTE: If the SSE decreases on each iteration, then $\lambda \to 0$, and you are essentially using the Gauss-Newton method. If SSE does not improve, then λ is increased until you are moving in the steepest descent direction.

Marquardt's method is equivalent to performing a series of ridge regressions, and it is useful when the parameter estimates are highly correlated or the objective function is not well approximated by a quadratic.

Steepest Descent (Gradient) Method

The steepest descent method is based directly on the gradient of $0.5\mathbf{r}(\boldsymbol{\beta})'\mathbf{r}(\boldsymbol{\beta})$:

$$\frac{1}{2}\frac{\partial \text{SSE}(\boldsymbol{\beta})}{\partial \boldsymbol{\beta}} = -\mathbf{X}'\mathbf{r}$$

The quantity $-\mathbf{X}'\mathbf{r}$ is the gradient along which $\boldsymbol{\epsilon}'\boldsymbol{\epsilon}$ increases. Thus $\mathbf{\Delta} = \mathbf{X}'\mathbf{r}$ is the direction of steepest descent.

If the automatic variables _WEIGHT_ and _RESID_ are used, then

$$\mathbf{\Delta} = \mathbf{X}'\mathbf{W}^{SSE}\mathbf{r}^*$$

is the direction, where

$\mathbf{W}^{SSE}$ is an $n \times n$ diagonal matrix with elements w_i^{SSE} of weights from the _WEIGHT_ variable. Each element w_i^{SSE} contains the value of _WEIGHT_ for the ith observation.

$\mathbf{r}^*$ is a vector with elements r_i^* from _RESID_. Each element r_i^* contains the value of _RESID_ evaluated for the ith observation.

Using the method of steepest descent, let

$$\boldsymbol{\beta}^{(k+1)} = \boldsymbol{\beta}^{(k)} + \alpha\mathbf{\Delta}$$

where the scalar α is chosen such that

$$\text{SSE}(\boldsymbol{\beta}_i + \alpha\mathbf{\Delta}) < \text{SSE}(\boldsymbol{\beta}_i)$$

CAUTION: The steepest-descent method can converge very slowly and is therefore not generally recommended. It is sometimes useful when the initial values are poor.

Step-Size Search

The default method of finding the step size k is step halving by using SMETHOD=HALVE. If SSE($\boldsymbol{\beta}^{(u)} + \boldsymbol{\Delta}$) > SSE($\boldsymbol{\beta}^{(u)}$), compute SSE($\boldsymbol{\beta}^{(u)} + 0.5\boldsymbol{\Delta}$), SSE($\boldsymbol{\beta}^{(u)} + 0.25\boldsymbol{\Delta}$), . . . , until a smaller SSE is found.

If you specify SMETHOD=GOLDEN, the step size k is determined by a golden section search. The parameter TAU determines the length of the initial interval to be searched, with the interval having length TAU (or 2 × TAU), depending on SSE($\boldsymbol{\beta}^{(u)} + \boldsymbol{\Delta}$). The RHO parameter specifies how fine the search is to be. The SSE at each endpoint of the interval is evaluated, and a new subinterval is chosen. The size of the interval is reduced until its length is less than RHO. One pass through the data is required each time the interval is reduced. Hence, if RHO is very small relative to TAU, a large amount of time can be spent determining a step size. For more information about the golden section search, see Kennedy and Gentle (1980).

If you specify SMETHOD=CUBIC, the NLIN procedure performs a cubic interpolation to estimate the step size. If the estimated step size does not result in a decrease in SSE, step halving is used.

Output Data Sets

The data set produced by the OUTEST= option in the PROC NLIN statement contains the parameter estimates on each iteration, including the grid search.

The variable _ITER_ contains the iteration number. The variable _TYPE_ denotes whether the observation contains iteration parameter estimates ("ITER"), final parameter estimates ("FINAL"), or covariance estimates ("COVB"). The variable _NAME_ contains the parameter name for covariances, and the variable _SSE_ contains the objective function value for the parameter estimates. The variable _STATUS_ indicates whether the estimates have converged.

The data set produced by the OUTPUT statement contains statistics calculated for each observation. In addition, the data set contains the variables from the input data set and any ID variables that are specified in the ID statement.

Confidence Intervals

Parameter Confidence Intervals

The parameter confidence intervals are computed using the Wald-based formula:

$$\widehat{\beta}_i \pm \text{stderr}_i \times t(n-p, 1-\alpha/2)$$

where $\widehat{\beta}_i$ is the ith parameter estimate, stderr_i is its estimated approximate standard error, $t(n-p, 1-\alpha/2)$ is a t statistic with $n-p$ degrees of freedom, n is the number of observations, and p is the number of parameters. The confidence intervals are only asymptotically valid. The significance level α used in the construction of these confidence limits can be set with the ALPHA= option in the PROC NLIN statement; the default value is $\alpha = 0.05$.

Model Confidence Intervals

Model confidence intervals are output when an OUT= data set is specified and one or more of the keywords LCLM, UCLM, LCL, UCL, L95M=, U95M=, L95=, and U95= is specified. The expressions for these terms are as follows:

$$\begin{aligned}
\text{LCLM} &= f(\boldsymbol{\beta}, \mathbf{z}_i) - \sqrt{MSE \times h_i / w_i} \times t(n-p, 1-\alpha/2) \\
\text{UCLM} &= f(\boldsymbol{\beta}, \mathbf{z}_i) + \sqrt{MSE \times h_i / w_i} \times t(n-p, 1-\alpha/2) \\
\text{LCL} &= f(\boldsymbol{\beta}, \mathbf{z}_i) - \sqrt{MSE(h_i + 1/w_i)} \times t(n-p, 1-\alpha/2) \\
\text{UCL} &= f(\boldsymbol{\beta}, \mathbf{z}_i) + \sqrt{MSE(h_i + 1/w_i)} \times t(n-p, 1-\alpha/2) \\
\text{L95M} &= f(\boldsymbol{\beta}, \mathbf{z}_i) - \sqrt{MSE \times h_i / w_i} \times t(n-p, 1-0.05/2) \\
\text{U95M} &= f(\boldsymbol{\beta}, \mathbf{z}_i) + \sqrt{MSE \times h_i / w_i} \times t(n-p, 1-0.05/2) \\
\text{L95} &= f(\boldsymbol{\beta}, \mathbf{z}_i) - \sqrt{MSE(h_i + 1/w_i)} \times t(n-p, 1-0.05/2) \\
\text{U95} &= f(\boldsymbol{\beta}, \mathbf{z}_i) + \sqrt{MSE(h_i + 1/w_i)} \times t(n-p, 1-0.05/2)
\end{aligned}$$

where $h_i = w_i \mathbf{x}_i (\mathbf{X}'\mathbf{W}\mathbf{X})^{-1} \mathbf{x}_i'$ is the leverage, $\mathbf{X} = \partial \mathbf{f} / \partial \boldsymbol{\beta}$, and $\mathbf{x}_i$ is the ith row of $\mathbf{X}$. These results are derived for linear systems. The intervals are approximate for nonlinear models. The value α in the preceding formulas for LCLM, UCLM, LCL, and UCL can be set with the ALPHA= option in the PROC NLIN statement or with the ALPHA= option in the OUTPUT statement. If both ALPHA= options are specified, the option in the OUTPUT takes precedence.

Covariance Matrix of Parameter Estimates

For unconstrained estimates (no active bounds), the covariance matrix of the parameter estimates is

$$\text{mse} \times (\mathbf{X}'\mathbf{X})^{-1}$$

for the gradient, Marquardt, and Gauss methods and

$$\text{mse} \times \mathbf{H}^{-1}$$

for the Newton method. Recall that $\mathbf{X}$ is the matrix of the first partial derivatives of the nonlinear model with respect to the parameters. The matrices are evaluated at the final parameter estimates. The mean squared error, the estimate of the residual variance σ^2, is computed as

$$\text{mse} = \mathbf{r}'\mathbf{r} / (n-p)$$

where n is the number of nonmissing (used) observations and p is the number of estimable parameters. The standard error reported for the parameter estimates is the square root of the corresponding diagonal element of this matrix. If you specify a value for the residual variance with the SIGSQ= option, then that value replaces mse in the preceding expressions.

Now suppose that restrictions or bounds are active. Equality restrictions can be written as a vector function, $h(\boldsymbol{\theta}) = \mathbf{0}$. Inequality restrictions are either active or inactive. When an inequality restriction is active, it is treated as an equality restriction.

Assume that the vector $h(\boldsymbol{\theta})$ contains the current active restrictions. The constraint matrix $\mathbf{A}$ is then

$$\mathbf{A}(\widehat{\boldsymbol{\theta}}) = \frac{\partial h(\widehat{\boldsymbol{\theta}})}{\partial \widehat{\boldsymbol{\theta}}}$$

The covariance matrix for the restricted parameter estimates is computed as

$$\mathbf{Z}(\mathbf{Z}'\mathbf{H}\mathbf{Z})^{-1}\mathbf{Z}'$$

where $\mathbf{H}$ is the Hessian (or approximation to the Hessian) and $\mathbf{Z}$ collects the last $(p-n_c)$ columns of $\mathbf{Q}$ from an LQ factorization of the constraint matrix. Further, n_c is the number of active constraints, and p denotes the number of parameters. See Gill, Murray, and Wright (1981) for more details about the LQ factorization. The covariance matrix for the Lagrange multipliers is computed as

$$\left(\mathbf{A}\mathbf{H}^{-1}\mathbf{A}'\right)^{-1}$$

Convergence Measures

The NLIN procedure computes and reports four convergence measures, labeled R, PPC, RPC, and OBJECT.

R is the primary convergence measure for the parameters. It measures the degree to which the residuals are orthogonal to the columns of $\mathbf{X}$, and it approaches 0 as the gradient of the objective function becomes small. R is defined as

$$\sqrt{\frac{\mathbf{r}'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{r}}{\text{LOSS}^i}}$$

PPC is the prospective parameter change measure. PPC measures the maximum relative change in the parameters implied by the parameter-change vector computed for the next iteration. At the kth iteration, PPC is the maximum over the parameters

$$\frac{|\widehat{\theta}_i^{(k+1)} - \widehat{\theta}_i^{(k)}|}{|\widehat{\theta}_i^{(k)}| + 1\text{E}-6}$$

where $\widehat{\theta}_i^{(k)}$ is the current value of the ith parameter and $\widehat{\theta}_i^{(k+1)}$ is the prospective value of this parameter after adding the change vector computed for the next iteration. These changes are measured before step length adjustments are made. The parameter with the maximum prospective relative change is displayed with the value of PPC, unless the PPC is nearly 0.

RPC is the retrospective parameter change measure. RPC measures the maximum relative change in the parameters from the previous iteration. At the kth iteration, RPC is the maximum over i of

$$\frac{|\widehat{\theta}_i^{(k)} - \widehat{\theta}_i^{(k-1)}|}{|\widehat{\theta}_i^{(k-1)}| + 1\text{E}-6}$$

where $\widehat{\theta}_i^{(k)}$ is the current value of the ith parameter and $\widehat{\theta}_i^{k-1}$ is the previous value of this parameter. These changes are measured before step length adjustments are made. The name of the parameter with the maximum retrospective relative change is displayed with the value of RPC, unless the RPC is nearly 0.

OBJECT measures the relative change in the objective function value between iterations:

$$\frac{|O^{(k)} - O^{(k-1)}|}{|O^{(k-1)} + 1\text{E} - 6|}$$

where $O^{(k-1)}$ is the value of the objective function ($O^{(k)}$) from the previous iteration. This is the old CONVERGEOBJ= criterion.

Displayed Output

In addition to the output data sets, PROC NLIN also produces the following output objects:

- the residual sums of squares associated with all or some of the combinations of possible starting values of the parameters
- the estimates of the parameters and the residual sums of squares at each iteration
- the estimation summary table, which displays information about the estimation method, the number of observations in the analysis, the objective function, and convergence measures
- the analysis of variance table, including sums of squares for the "Model," "Residual," and "Total" sources of variation ("Corrected Total" or "Uncorrected Total"), and the model F test. Note that beginning in SAS® 9, only the uncorrected total SS is reported and the respective F test is based on the uncorrected total SS if PROC NLIN determines the model does not include an intercept. If PROC NLIN determines the model does include an intercept, only the corrected total SS is reported and the respective F test is based on the corrected total SS.
- the table of parameter estimates, which contains for each parameter in the model its estimate, the approximate standard error of the estimate, and a 95% confidence interval based on the approximate standard error. The confidence level can be changed with the ALPHA= option in the PROC NLIN statement. The HOUGAARD option in the PROC NLIN statement requests that Hougaard's skewness measure be added for each parameter. The standard errors and confidence limits are labeled approximate because they are valid asymptotically as the number of observations grows. If your model is linear in the parameters, the standard errors and confidence intervals are not approximate.
- the approximate correlation matrix of the parameter estimates. This correlation matrix is labeled approximate because it is computed from the approximate covariance matrix of the parameter estimates. If your model is linear in the parameters, the correlation matrix is not approximate.

Incompatibilities with SAS 6.11 and Earlier Versions of PROC NLIN

The NLIN procedure now uses a compiler that is different from the DATA step compiler. The compiler was changed so that analytical derivatives could be computed automatically. For the most part, the syntax accepted by the old NLIN procedure can be used in the new NLIN procedure. However, there are several differences that should be noted:

- You cannot specify a character index variable in the DO statement, and you cannot specify a character test in the IF statement. Thus **`do i=1,2,3;`** is supported, but **`do i='ONE','TWO','THREE';`** is not supported. And **`if 'THIS' < 'THAT' then ...;`** is supported, but **`if 'THIS' THEN ...;`** is not supported.
- The PUT statement, which is used mostly for program debugging in PROC NLIN, supports only some of the features of the DATA step PUT statement, and it has some new features that the DATA step PUT statement does not.
  - The PUT statement does not support line pointers, factored lists, iteration factors, overprinting, the _INFILE_ option, the ':' format modifier, or the symbol '$'.
  - The PUT statement does support expressions inside of parentheses. For example, **`put (sqrt(X));`** produces the square root of X.
  - The PUT statement also supports the option _PDV_ to display a formatted listing of all the variables in the program. The statement **`put _pdv_;`** prints a much more readable listing of the variables than **`put _all_;`** does.
- You cannot use the '*' subscript, but you can specify an array name in a PUT statement without subscripts. Thus, **`array a ...; put a;`** is acceptable, but **`put a[*];`** is not. The statement **`put a;`** displays all the elements of the array a. The **`put a=;`** statement displays all the elements of A with each value labeled by the name of the element variable.
- You cannot specify arguments in the ABORT statement.
- You can specify more than one target statement in the WHEN and OTHERWISE statements. That is, DO/END groups are not necessary for multiple WHEN statements, such as **`select; when(exp1); stmt1; stmt2; when(exp2); stmt3; stmt4; end;`**.
- You can specify only the options LOG, PRINT, and LIST in the FILE statement.
- The RETAIN statement retains only values across one pass through the data set. If you need to retain values across iterations, use the CONTROL statement to make a control variable.

The ARRAY statement in PROC NLIN is similar to, but not the same as, the ARRAY statement in the DATA step. The ARRAY statement is used to associate a name (of no more than 8 characters) with a list of variables and constants. The array name can then be used with subscripts in the program to refer to the items in the list.

The ARRAY statement supported by PROC NLIN does not support all the features of the DATA step ARRAY statement. You cannot specify implicit indexing variables; all array references must have explicit

subscript expressions. You can specify simple array dimensions; lower bound specifications are not supported. A maximum of six dimensions are accepted.

On the other hand, the ARRAY statement supported by PROC NLIN does accept both variables and constants as array elements. In the following statements, `b` is a constant array and `c` is a variable array. Note that the constant array elements cannot be changed with assignment statements.

```
proc nlin data=nld;
array b[4] 1 2 3 4;      /* Constant array */
array c[4] ( 1 2 3 4 ); /* Numeric array with initial values */

b[1] = 2;                /* This is an ERROR, b is a constant array*/
c[2] = 7.5;              /* This is allowed */
```

Both dimension specification and the list of elements are optional, but at least one must be specified. When the list of elements is not specified, or fewer elements than the size of the array are listed, array variables are created by suffixing element numbers to the array name to complete the element list.

If the array is used as a pure array in the program rather than a list of symbols (the individual symbols of the array are not referenced in the code), the array is converted to a numerical array. A pure array is literally a vector of numbers that are accessed only by index. Using these types of arrays results in faster derivatives and compiled code. The assignment to `c1` in the following statements forces the array to be treated as a list of symbols:

```
proc nlin data=nld;
array c[4] ( 1 2 3 4 ); /* Numeric array with initial values */

c[2] = 7.5;              /* This is C used as a pure array  */
c1 = -92.5;              /* This forces C to be a list of symbols */
```

ODS Table Names

PROC NLIN assigns a name to each table it creates. You can use these names to refer to the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 62.5. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 62.5 ODS Tables Produced by PROC NLIN

ODS Table Name	Description	Statement
ANOVA	Analysis of variance	default
CodeDependency	Variable cross reference	LISTDEP
CodeList	Listing of program statements	LISTCODE
ConvergenceStatus	Convergence status	default
CorrB	Correlation of the parameters	default
EstSummary	Summary of the estimation	default
FirstDerivatives	First derivative table	LISTDER
IterHistory	Iteration output	default
MissingValues	Missing values generated by the program	default
NonlinearityMeasures	Global nonlinearity measures	NLINMEASURES
ParameterEstimates	Parameter estimates	default

ODS Graphics (Experimental)

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, "Statistical Graphics Using ODS."

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section "Enabling and Disabling ODS Graphics" on page 612 in Chapter 21, "Statistical Graphics Using ODS."

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section "A Primer on ODS Statistical Graphics" on page 611 in Chapter 21, "Statistical Graphics Using ODS."

PROC NLIN assigns a name to each graph it creates using ODS. You can use these names to refer to the graphs when using ODS. The names are listed in Table 62.6.

Table 62.6 Graphs Produced by PROC NLIN

ODS Graph Name	Plot Description	PLOTS Option
ContourFitPlot	Contour fit plot for models with two regressors	FIT
FitPlot	Fit plot for models with one regressor	FIT
FitDiagnosticsPanel	Panel of fit diagnostics	DIAGNOSTICS
LeveragePlot	Tangential and Jacobian leverages versus observation number	DIAGNOSTICS
LocalInfluencePlot	Local influence versus observation number	DIAGNOSTICS

Table 62.6 *continued*

ODS Graph Name	Plot Description	PLOTS Option
ObservedByPredictedPlot	Dependent variable versus predicted values	DIAGNOSTICS(UNPACK)
ProjectedResidualHistogram	A histogram of the projected residuals	DIAGNOSTICS(UNPACK)
RawResidualExpectationPlot	Raw residual expectation versus predicted values	DIAGNOSTICS(UNPACK)
RawResidualHistogram	A histogram of the raw residuals	DIAGNOSTICS(UNPACK)
ResidualBoxPlot	A box plot of the raw and projected residuals	DIAGNOSTICS(UNPACK)
ResidualPanel	A panel of the raw and projected residuals versus the regressors	RESIDUALS
ResidualPlot	A plot of the raw and projected residuals versus the regressors	RESIDUALS(UNPACK)
ResidualByPredictedPlot	Raw and projected residuals versus the predicted values	DIAGNOSTICS(UNPACK)
RStudentByJacLeveragePlot	Standardized raw and projected residuals versus Jacobian leverage	DIAGNOSTICS(UNPACK)
RStudentByPredictedPlot	Standardized raw and projected residuals versus the predicted values	DIAGNOSTICS(UNPACK)
RStudentByTanLeveragePlot	Standardized raw and projected residuals versus tangential leverage	DIAGNOSTICS(UNPACK)

Convergence Status Table

The "Convergence Status" table can be used to programmatically check the status of an estimation. This table contains the Status variable that takes on the value 0, 1, 2, or 3. If Status takes on a value less than 3, the convergence criterion was met. Specifically, the values mean the following:

Status=0 indicates that the convergence criterion was met and no warning or error messages were issued during the PROC NLIN run. Also, no notes that could indicate a problem with the model were issued.

Status=1 indicates that the convergence criterion was met and notes were written to the log that might indicate a problem with the model.

Status=2 indicates that the convergence criterion was met and one or more warning messages were produced during the PROC NLIN run.

Status=3 indicates that the convergence criterion was not met.

The following sample program demonstrates how the "Convergence Status" table can be used:

```
ods output ConvergenceStatus=ConvStatus;
proc nlin data=YourData;
   parameters a=1 b=1 c=1;
   model wgt = a + x / (b*y+c*z);
run;

data _null_;
  set ConvStatus;
  if status > 0 then put "A problem occurred";
run;
```

Examples: NLIN Procedure

Example 62.1: Segmented Model

Suppose you are interested in fitting a model that consists of two segments that connect in a smooth fashion. For example, the following model states that for values of x less than x_0 the mean of Y is a quadratic function in x, and for values of x greater than x_0 the mean of Y is constant:

$$\mathrm{E}[Y|x] = \begin{cases} \alpha + \beta x + \gamma x^2 & \text{if } x < x_0 \\ c & \text{if } x \geq x_0 \end{cases}$$

In this model equation α, β, and γ are the coefficients of the quadratic segment, and c is the plateau of the mean function. The NLIN procedure can fit such a segmented model even when the join point, x_0, is unknown.

We also want to impose conditions on the two segments of the model. First, the curve should be continuous—that is, the quadratic and the plateau section need to meet at x_0. Second, the curve should be smooth—that is, the first derivative of the two segments with respect to x need to coincide at x_0.

The continuity condition requires that

$$p = \mathrm{E}[Y|x_0] = \alpha + \beta x_0 + \gamma x_0^2$$

The smoothness condition requires that

$$\frac{\partial \mathrm{E}[Y|x_0]}{\partial x} = \beta + 2\gamma x_0 \equiv 0$$

If you solve for x_0 and substitute into the expression for c, the two conditions jointly imply that

$$x_0 = -\beta/2\gamma$$
$$c = \alpha - \beta^2/4\gamma$$

Although there are apparently four unknowns, the model contains only three parameters. The continuity and smoothness restrictions together completely determine one parameter given the other three.

The following DATA step creates the SAS data set for this example:

```
data a;
   input y x @@;
   datalines;
.46 1  .47  2 .57  3 .61  4 .62  5 .68  6 .69  7
.78 8  .70  9 .74 10 .77 11 .78 12 .74 13 .80 13
.80 15 .78 16
 ;
```

The following PROC NLIN statements fit this segmented model:

```
title 'Quadratic Model with Plateau';
proc nlin data=a;
   parms alpha=.45 beta=.05 gamma=-.0025;

   x0 = -.5*beta / gamma;

   if (x < x0) then
        mean = alpha + beta*x  + gamma*x*x;
   else mean = alpha + beta*x0 + gamma*x0*x0;
   model y = mean;

   if _obs_=1 and _iter_ =.  then do;
      plateau =alpha + beta*x0 + gamma*x0*x0;
      put /  x0= plateau=  ;
   end;
   output out=b predicted=yp;
run;
```

The parameters of the model are α, β, and γ, respectively. They are represented in the PROC NLIN statements by the variables alpha, beta, and gamma, respectively. In order to model the two segments, a conditional statement is used that assigns the appropriate expression to the mean function depending on the value of x_0. A PUT statement is used to print the constrained parameters every time the program is executed for the first observation. The OUTPUT statement computes predicted values for plotting and saves them to data set b.

Note that there are other ways in which you can write the conditional expressions for this model. For example, you could formulate a condition with two model statements, as follows:

```
proc nlin data=a;
   parms alpha=.45 beta=.05 gamma=-.0025;
   x0 = -.5*beta / gamma;
   if (x < x0) then
        model y = alpha+beta*x+gamma*x*x;
   else model y = alpha+beta*x0+gamma*x0*x0;
run;
```

Or you could use a single expression with a conditional evaluation, as in the following statements:

```
proc nlin data=a;
   parms alpha=.45 beta=.05 gamma=-.0025;
   x0 = -.5*beta / gamma;
   model y = (x <x0)*(alpha+beta*x +gamma*x*x) +
             (x>=x0)*(alpha+beta*x0+gamma*x0*x0);
run;
```

The results from fitting this model with PROC NLIN are shown in Output 62.1.1–Output 62.1.3. The iterative optimization converges after six iterations (Output 62.1.1). Output 62.1.1 indicates that the join point is 12.747 and the plateau value is 0.777.

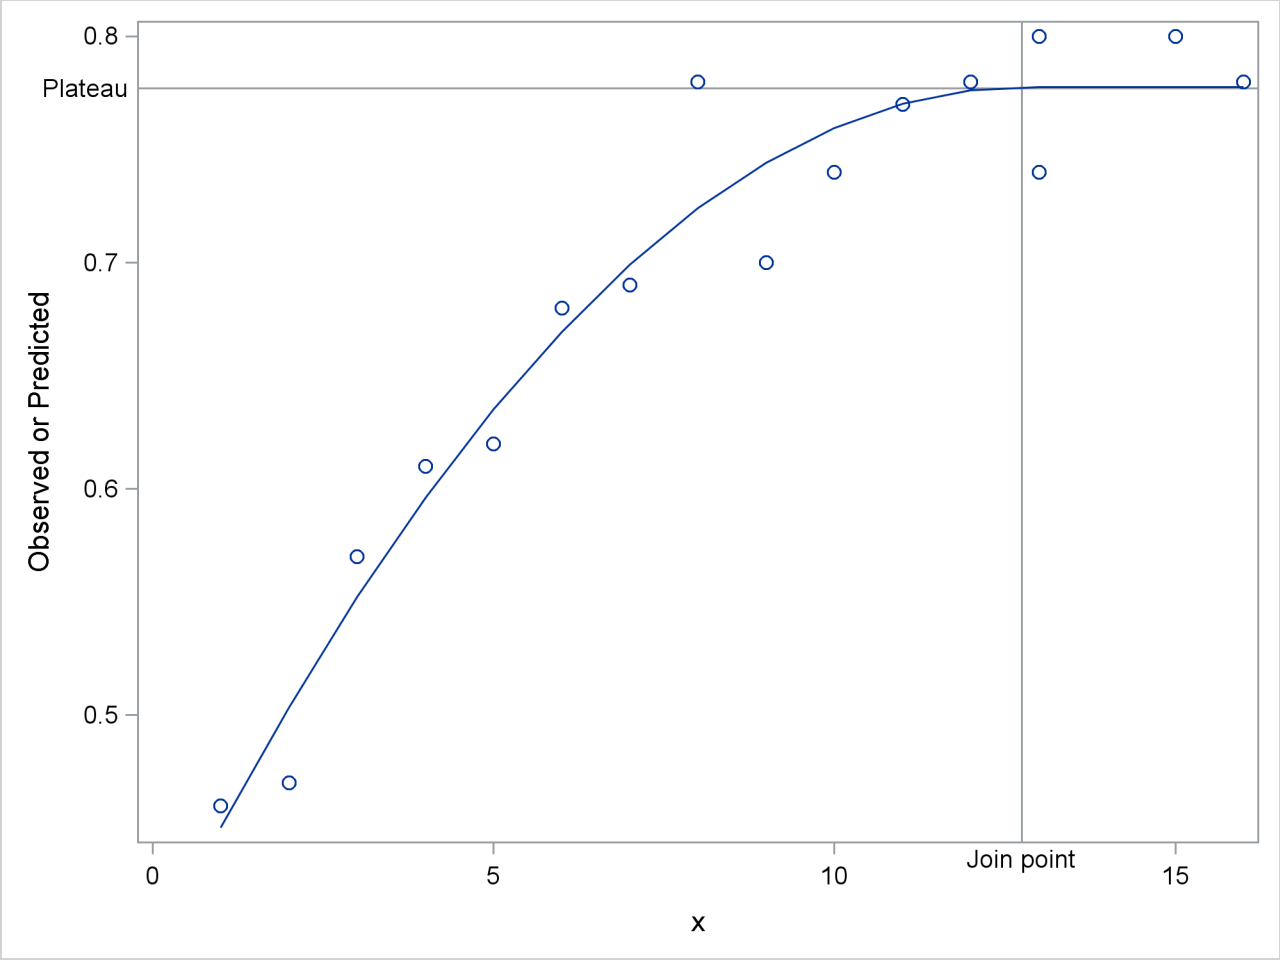
The following statements produce a graph of the observed and predicted values with reference lines for the join point and plateau estimates (Output 62.1.4):

```
proc sgplot data=b noautolegend;
   yaxis label='Observed or Predicted';
   refline 0.777  / axis=y label="Plateau"    labelpos=min;
   refline 12.747 / axis=x label="Join point" labelpos=min;
   scatter y=y  x=x;
   series  y=yp x=x;
run;
```

Output 62.1.4 Observed and Predicted Values for the Quadratic Model



If you want to estimate the join point directly, you can use the relationship between the parameters to change the parameterization of the model in such a way that the mean function depends directly on x_0. Using the smoothness condition that relates x_0 to γ,

$$x_0 = -\beta/2\gamma$$

you can express γ as a function of β and x_0:

$$\gamma = -\beta/(2x_0)$$

Substituting for γ in the model equation

$$\mathrm{E}[Y|x] = \begin{cases} \alpha + \beta x + \gamma x^2 & \text{if } x < x_0 \\ \alpha - \beta^2/(4\gamma) & \text{if } x \geq x_0 \end{cases}$$

yields the reparameterized model

$$\mathrm{E}[Y|x] = \begin{cases} \alpha + \beta x(1 - x/(2x_0)) & \text{if } x < x_0 \\ \alpha + \beta x_0/2 & \text{if } x \geq x_0 \end{cases}$$

This model is fit with the following PROC NLIN statements:

```
proc nlin data=a;
   parms alpha=.45 beta=.05 x0=10;
   if (x<x0) then
        mean = alpha + beta*x *(1-x/(2*x0));
   else mean = alpha + beta*x0/2;
   model y = mean;
run;
```

Output 62.1.5 Results from Reparameterized Model

The analysis of variance table in the reparameterized model is the same as in the earlier analysis (compare Output 62.1.5 and Output 62.1.3). Changing the parameterization of a model does not affect the fit. The "Parameter Estimates" table now shows x0 as a parameter in the model. The estimate agrees with the earlier result that uses the PUT statement (Output 62.1.2). Since x_0 is now a model parameter, the NLIN procedure also reports its asymptotic standard error and its approximate 95% confidence interval.

Example 62.2: Iteratively Reweighted Least Squares

With the NLIN procedure you can perform weighted nonlinear least squares regression in situations where the weights are functions of the parameters. To minimize a weighted sum of squares, you assign an expression to the _WEIGHT_ variable in your PROC NLIN statements. When the _WEIGHT_ variable depends on the model parameters, the estimation technique is known as iteratively reweighted least squares (IRLS). In this situation you should employ the NOHALVE option in the PROC NLIN statement. Because the weights change from iteration to iteration, it is not reasonable to expect the *weighted* residual sum of squares to decrease between iterations. The NOHALVE option removes that restriction.

Examples where IRLS estimation is used include robust regression via M-estimation (Huber 1964, 1973), generalized linear models (McCullagh and Nelder 1989), and semivariogram fitting in spatial statistics (Schabenberger and Pierce 2002, Sect. 9.2). There are dedicated SAS/STAT procedures for robust regression (the ROBUSTREG procedure) and generalized linear models (the GENMOD and GLIMMIX procedures). Examples of weighted least squares fitting of a semivariogram function can be found in Chapter 98, "The VARIOGRAM Procedure."

In this example we show an application of PROC NLIN for M-estimation only to illustrate the connection between robust regression and weighted least squares. The ROBUSTREG procedure is the appropriate tool to fit these models with SAS/STAT software.

M-estimation was introduced by Huber (1964, 1973) to estimate location parameters robustly. Beaton and Tukey (1974) applied the idea of M-estimation in regression models and introduced the biweight (or bisquare) weight function. See Holland and Welsch (1977) for this and other robust methods. Consider a linear regression model of the form

$$\mathrm{E}[Y_i|x] = \mathbf{x}_i'\boldsymbol{\beta} + \epsilon_i$$

In weighted least squares estimation you seek the parameters $\widehat{\boldsymbol{\beta}}$ that minimize

$$\sum_{i=1}^{n} w_i \left(y_i - \mathbf{x}_i'\boldsymbol{\beta}\right)^2 = \sum_{i=1}^{n} w_i e_i^2$$

where w_i is the weight associated with the ith observation. The *normal* equations of this minimization problem can be written as

$$\sum_{i=1}^{n} w_i e_i \mathbf{x}_i = \mathbf{0}$$

In M-estimation the corresponding equations take on the form

$$\sum_{i=1}^{n} \psi(e_i)\mathbf{x}_i = \mathbf{0}$$

where $\psi(\cdot)$ is a weighing function. The Beaton-Tukey biweight, for example, can be written as

$$\psi(e_i) = \begin{cases} e_i\left(1 - \left(\frac{e_i}{\sigma k}\right)^2\right)^2 & |e_i/\sigma| \le k \\ 0 & |e_i/\sigma| > k \end{cases}$$

Substitution into the estimating equation for M-estimation yields weighted least squares equations

$$\sum_{i=1}^{n} \psi(e_i)\mathbf{x}_i = \sum_{i=1}^{n} w_i e_i \mathbf{x}_i = \mathbf{0}$$

$$w_i = \begin{cases} \left(1 - \left(\frac{e_i}{\sigma k}\right)^2\right)^2 & |e_i/\sigma| \le k \\ 0 & |e_i/\sigma| > k \end{cases}$$

The biweight function involves two constants, σ and k. The scale σ can be fixed or estimated from the fit in the previous iteration. If σ is estimated, a robust estimator of scale is typically used. In this example σ is fixed at 2. A common value for the constant k is $k = 4.685$.

The following DATA step creates a SAS data set of the population of the United States (in millions), recorded at 10-year intervals starting in 1790 and ending in 1990. The aim is to fit a quadratic linear model to the population over time.

```
title 'U.S. Population Growth';
data uspop;
   input pop :6.3 @@;
   retain year 1780;
   year   = year+10;
   yearsq = year*year;
   datalines;

226542 248710
;
```

The PROC NLIN code that follows fits this linear model by M-estimation and IRLS. The weight function is set to a zero or nonzero value depending on the value of the scaled residual. The NOHALVE option removes the requirement that the (weighted) residual sum of squares must decrease between iterations.

```
title 'Beaton/Tukey Biweight Robust Regression using IRLS';
proc nlin data=uspop nohalve;
   parms b0=20450.43 b1=-22.7806 b2=.0063456;
   model pop=b0+b1*year+b2*year*year;
   resid = pop-model.pop;
   sigma = 2;
   k     = 4.685;
   if abs(resid/sigma)<=k then _weight_=(1-(resid / (sigma*k))**2)**2;
   else _weight_=0;
   output out=c r=rbi;
run;
```

Parameter estimates from this fit are shown in Output 62.2.1, and the computed weights at the final iteration are displayed in Output 62.2.2. The observations for 1940 and 1950 are highly discounted because of their large residuals.

21	248.710	1990	3960100	−1.33067	2	4.685	0.96007

You can obtain this analysis more conveniently with PROC ROBUSTREG. The procedure re-estimates the scale parameter robustly between iterations. To obtain an analysis with a fixed scale parameter as in this example, use the following PROC ROBUSTREG statements:

```
proc robustreg data=uspop method=m(scale=2);
   model pop = year year*year;
   output out=weights weight=w;
run;

proc print data=weights;
run;
```

Note that the computation of standard errors in the ROBUSTREG procedure is different from the calculations in the NLIN procedure.

Example 62.3: Probit Model with Likelihood Function

The data in this example, taken from Lee (1974), consist of patient characteristics and a variable indicating whether cancer remission occurred. This example demonstrates how to use PROC NLIN with a likelihood function. In this case, twice the negative of the log-likelihood function is to be minimized. This is the objective function for the analysis:

$$-2\log L = -2\sum_{i=1}^{n}\log\{\pi_i(y_i, \mathbf{x}_i)\}$$

In this expression, π_i denotes the success probability of the n Bernoulli trials, and $\log L$ is the log likelihood of n independent binary (Bernoulli) observations. The probability π_i depends on the observations through the linear predictor η_i,

$$\pi_i(y_i, \mathbf{x}_i) = \begin{cases} 1-\Phi(\eta_i) & y_i = 1 \\ \Phi(\eta_i) & y_i = 0 \end{cases}$$

The linear predictor takes the form of a regression equation that is linear in the parameters,

$$\eta_i = \beta_0 + \beta_1 z_{1i} + \beta_2 z_{2i} + \cdots \beta_k z_{ki} = \mathbf{z}_i\boldsymbol{\beta}$$

Despite this linearity of η in the z variables, the probit model is nonlinear, because the linear predictor appears inside the nonlinear probit function.

In order to use the NLIN procedure to minimize the function, the estimation problem must be cast in terms of a nonlinear least squares problem with objective function

$$\sum_{i=1}^{n}(y_i - f(\boldsymbol{\beta}, \mathbf{z}_i')^2$$

This can be accomplished by setting $y_i = 0$ and $f(\boldsymbol{\beta}, \mathbf{z}_i') = \sqrt{(}-2\log\{\pi_i\})$. Because $0 \le \pi \le 1$, the function $-2\log\{\pi_i\}$ is strictly positive and the square root can be taken safely.

The following DATA step creates the data for the probit analysis. The variable like is created in the DATA step, and it contains the value 0 throughout. This variable serves as the "dummy" response variable in the PROC NLIN step. The variable remiss indicates whether cancer remission occurred. It is the binary outcome variable of interest and is used to determine the relevant probability for observation i as the success or failure probability of a Bernoulli experiment.

```
data remiss;
   input remiss cell smear infil li blast temp;

 1 1    .60 .60 1.7 0.964  .990
 1 1    .69 .69 0.9 0.398  .986
 0 1    .73 .73 0.7 0.398  .986
 ;
```

The following NLIN statements fit the probit model:

```
proc nlin data=remiss method=newton sigsq=1;
   parms int=-10 a = -2 b = -1 c=6;

   linp = int + a*cell + b*li + c*temp;
   p   = probnorm(linp);

   if (remiss = 1) then pi = 1-p;
                   else pi = p;

   model.like = sqrt(- 2 * log(pi));
   output out=p p=predict;
run;
```

The assignment to the variable linp creates the linear predictor of the generalized linear model,

$$\eta = \beta_0 + \beta_1 \text{cell}_i + \beta_2 \text{li}_i + \beta_3 * \text{temp}_i$$

In this example, the variables cell, li, and temp are used as regressors.

By default, the NLIN procedure computes the covariance matrix of the parameter estimates based on the nonlinear least squares assumption. That is, the procedure computes the estimate of the residual variance as the mean squared error and uses that to multiply the inverse crossproduct matrix or the inverse Hessian matrix. (See the section "Covariance Matrix of Parameter Estimates" on page 5139 for details.) In the probit model, there is no residual variance. In addition, standard errors in maximum likelihood estimation are based on the inverse Hessian matrix. The METHOD=NEWTON option in the PROC NLIN statement is used to employ the Hessian matrix in computing the covariance matrix of the parameter estimates. The SIGSQ=1 option replaces the residual variance estimate that PROC NLIN would use by default as a multiplier of the inverse Hessian with the value 1.0.

Output 62.3.1 shows the results of this analysis. The analysis of variance table shows an apparently strange result. The total sum of squares is zero, and the model sum of squares is negative. Recall that the values of the response variable were set to zero and the mean function was constructed as $-2\log\{\pi_i\}$ in order for the NLIN procedure to minimize a log-likelihood function in terms of a nonlinear least squares problem. The value 21.9002 shown as the "Error" sum of squares is the value of the function $-2\log L$.

Output 62.3.1 Nonlinear Least-Squares Analysis from PROC NLIN

The NLIN Procedure

NOTE: An intercept was not specified for this model.

The problem can be more simply solved using dedicated procedures for generalized linear models:

```
proc glimmix data=remiss;
   model remiss = cell li temp / dist=binary link=probit s;
run;

proc genmod data=remiss;
   model remiss = cell li temp / dist=bin link=probit;
run;
```

```
proc logistic data=remiss;
   model remiss = cell li temp / link=probit technique=newton;
run;
```

Example 62.4: Affecting Curvature through Parameterization

The work of Ratkowksy (1983, 1990) has brought into focus the importance of close-to-linear behavior of parameters in nonlinear regression models. The curvature in a nonlinear model consists of two components: the intrinsic curvature and the parameter-effects curvature. See the section "Relative Curvature Measures of Nonlinearity" on page 5125 for details. Intrinsic curvature expresses the degree to which the nonlinear model bends as values of the *parameters* change. This is not the same as the curviness of the model as a function of the covariates (the x variables). Intrinsic curvature is a function of the type of model you are fitting and the data. This curvature component cannot be affected by reparameterization of the model. According to Ratkowsky (1983), the intrinsic curvature component is typically smaller than the parameter-effects curvature, which can be affected by altering the parameterization of the model.

In models with low curvature, the nonlinear least squares parameter estimators behave similarly to least squares estimators in linear regression models, which have a number of desirable properties. If the model is correct, they are best linear unbiased estimators and are normally distributed if the model errors are normal (otherwise they are asymptotically normal). As you lower the curvature of a nonlinear model, you can expect that the parameter estimators approach the behavior of the linear regression model estimators: they behave "close to linear."

This example uses a simple data set and a commonly applied model for dose-response relationships to examine how the parameter-effects curvature can be reduced. The statistics by which an estimator's behavior is judged are Box's bias (Box 1971) and Hougaard's measure of skewness (Hougaard 1982, 1985).

The log-logistic model

$$\mathrm{E}[Y|x] = \delta + \frac{\alpha - \delta}{1 + \gamma \exp\{\beta \ln(x)\}}$$

is a popular model to express the response Y as a function of dose x. The response is bounded between the asymptotes α and δ. The term in the denominator governs the transition between the asymptotes and depends on two parameters, γ and β. The log-logistic model can be viewed as a member of a broader class of dose-response functions, those relying on *switch-on* or *switch-off* mechanisms (see, for example, Schabenberger and Pierce 2002, sec. 5.8.6). A switch function is usually a monotonic function $S(x, \boldsymbol{\theta})$ that takes values between 0 and 1. A switch-on function increases in x; a switch-off function decreases in x. In the log-logistic case, the function

$$S(x, [\beta, \gamma]) = \frac{1}{1 + \gamma \exp\{\beta \ln(x)\}}$$

is a switch-off function for $\beta > 0$ and a switch-on function for $\beta < 0$. You can write general dose-response functions with asymptotes simply as

$$\mathrm{E}[Y|x] = \mu_{\min} + (\mu_{\max} - \mu_{\min}) S(x, \boldsymbol{\theta})$$

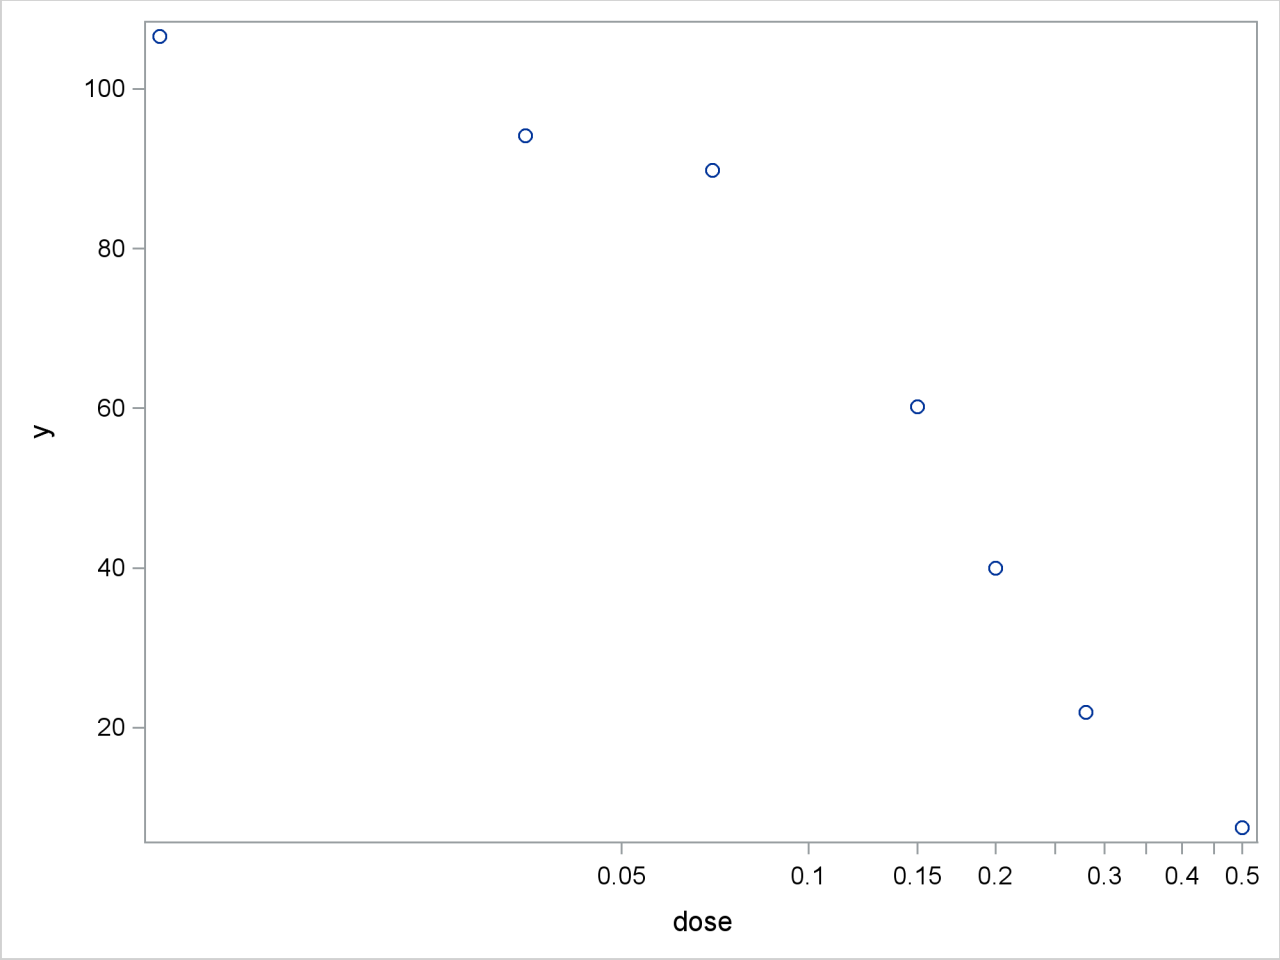
The following DATA step creates a small data set from a dose-response experiment with response y:

```
data logistic;
   input dose y;
   logdose = log(dose);
   datalines;
0.009  106.56
0.035   94.12
0.07    89.76
0.15    60.21
0.20    39.95
0.28    21.88
0.50     7.46
;
```

A graph of these data is produced with the following statements:

```
proc sgplot data=logistic;
   scatter y=y x=dose;
   xaxis type=log logstyle=linear;
run;
```

Output 62.4.1 Observed Data in Dose-Response Experiment



When dose is expressed on the log scale, the sigmoidal shape of the dose-response relationship is clearly visible (Output 62.4.1). The log-logistic switching model in the preceding parameterization is fit with the following statements in the NLIN procedure:

```
proc nlin data=logistic bias hougaard nlinmeasures;
   parameters alpha=100 beta=3 gamma=300;
   delta = 0;
   Switch = 1/(1+gamma*exp(beta*log(dose)));
   model y = delta + (alpha - delta)*Switch;
run;
```

The lower asymptote δ is assumed to be 0 in this case. Since δ is not listed in the PARAMETERS statement and is assigned a value in the program, it is assumed to be constant. Note that the term Switch is the switch-off function in the log-logistic model. The BIAS and HOUGAARD options in the PROC NLIN statement request that Box's bias, percentage bias, and Hougaard's skewness measure be added to the table of parameter estimates, and the NLINMEASURES option requests that the global nonlinearity measures be produced.

The NLIN procedure converges after 10 iterations and achieves a residual mean squared error of 15.1869 (Output 62.4.2). This value is not that important by itself, but it is worth noting since this model fit is compared to the fit with other parameterizations later on.

Output 62.4.2 Iteration History and Analysis of Variance

The NLIN Procedure
Dependent Variable y
Method: Gauss-Newton

Iterative Phase

The table of parameter estimates displays the estimates of the three model parameters, their approximate standard errors, 95% confidence limits, Hougaard's skewness measure, Box's bias, and percentage bias (Output 62.4.3). Parameters for which the skewness measure is less than 0.1 in absolute value and with percentage bias less than 1% exhibit very close-to-linear behavior, and skewness values less than 0.25 in absolute value indicate reasonably close-to-linear behavior (Ratkowsky 1990). According to these rules, the estimators $\widehat{\beta}$ and $\widehat{\gamma}$ suffer from substantial curvature. The estimator $\widehat{\gamma}$ is especially "far-from-linear." Inferences that involve $\widehat{\gamma}$ and rely on the reported standard errors or confidence limits (or both) for this parameter might be questionable.

Output 62.4.3 Parameter Estimates, Hougaard's Skewness, and Box's Bias

Parameter	Estimate	Approx Std Error	Approximate 95% Confidence Limits		Skewness	Bias	Percent Bias

The related global nonlinearity measures output table (Output 62.4.4) shows that both the maximum and RMS parameter-effects curvature are substantially larger than the critical curvature value recommended by Bates and Watts (1980). In contrast, the intrinsic curvatures of the model are less than the critical value. This implies that most of the nonlinearity can be removed by reparameterization.

Output 62.4.4 Global Nonlinearity Measures

Global Nonlinearity Measures	
Max Intrinsic Curvature	0.2397
RMS Intrinsic Curvature	0.1154

Raw Residual Variance	15.187
Projected Residual Variance	5.922

One method of reducing the parameter-effects curvature, and thereby reduce the bias and skewness of the parameter estimators, is to replace a parameter with its expected-value parameterization. Schabenberger et al. (1999) and Schabenberger and Pierce (2002, sec. 5.7.2) refer to this method as *reparameterization through defining relationships*. A defining relationship is obtained by equating the mean response at a chosen value of x (say, x^*) to the model:

$$\mathrm{E}[Y|x^*] = \delta + \frac{\alpha - \delta}{1 + \gamma \exp\{\beta \ln(x^*)\}}$$

This equation is then solved for a parameter that is subsequently replaced in the original equation. This method is particularly useful if x^* has an interesting interpretation. For example, let λ_K denote the value that reduces the response by $K \times 100\%$,

$$\mathrm{E}[Y|\lambda_K] = \delta + \left(\frac{100 - K}{100}\right)(\alpha - \delta)$$

Because γ exhibits large bias and skewness, it is the target in the first round of reparameterization. Setting the expression for the conditional mean at λ_K equal to the mean function when $x = \lambda_K$ yields the following expression:

$$\delta + \left(\frac{100 - K}{100}\right)(\alpha - \delta) = \delta + \frac{\alpha - \delta}{1 + \gamma \exp\{\beta \ln(\lambda_K)\}}$$

This expression is solved for γ, and the result is substituted back into the model equation. This leads to a log-logistic model in which γ is replaced by the parameter λ_K, the dose at which the response was reduced by $K \times 100\%$. The new model equation is

$$\mathrm{E}[Y|x] = \delta + \frac{\alpha - \delta}{1 + K/(100 - K)\exp\{\beta \ln(x/\lambda_K)\}}$$

A particularly interesting choice is $K = 50$, since λ_{50} is the dose at which the response is halved. In studies of mortality, this concentration is also known as the LD50. For the special case of λ_{50} the model equation becomes

$$\mathrm{E}[Y|x] = \delta + \frac{\alpha - \delta}{1 + \exp\{\beta \ln(x/\lambda_{50})\}}$$

You can fit the model in the LD50 parameterization with the following statements:

```
proc nlin data=logistic bias hougaard;
   parameters alpha=100 beta=3 LD50=0.15;
   delta = 0;
   Switch = 1/(1+exp(beta*log(dose/LD50)));
   model y = delta + (alpha - delta)*Switch;
   output out=nlinout pred=p lcl=lcl ucl=ucl;
run;
```

Partial results from this NLIN run are shown in Output 62.4.5. The analysis of variance tables in Output 62.4.2 and Output 62.4.5 are identical. Changing the parameterization of a model does not affect the model fit. It does, however, affect the interpretation of the parameters and the statistical properties (close-to-linear behavior) of the parameter estimators. The skewness and bias measures of the parameter LD50 is considerably reduced compared to those values for the parameter γ in the previous parameterization. Also, γ has been replaced by a parameter with a useful interpretation, the dose that yields a 50% reduction in mean response. Also notice that the bias and skewness measures of α and β are not affected by the $\gamma \rightarrow$ LD50 reparameterization.

Output 62.4.5 ANOVA Table and Parameter Estimates in LD50 Parameterization

alpha	101.8	3.0034	93.4752	110.2	0.1415	0.1512	0.15
beta	2.3570	0.2928	1.5440	3.1699	0.4987	0.0303	1.29
LD50	0.1681	0.00915	0.1427	0.1935	−0.0605	−0.00013	−0.08

To reduce the parameter-effects curvature of the β parameter, you can use the technique of defining relationships again. This can be done generically, by solving

$$\mu^* = \delta + \frac{\alpha - \delta}{1 + \exp\{\beta \ln(x/\lambda)\}}$$

for β, treating μ^* as the new parameter (in lieu of β), and choosing a value for x^* that leads to low skewness. This results in the expected-value parameterization of β. Solving for β yields

$$\beta = \frac{\log\left(\frac{\alpha-\mu^*}{\mu^*-\delta}\right)}{\log\left(x^*/\lambda\right)}$$

The interpretation of the parameter μ^* that replaces β in the model equation is simple: it is the mean dose response when the dose is x^*. Fixing $x^* = 0.3$, the following PROC NLIN statements fit this model:

```
proc nlin data=logistic bias hougaard nlinmeasures;
   parameters alpha=100 mustar=20 LD50=0.15;
   delta   = 0;
   xstar   = 0.3;
   beta    = log((alpha - mustar)/(mustar - delta)) / log(xstar/LD50);
   Switch  = 1/(1+exp(beta*log(dose/LD50)));
   model y = delta + (alpha - delta)*Switch;
   output out=nlinout pred=p lcl=lcl ucl=ucl;
run;
```

Note that the switch-off function continues to be written in terms of β and the LD50. The only difference from the previous model is that β is now expressed as a function of the parameter μ^*. Using expected-value parameterizations is a simple mechanism to lower the curvature in a model and to arrive at starting values. The starting value for μ^* can be gleaned from Output 62.4.1 at $x = 0.3$.

Output 62.4.6 shows selected results from this NLIN run. The ANOVA table is again unaffected by the change in parameterization. The skewness for μ^* is significantly reduced in comparison to those of the β parameter in the previous model (compare Output 62.4.6 and Output 62.4.5), while its bias remains on the same scale from Output 62.4.5 to Output 62.4.6. Also note the substantial reduction in the parameter-effects curvature values. As expected, the intrinsic curvature values remain intact.

Example 62.5: Comparing Nonlinear Trends among Groups

When you model nonlinear trends in the presence of group (classification) variables, two questions often arise: whether the trends should be varied by group, and how to decide which parameters should be varied across groups. A large battery of tools is available on linear statistical models to test hypotheses involving the model parameters, especially to test linear hypotheses. To test similar hypotheses in nonlinear models, you can draw on analogous tools. Especially important in this regard are comparisons of nested models by contrasting their residual sums of squares.

In this example, a two-group model from a pharmacokinetic application is fit to data that are in part based on the theophylline data from Pinheiro and Bates (1995) and the first example in the documentation for the NLMIXED procedure. In a pharmacokinetic application you study how a drug is dispersed through a living organism. The following data represent concentrations of the drug theophylline over a 25-hour period following oral administration. The data are derived by collapsing and averaging the subject-specific data from Pinheiro and Bates (1995) in a particular, yet unimportant, way. The purpose of arranging the data in this way is purely to demonstrate the methodology.

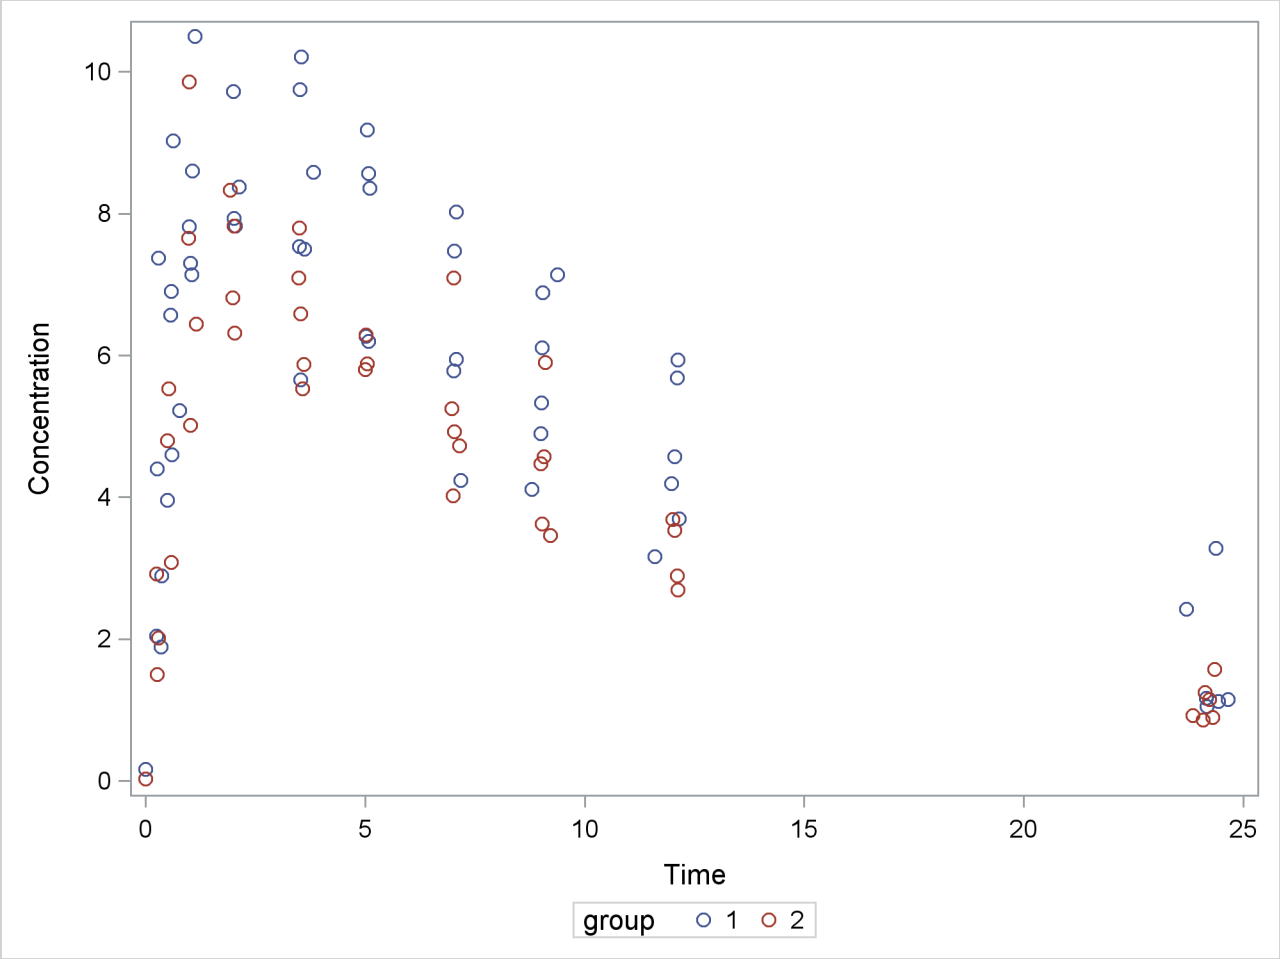
The following code plots the theophylline concentration data over time for the two groups (Output 62.5.1). In each group the concentration tends to rise sharply right after the drug is administered, followed by a prolonged tapering of the concentration.

```
proc sgplot data=theop;
   scatter x=time y=conc / group=group;
   yaxis label='Concentration';
   xaxis label='Time';
run;
```

Output 62.5.1 Observed Responses in Two Groups



In the context of nonlinear mixed models, Pinheiro and Bates (1995) consider a first-order compartment model for these data. In terms of two fixed treatment groups, the model can be written as

$$C_{it} = \frac{D k_{e_i} k_{a_i}}{Cl_i (k_{a_i} - k_{e_i})} [\exp(-k_{e_i} t) - \exp(-k_{a_i} t)] + \epsilon_{it}$$

where C_{it} is the observed concentration in group i at time t, D is the dose of theophylline, k_{e_i} is the elimination rate in group i, k_{a_i} is the absorption rate in group i, Cl_i is the clearance in group i, and ϵ_{it} denotes the model error. Because the rates and the clearance must be positive, you can parameterize the model in terms of log rates and the log clearance:

$$\begin{aligned} Cl_i &= \exp\{\beta_{1i}\} \\ k_{a_i} &= \exp\{\beta_{2i}\} \\ k_{e_i} &= \exp\{\beta_{3i}\} \end{aligned}$$

In this parameterization the model contains six parameters, and the rates and clearance vary by group. This produces two separate response profiles, one for each group. On the other extreme, you could model the trends as if there were no differences among the groups:

$$\begin{aligned} Cl_i &= \exp\{\beta_1\} \\ k_{a_i} &= \exp\{\beta_2\} \\ k_{e_i} &= \exp\{\beta_3\} \end{aligned}$$

In between these two extremes lie other models, such as a model where both groups have the same absorption and elimination rate, but different clearances. The question then becomes how to go about building a model in an organized manner.

To test hypotheses about nested nonlinear models, you can apply the idea of a "Sum of Squares Reduction Test." A reduced model is nested within a full model if you can impose q constraints on the full model to obtain the reduced model. Then, if SSE_r and SSE_f denote the residual sum of squares in the reduced and the full model, respectively, the test statistic is

$$F_R = \frac{\left(\text{SSE}_r - \text{SSE}_f\right)/q}{\text{SSE}_f/(n-p)} = \frac{\left(\text{SSE}_r - \text{SSE}_f\right)/q}{\text{MSE}_f}$$

where n are the number of observations used and p are the number of parameters in the full model. The numerator of the F_R statistic is the average reduction in residual sum of squares per constraint. The mean squared error of the full model is used to scale this average because it is less likely to be a biased estimator of the residual variance than the variance estimate from a constrained (reduced) model. The F_R statistic is then compared against quantiles from an F distribution with q numerator and $n-p$ denominator degrees of freedom. Schabenberger and Pierce (2002) discuss the justification for this test and compare it to other tests in nonlinear models.

In the present application we might phrase the initial question akin to the overall F test for a factor in a linear model: Should any parameters be varied between the two groups? The corresponding null hypothesis is

$$H: \begin{cases} \beta_{11} = \beta_{12} \\ \beta_{21} = \beta_{22} \\ \beta_{31} = \beta_{32} \end{cases}$$

where the first subscript identifies the type of the parameter and the second subscript identifies the group. Note that this hypothesis implies

$$H: \begin{cases} Cl_1 = Cl_2 \\ k_{a_1} = k_{a_2} \\ k_{e_1} = k_{e_2} \end{cases}$$

If you fail to reject this hypothesis, there is no need to further examine individual parameter differences.

The reduced model—the model subject to the null hypothesis—is fit with the following PROC NLIN statements:

```
proc nlin data=theop;
   parms beta1=-3.22 beta2=0.47 beta3=-2.45;
   cl   = exp(beta1);
   ka   = exp(beta2);
   ke   = exp(beta3);
   mean = dose*ke*ka*(exp(-ke*time)-exp(-ka*time))/cl/(ka-ke);
   model conc = mean;
   ods output Anova=aovred(rename=(ss=ssred ms=msred df=dfred));
run;
```

The clearance, the rates, and the mean function are formed independently of the group membership. The analysis of variance table is saved to the data set aovred, and some of its variables are renamed. This is done so that the data set can be merged easily with the analysis of variance table for the full model (see following).

The converged model has a residual sum of square of $\text{SSE}_r = 286.4$ and a mean squared error of 3.0142 (Output 62.5.2). The table of parameter estimates gives the values for the estimated log clearance ($\widehat{\beta}_1 = -3.2991$), the estimated log absorption rate ($\widehat{\beta}_2 = 0.4769$), and the estimated log elimination rate ($\widehat{\beta}_3 = -2.5555$).

Output 62.5.2 Fit Results for the Reduced Model

The NLIN Procedure
Dependent Variable conc
Method: Gauss-Newton

NOTE: Convergence criterion met.

NOTE: An intercept was not specified for this model.

Source	DF	Sum of Squares	Mean Square	F Value	Approx Pr > F
Model	3	3100.5	1033.5	342.87	<.0001
Error	95	286.4	3.0142		
Uncorrected Total	98	3386.8			

Parameter	Estimate	Approx Std Error	Approximate 95% Confidence Limits	
beta1	-3.2991	0.0956	-3.4888	-3.1094
beta2	0.4769	0.1640	0.1512	0.8025
beta3	-2.5555	0.1410	-2.8354	-2.2755

The full model, in which all three parameters are varied by group, can be fit with the following statements in the NLIN procedure:

```
proc nlin data=theop;
   parms beta1_1=-3.22 beta2_1=0.47 beta3_1=-2.45
         beta1_2=-3.22 beta2_2=0.47 beta3_2=-2.45;
   if (group=1) then do;
      cl   = exp(beta1_1);
      ka   = exp(beta2_1);
      ke   = exp(beta3_1);
   end; else do;
      cl   = exp(beta1_2);
      ka   = exp(beta2_2);
      ke   = exp(beta3_2);
   end;
   mean = dose*ke*ka*(exp(-ke*time)-exp(-ka*time))/cl/(ka-ke);
   model conc = mean;
   ods output Anova=aovfull;
run;
```

Separate parameters for the groups are now specified in the PARMS statement, and the value of the model variables cl, ka, and ke is assigned conditional on the group membership of an observation. Notice that the same expression as in the previous run can be used to model the mean function.

The results from this PROC NLIN run are shown in Output 62.5.3. The residual sum of squares in the full model is only $\text{SSE}_f = 138.9$, compared to $\text{SSE}_r = 286.4$ in the reduced model (Output 62.5.3).

Output 62.5.3 Fit Results for the Full Model

      beta3_2        -2.4442        0.1618     -2.7655     -2.1229
```

Whether this reduction in sum of squares is sufficient to declare that the full model provides a significantly better fit than the reduced model depends on the number of constraints imposed on the full model and on the variability in the data. In other words, before drawing any conclusions, you have to take into account how many parameters have been dropped from the model and how much variation around the regression trends the data exhibit. The F_R statistic sets these quantities into relation. The following macro merges the analysis of variance tables from the full and reduced model, and computes F_R and its p-value:

```
%macro SSReductionTest;
   data aov; merge aovred aovfull;
     if (Source='Error') then do;
        Fstat  = ((SSred-SS)/(dfred-df))/ms;
        pvalue = 1-Probf(Fstat,dfred-df,df);
        output;
     end;
   run;
   proc print data=aov label noobs;
      label Fstat  = 'F Value'
            pValue = 'Prob > F';
      format pvalue pvalue8.;
      var Fstat pValue;
   run;
%mend;
%SSReductionTest;
```

Output 62.5.4 F Statistic and P-value for Hypothesis of Equal Trends

F Value	Prob > F
32.5589	<.000001

There is clear evidence that the model with separate trends fits these data significantly better (Output 62.5.4). To decide whether all parameters should be varied between the groups or only one or two of them, we first refit the model in a slightly different parameterization:

```
proc nlin data=theop;
   parms beta1_1=-3.22 beta2_1=0.47 beta3_1=-2.45
         beta1_diff=0 beta2_diff=0 beta3_diff=0;
   if (group=1) then do;
      cl   = exp(beta1_1);
      ka   = exp(beta2_1);
      ke   = exp(beta3_1);
   end; else do;
      cl   = exp(beta1_1 + beta1_diff);
      ka   = exp(beta2_1 + beta2_diff);
      ke   = exp(beta3_1 + beta3_diff);
   end;
   mean = dose*ke*ka*(exp(-ke*time)-exp(-ka*time))/cl/(ka-ke);
   model conc = mean;
run;
```

In the preceding statements, the parameters in the second group were expressed using offsets from parameters in the first group. For example, the parameter beta1_diff measures the change in log clearance between group 2 and group 1.

This simple reparameterization does not affect the model fit. The analysis of variance tables in Output 62.5.5 and Output 62.5.3 are identical. It does, however, affect the interpretation of the estimated quantities. Since the parameter beta1_diff measures the change in the log clearance rates between the groups, you can use the approximate 95% confidence limits in Output 62.5.5 to assess whether that quantity in the pharmacokinetic equation varies between groups. Only the confidence interval for the difference in the log clearances excludes 0. The intervals for beta2_diff and beta3_diff include 0.

Output 62.5.5 Fit Results for the Full Model in Difference Parameterization

The NLIN Procedure
Dependent Variable conc
Method: Gauss-Newton

NOTE: Convergence criterion met.

NOTE: An intercept was not specified for this model.

Source	DF	Sum of Squares	Mean Square	F Value	Approx Pr > F
Model	6	3247.9	541.3	358.56	<.0001
Error	92	138.9	1.5097		
Uncorrected Total	98	3386.8			

Parameter	Estimate	Approx Std Error	Approximate 95% Confidence Limits	
beta1_1	-3.5671	0.0864	-3.7387	-3.3956
beta2_1	0.4421	0.1349	0.1742	0.7101
beta3_1	-2.6230	0.1265	-2.8742	-2.3718
beta1_diff	0.5560	0.1368	0.2842	0.8278
beta2_diff	-0.0444	0.2402	-0.5214	0.4326
beta3_diff	0.1788	0.2054	-0.2291	0.5866

This suggests as the final model one where the absorption and elimination rates are the same for both groups and only the clearances are varied. The following statements fit this model and perform the sum of squares reduction test:

```
proc nlin data=theop;
   parms beta1_1=-3.22 beta2_1=0.47 beta3_1=-2.45
         beta1_diff=0;
   ka = exp(beta2_1);
   ke = exp(beta3_1);
   if (group=1) then do;
      cl = exp(beta1_1);
   end; else do;
      cl = exp(beta1_1 + beta1_diff);
   end;
   mean = dose*ke*ka*(exp(-ke*time)-exp(-ka*time))/cl/(ka-ke);
   model conc = mean;
   ods output Anova=aovred(rename=(ss=ssred ms=msred df=dfred));
   output out=predvals predicted=p;
run;
%SSReductionTest;
```

The results for this model with common absorption and elimination rates are shown in Output 62.5.6. The sum-of-squares reduction test comparing this model against the full model with six parameters shows—as expected—that the full model does not fit the data significantly better ($p = 0.6193$, Output 62.5.7).

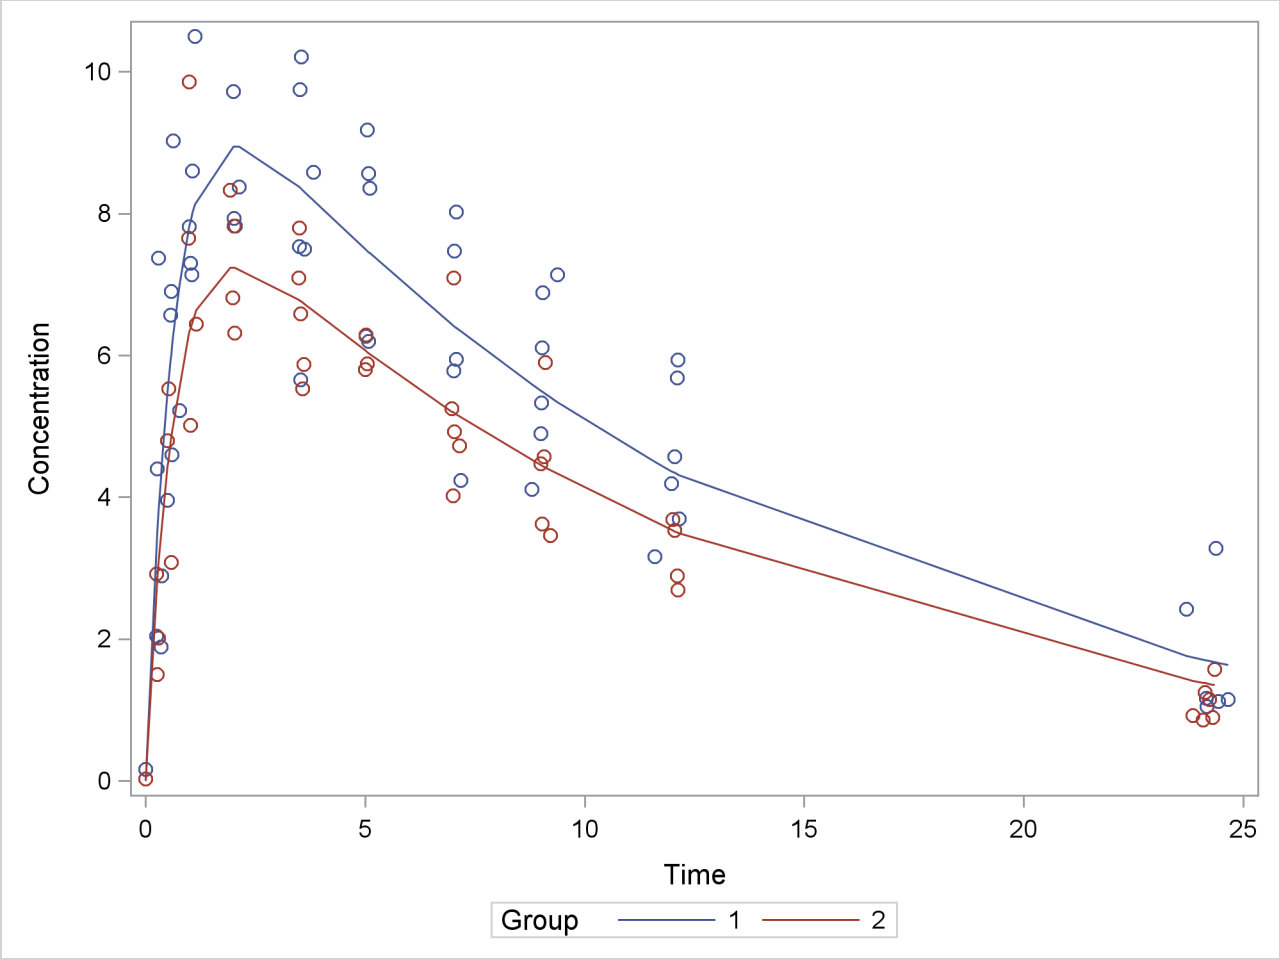
                          0.48151    0.619398
```

A plot of the observed and predicted values for this final model is obtained with the following statements:

```
proc sgplot data=predvals;
   scatter x=time y=conc / group=group;
   series  x=time y=p    / group=group name='fit';
   keylegend 'fit'       / across=2 title='Group';
   yaxis label='Concentration';
   xaxis label='Time';
run;
```

The plot is shown in Output 62.5.8.

Output 62.5.8 Observed and Fitted Values for Theophylline Data



The sum-of-squares reduction test is not the only possibility of performing linear-model style hypothesis testing in nonlinear models. You can also perform Wald-type testing of linear hypotheses about the parameter estimates. See Example 40.17 in Chapter 40, "The GLIMMIX Procedure," for an application of this example that uses the NLIN and GLIMMIX procedures to compare the parameters across groups and adjusts *p*-values for multiplicity.

Example 62.6: ODS Graphics and Diagnostics (Experimental)

The model in this example, taken from St. Laurent and Cook (1993), shows an unusual behavior in that the intrinsic curvature is substantially larger than the parameter-effects curvature. This example demonstrates how the new experimental features of PROC NLIN can be used to perform postconvergence diagnostics.

The model takes the form

$$\mathrm{E}[Y|x_1, x_2] = \alpha x_1 + \exp\{\gamma x_2\}$$

The following DATA step creates a small data set to be used in this example:

```
data contrived;
   input x1 x2 y;
   datalines;
-4.0   -2.5  -10.0
-3.0   -2.0   -5.0
-2.0   -1.5   -2.0
-1.0   -1.0   -1.0
 0.0    0.0    1.5
 1.0    1.0    4.0
 2.0    1.5    5.0
 3.0    2.0    6.0
 4.0    2.5    7.0
-3.5   -2.2   -7.1
-3.5   -1.7   -5.1
 3.5    0.7    6.1
 2.5    1.2    7.5
;
```

The model is fit with the following statements in the NLIN procedure:

```
ods graphics on;
proc nlin data=contrived bias hougaard
        NLINMEASURES plots(stats=all)=(diagnostics);
   parms alpha=2.0
         gamma=0.0;
   model y = alpha*x1 + exp(gamma*x2);
run;
ods graphics off;
```

Output 62.6.1 Bias, Skewness, and Global Nonlinearity Measures

The NLIN Procedure

Parameter	Estimate	Approx Std Error	Approximate 95% Confidence Limits		Skewness	Bias	Percent Bias
alpha	1.9378	0.4704	0.9024	2.9733	6.6491	0.5763	29.7
gamma	0.0718	0.7923	-1.6720	1.8156	-7.5596	-0.9982	-1390

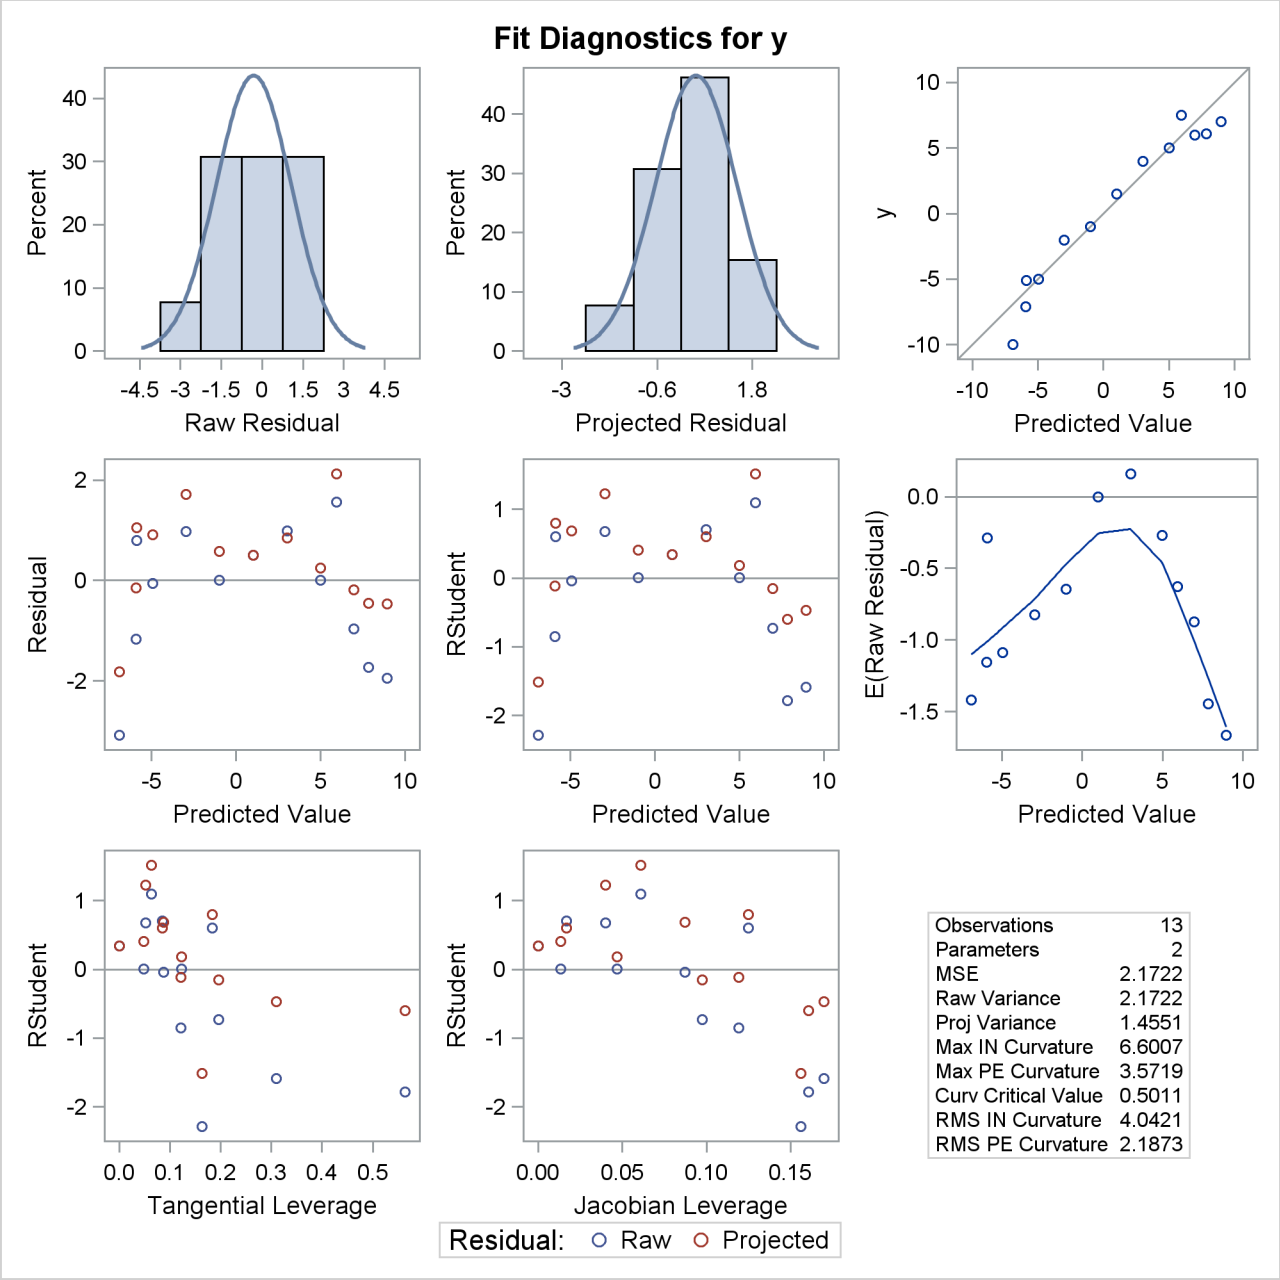
Output 62.6.1 *continued*

Global Nonlinearity Measures	
Max Intrinsic Curvature	6.6007
RMS Intrinsic Curvature	4.0421
Max Parameter-Effects Curvature	3.5719
RMS Parameter-Effects Curvature	2.1873
Curvature Critical Value	0.5011
Raw Residual Variance	2.1722
Projected Residual Variance	1.4551

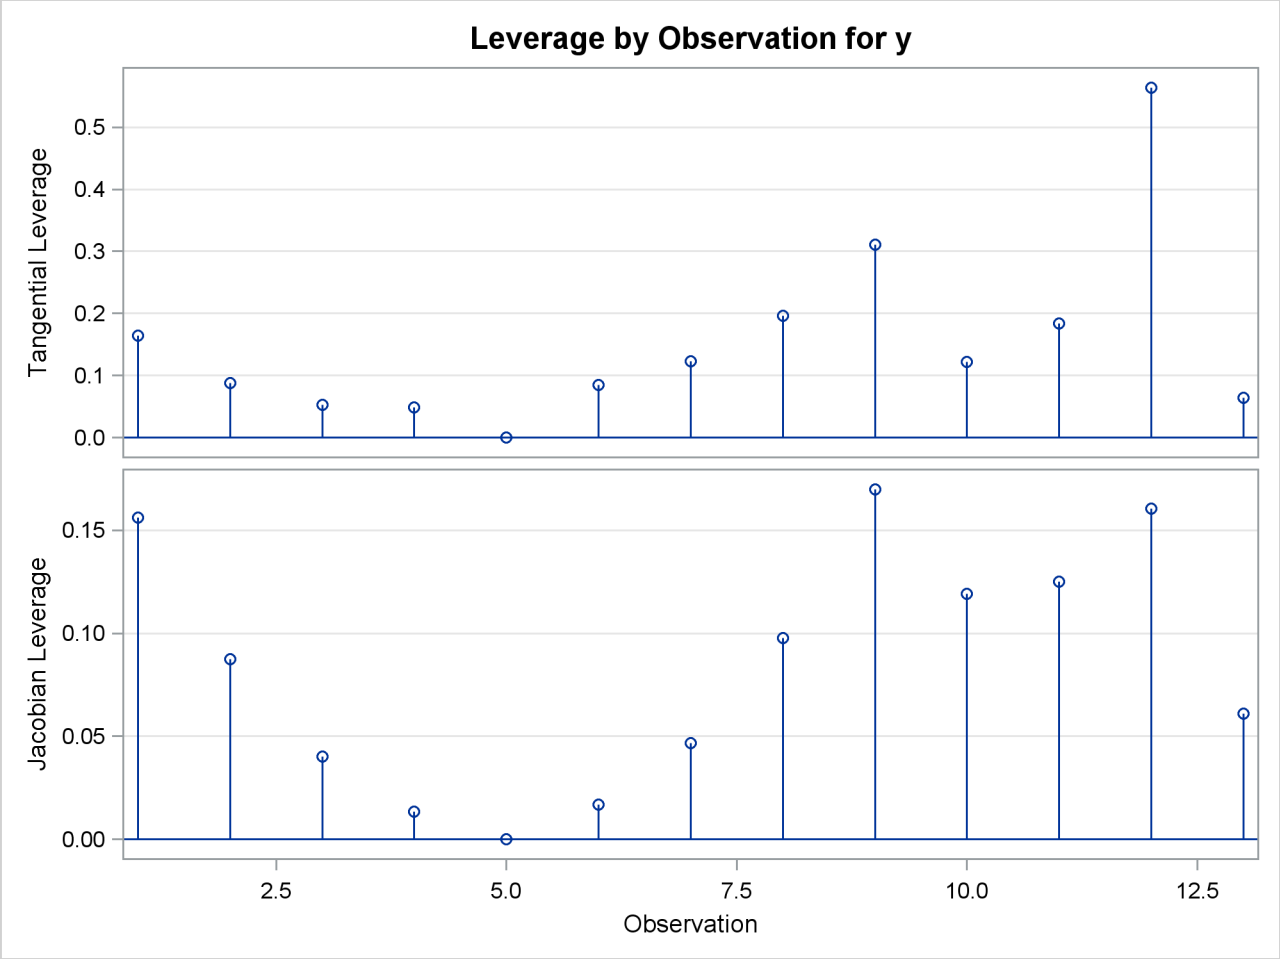
The bias, skewness, and both the maximum and RMS intrinsic curvatures, compared to the critical curvature value, show that the model is highly nonlinear (Output 62.6.1). As such, performing diagnostics with the raw residuals can be problematic because they might have undesirable statistical properties: a nonzero mean and a negative semidefinite (instead of zero) covariance with the predicted values and different variances. In addition, the use of tangential leverage is questionable in this case.

The partial results from this NLIN run are shown in Output 62.6.2, Output 62.6.3, and Output 62.6.4. The diagnostics plots corroborate the previously mentioned expectations: highly correlated raw residuals (with the predicted values), significant differences between tangential and Jacobian leverages and projected residuals which overcome some of the shortcomings of the raw residuals. Finally, considering the large intrinsic curvature, reparameterization might not make the model close-to-linear, perhaps necessitating the construction of another model.

Output 62.6.2 Diagnostics Panel



Output 62.6.3 Leverage Plots



Output 62.6.4 Local Influence Plot

Chapter 63

The NLMIXED Procedure

Contents

Overview: NLMIXED Procedure

Introduction

The NLMIXED procedure fits nonlinear mixed models—that is, models in which both fixed and random effects enter nonlinearly. These models have a wide variety of applications, two of the most common being pharmacokinetics and overdispersed binomial data. PROC NLMIXED enables you to specify a conditional distribution for your data (given the random effects) having either a standard form (normal, binomial, Poisson) or a general distribution that you code using SAS programming statements.

PROC NLMIXED fits nonlinear mixed models by maximizing an approximation to the likelihood integrated over the random effects. Different integral approximations are available, the principal ones being adaptive Gaussian quadrature and a first-order Taylor series approximation. A variety of alternative optimization techniques are available to carry out the maximization; the default is a dual quasi-Newton algorithm.

Successful convergence of the optimization problem results in parameter estimates along with their approximate standard errors based on the second derivative matrix of the likelihood function. PROC NLMIXED enables you to use the estimated model to construct predictions of arbitrary functions by using empirical Bayes estimates of the random effects. You can also estimate arbitrary functions of the nonrandom parameters, and PROC NLMIXED computes their approximate standard errors by using the delta method.

Literature on Nonlinear Mixed Models

Davidian and Giltinan (1995) and Vonesh and Chinchilli (1997) provide good overviews as well as general theoretical developments and examples of nonlinear mixed models. Pinheiro and Bates (1995) is a primary reference for the theory and computational techniques of PROC NLMIXED. They describe and compare several different integrated likelihood approximations and provide evidence that adaptive Gaussian quadrature is one of the best methods. Davidian and Gallant (1993) also use Gaussian quadrature for nonlinear

mixed models, although the smooth nonparametric density they advocate for the random effects is currently not available in PROC NLMIXED.

Traditional approaches to fitting nonlinear mixed models involve Taylor series expansions, expanding around either zero or the empirical best linear unbiased predictions of the random effects. The former is the basis for the well-known first-order method of Beal and Sheiner (1982, 1988) and Sheiner and Beal (1985), and it is optionally available in PROC NLMIXED. The latter is the basis for the estimation method of Lindstrom and Bates (1990), and it is not available in PROC NLMIXED. However, the closely related Laplacian approximation is an option; it is equivalent to adaptive Gaussian quadrature with only one quadrature point. The Laplacian approximation and its relationship to the Lindstrom-Bates method are discussed by Beal and Sheiner (1992), Wolfinger (1993), Vonesh (1992, 1996), Vonesh and Chinchilli (1997), and Wolfinger and Lin (1997).

A parallel literature exists in the area of generalized linear mixed models, in which random effects appear as a part of the linear predictor inside a link function. Taylor-series methods similar to those just described are discussed in articles such as Harville and Mee (1984), Stiratelli, Laird, and Ware (1984), Gilmour, Anderson, and Rae (1985), Goldstein (1991), Schall (1991), Engel and Keen (1992), Breslow and Clayton (1993), Wolfinger and O'Connell (1993), and McGilchrist (1994), but such methods have not been implemented in PROC NLMIXED because they can produce biased results in certain binary data situations (Rodriguez and Goldman 1995, Lin and Breslow 1996). Instead, a numerical quadrature approach is available in PROC NLMIXED, as discussed in Pierce and Sands (1975), Anderson and Aitkin (1985), Crouch and Spiegelman (1990), Hedeker and Gibbons (1994), Longford (1994), McCulloch (1994), Liu and Pierce (1994), and Diggle, Liang, and Zeger (1994).

Nonlinear mixed models have important applications in pharmacokinetics, and Roe (1997) provides a wide-ranging comparison of many popular techniques. Yuh et al. (1994) provide an extensive bibliography on nonlinear mixed models and their use in pharmacokinetics.

PROC NLMIXED Compared with Other SAS Procedures and Macros

The models fit by PROC NLMIXED can be viewed as generalizations of the random coefficient models fit by the MIXED procedure. This generalization allows the random coefficients to enter the model nonlinearly, whereas in PROC MIXED they enter linearly. With PROC MIXED you can perform both maximum likelihood and restricted maximum likelihood (REML) estimation, whereas PROC NLMIXED implements only maximum likelihood. This is because the analog to the REML method in PROC NLMIXED would involve a high-dimensional integral over all of the fixed-effects parameters, and this integral is typically not available in closed form. Finally, PROC MIXED assumes the data to be normally distributed, whereas PROC NLMIXED enables you to analyze data that are normal, binomial, or Poisson or that have any likelihood programmable with SAS statements.

PROC NLMIXED does not implement the same estimation techniques available with the NLINMIX macro or the default estimation method of the GLIMMIX procedure. These are based on the estimation methods of Lindstrom and Bates (1990), Breslow and Clayton (1993), and Wolfinger and O'Connell (1993), and they iteratively fit a set of generalized estimating equations (see Chapters 14 and 15 of Littell et al. 2006 and Wolfinger 1997). In contrast, PROC NLMIXED directly maximizes an approximate integrated likelihood. This remark also applies to the SAS/IML macros MIXNLIN (Vonesh and Chinchilli 1997) and NLMEM (Galecki 1998).

The GLIMMIX procedure also fits mixed models for nonnormal data with nonlinearity in the conditional mean function. In contrast to the NLMIXED procedure, PROC GLIMMIX assumes that the model contains a linear predictor that links covariates to the conditional mean of the response. The NLMIXED procedure is designed to handle general conditional mean functions, whether they contain a linear component or not. As mentioned earlier, the GLIMMIX procedure by default estimates parameters in generalized linear mixed models by pseudo-likelihood techniques, whereas PROC NLMIXED by default performs maximum likelihood estimation by adaptive Gauss-Hermite quadrature. This estimation method is also available with the GLIMMIX procedure (METHOD=QUAD in the PROC GLIMMIX statement).

PROC NLMIXED has close ties with the NLP procedure in SAS/OR software. PROC NLMIXED uses a subset of the optimization code underlying PROC NLP and has many of the same optimization-based options. Also, the programming statement functionality used by PROC NLMIXED is the same as that used by PROC NLP and the MODEL procedure in SAS/ETS software.

Getting Started: NLMIXED Procedure

Nonlinear Growth Curves with Gaussian Data

As an introductory example, consider the orange tree data of Draper and Smith (1981). These data consist of seven measurements of the trunk circumference (in millimeters) on each of five orange trees. You can input these data into a SAS data set as follows:

```
data tree;
  input tree day y;
  datalines;
1  118   30
1  484   58

   ... more lines ...

5 1582  177
;
```

Lindstrom and Bates (1990) and Pinheiro and Bates (1995) propose the following logistic nonlinear mixed model for these data:

$$y_{ij} = \frac{b_1 + u_{i1}}{1 + \exp[-(d_{ij} - b_2)/b_3]} + e_{ij}$$

Here, y_{ij} represents the jth measurement on the ith tree ($i = 1, \ldots, 5$; $j = 1, \ldots, 7$), d_{ij} is the corresponding day, b_1, b_2, b_3 are the fixed-effects parameters, u_{i1} are the random-effect parameters assumed to be iid $N(0, \sigma_u^2)$, and e_{ij} are the residual errors assumed to be iid $N(0, \sigma_e^2)$ and independent of the u_{i1}. This model has a logistic form, and the random-effect parameters u_{i1} enter the model linearly.

The statements to fit this nonlinear mixed model are as follows:

```
proc nlmixed data=tree;
   parms b1=190 b2=700 b3=350 s2u=1000 s2e=60;
   num = b1+u1;
   ex  = exp(-(day-b2)/b3);
   den = 1 + ex;
   model y ~ normal(num/den,s2e);
   random u1 ~ normal(0,s2u) subject=tree;
run;
```

The PROC NLMIXED statement invokes the procedure and inputs the tree data set. The PARMS statement identifies the unknown parameters and their starting values. Here there are three fixed-effects parameters (b1, b2, b3) and two variance components (s2u, s2e).

The next three statements are SAS programming statements specifying the logistic mixed model. A new variable u1 is included to identify the random effect. These statements are evaluated for every observation in the data set when the NLMIXED procedure computes the log likelihood function and its derivatives.

The MODEL statement defines the dependent variable and its conditional distribution given the random effects. Here a normal (Gaussian) conditional distribution is specified with mean num/den and variance s2e.

The RANDOM statement defines the single random effect to be u1, and specifies that it follow a normal distribution with mean 0 and variance s2u. The SUBJECT= argument in the RANDOM statement defines a variable indicating when the random effect obtains new realizations; in this case, it changes according to the values of the tree variable. PROC NLMIXED assumes that the input data set is clustered according to the levels of the tree variable; that is, all observations from the same tree occur sequentially in the input data set.

The output from this analysis is as follows.

Figure 63.1 Model Specifications

The NLMIXED Procedure

Specifications

Data Set	WORK.TREE
Dependent Variable	y
Distribution for Dependent Variable	Normal
Random Effects	u1
Distribution for Random Effects	Normal
Subject Variable	tree
Optimization Technique	Dual Quasi-Newton
Integration Method	Adaptive Gaussian Quadrature

The "Specifications" table lists basic information about the nonlinear mixed model you have specified (Figure 63.1). Included are the input data set, the dependent and subject variables, the random effects, the relevant distributions, and the type of optimization. The "Dimensions" table lists various counts related to the model, including the number of observations, subjects, and parameters (Figure 63.2). These quantities are useful for checking that you have specified your data set and model correctly. Also listed is the number of quadrature points that PROC NLMIXED has selected based on the evaluation of the log likelihood at the

starting values of the parameters. Here, only one quadrature point is necessary because the random-effect parameters u_{i1} enter the model linearly. (The Gauss-Hermite quadrature with a single quadrature point results in the Laplace approximation of the log likelihood.)

3	8	131.614077	0.030583	0.009809	-0.02796
4	10	131.572522	0.041555	0.001186	-0.01344
5	11	131.571895	0.000627	0.0002	-0.00121
6	13	131.571889	5.549E-6	0.000092	-7.68E-6
7	15	131.571888	1.096E-6	6.097E-6	-1.29E-6

NOTE: GCONV convergence criterion satisfied.

The "Iteration History" table records the history of the minimization of the negative log likelihood (Figure 63.4). For each iteration of the quasi-Newton optimization, values are listed for the number of function calls, the value of the negative log likelihood, the difference from the previous iteration, the absolute value of the largest gradient, and the slope of the search direction. The note at the bottom of the table indicates that the algorithm has converged successfully according to the GCONV convergence criterion, a standard criterion computed using a quadratic form in the gradient and the inverse Hessian.

The final maximized value of the log likelihood as well as the information criterion of Akaike (AIC), its small sample bias corrected version (AICC), and the Bayesian information criterion (BIC) in the "smaller is better" form appear in the "Fit Statistics" table (Figure 63.5). These statistics can be used to compare different nonlinear mixed models.

Figure 63.5 Fit Statistics for Growth Curve Model

Fit Statistics

-2 Log Likelihood	263.1
AIC (smaller is better)	273.1
AICC (smaller is better)	275.2
BIC (smaller is better)	271.2

Figure 63.6 Parameter Estimates at Convergence

Parameter Estimates

Parameter	Estimate	Standard Error	DF	t Value	Pr > |t|	Alpha	Lower
b1	192.05	15.6473	4	12.27	0.0003	0.05	148.61
b2	727.90	35.2472	4	20.65	<.0001	0.05	630.04
b3	348.07	27.0790	4	12.85	0.0002	0.05	272.88
s2u	999.88	647.44	4	1.54	0.1974	0.05	-797.70
s2e	61.5139	15.8831	4	3.87	0.0179	0.05	17.4153

Parameter Estimates

Parameter	Upper	Gradient
b1	235.50	1.154E-6
b2	825.76	5.289E-6
b3	423.25	-6.1E-6
s2u	2797.45	-3.84E-6
s2e	105.61	2.892E-6

The maximum likelihood estimates of the five parameters and their approximate standard errors computed using the final Hessian matrix are displayed in the "Parameter Estimates" table (Figure 63.6). Approximate t-values and Wald-type confidence limits are also provided, with degrees of freedom equal to the number of subjects minus the number of random effects. You should interpret these statistics cautiously for variance parameters like s2u and s2e. The final column in the output shows the gradient vector at the optimization solution. Each element appears to be sufficiently small to indicate a stationary point.

Since the random-effect parameters u_{i1} enter the model linearly, you can obtain equivalent results by using the first-order method (specify METHOD=FIRO in the PROC NLMIXED statement).

Logistic-Normal Model with Binomial Data

This example analyzes the data from Beitler and Landis (1985), which represent results from a multi-center clinical trial investigating the effectiveness of two topical cream treatments (active drug, control) in curing an infection. For each of eight clinics, the number of trials and favorable cures are recorded for each treatment. The SAS data set is as follows.

```
data infection;
  input clinic t x n;
  datalines;
1 1 11 36
1 0 10 37
2 1 16 20
2 0 22 32
3 1 14 19
3 0  7 19
4 1  2 16
4 0  1 17
5 1  6 17
5 0  0 12
6 1  1 11
6 0  0 10
7 1  1  5
7 0  1  9
8 1  4  6
8 0  6  7
;
```

Suppose n_{ij} denotes the number of trials for the ith clinic and the jth treatment ($i = 1, \ldots, 8; j = 0, 1$), and x_{ij} denotes the corresponding number of favorable cures. Then a reasonable model for the preceding data is the following logistic model with random effects:

$$x_{ij}|u_i \sim \text{Binomial}(n_{ij}, p_{ij})$$

and

$$\eta_{ij} = \log\left(\frac{p_{ij}}{1-p_{ij}}\right) = \beta_0 + \beta_1 t_j + u_i$$

The notation t_j indicates the jth treatment, and the u_i are assumed to be iid $N(0, \sigma_u^2)$.

The PROC NLMIXED statements to fit this model are as follows:

```
proc nlmixed data=infection;
   parms beta0=-1 beta1=1 s2u=2;
   eta    = beta0 + beta1*t + u;
   expeta = exp(eta);
   p      = expeta/(1+expeta);
   model x ~ binomial(n,p);
   random u ~ normal(0,s2u) subject=clinic;
   predict eta out=eta;
   estimate '1/beta1' 1/beta1;
run;
```

The PROC NLMIXED statement invokes the procedure, and the PARMS statement defines the parameters and their starting values. The next three statements define p_{ij}, and the MODEL statement defines the conditional distribution of x_{ij} to be binomial. The RANDOM statement defines u to be the random effect with subjects defined by the clinic variable.

The PREDICT statement constructs predictions for each observation in the input data set. For this example, predictions of η_{ij} and approximate standard errors of prediction are output to a data set named eta. These predictions include empirical Bayes estimates of the random effects u_i.

The ESTIMATE statement requests an estimate of the reciprocal of β_1.

The output for this model is as follows.

Figure 63.7 Model Information and Dimensions for Logistic-Normal Model

The NLMIXED Procedure

Specifications

Data Set	WORK.INFECTION
Dependent Variable	x
Distribution for Dependent Variable	Binomial
Random Effects	u
Distribution for Random Effects	Normal
Subject Variable	clinic
Optimization Technique	Dual Quasi-Newton
Integration Method	Adaptive Gaussian Quadrature

Dimensions

Observations Used	16
Observations Not Used	0
Total Observations	16
Subjects	8
Max Obs Per Subject	2
Parameters	3
Quadrature Points	5

The "Specifications" table provides basic information about the nonlinear mixed model (Figure 63.7). For example, the distribution of the response variable, conditional on normally distributed random effects, is binomial. The "Dimensions" table provides counts of various variables. You should check this table to make sure the data set and model have been entered properly. PROC NLMIXED selects five quadrature points to achieve the default accuracy in the likelihood calculations.

Figure 63.8 Starting Values of Parameter Estimates

Parameters

beta0	beta1	s2u	NegLogLike
-1	1	2	37.5945925

The "Parameters" table lists the starting point of the optimization and the negative log likelihood at the starting values (Figure 63.8).

Figure 63.9 Iteration History and Fit Statistics for Logistic-Normal Model

Iteration History

Iter	Calls	NegLogLike	Diff	MaxGrad	Slope
1	2	37.3622692	0.232323	2.882077	-19.3762
2	3	37.1460375	0.216232	0.921926	-0.82852
3	5	37.0300936	0.115944	0.315897	-0.59175
4	6	37.0223017	0.007792	0.01906	-0.01615
5	7	37.0222472	0.000054	0.001743	-0.00011
6	9	37.0222466	6.57E-7	0.000091	-1.28E-6
7	11	37.0222466	5.38E-10	2.078E-6	-1.1E-9

NOTE: GCONV convergence criterion satisfied.

Fit Statistics

-2 Log Likelihood	74.0
AIC (smaller is better)	80.0
AICC (smaller is better)	82.0
BIC (smaller is better)	80.3

The "Iteration History" table indicates successful convergence in seven iterations (Figure 63.9). The "Fit Statistics" table lists some useful statistics based on the maximized value of the log likelihood.

Figure 63.10 Parameter Estimates for Logistic-Normal Model

Parameter Estimates

Parameter	Estimate	Standard Error	DF	t Value	Pr > |t|	Alpha	Lower
beta0	-1.1974	0.5561	7	-2.15	0.0683	0.05	-2.5123
beta1	0.7385	0.3004	7	2.46	0.0436	0.05	0.02806
s2u	1.9591	1.1903	7	1.65	0.1438	0.05	-0.8554

Parameter Estimates

Parameter	Upper	Gradient
beta0	0.1175	-3.1E-7
beta1	1.4488	-2.08E-6
s2u	4.7736	-2.48E-7

The "Parameter Estimates" table indicates marginal significance of the two fixed-effects parameters (Figure 63.10). The positive value of the estimate of β_1 indicates that the treatment significantly increases the chance of a favorable cure.

Figure 63.11 Table of Additional Estimates

Additional Estimates

Label	Estimate	Standard Error	DF	t Value	Pr > |t|	Alpha	Lower	Upper
1/beta1	1.3542	0.5509	7	2.46	0.0436	0.05	0.05146	2.6569

The "Additional Estimates" table displays results from the ESTIMATE statement (Figure 63.11). The estimate of $1/\beta_1$ equals $1/0.7385 = 1.3542$ and its standard error equals $0.3004/0.7385^2 = 0.5509$ by the delta method (Billingsley 1986, Cox 1998). Note that this particular approximation produces a t-statistic identical to that for the estimate of β_1.

Not shown is the eta data set, which contains the original 16 observations and predictions of the η_{ij}.

Syntax: NLMIXED Procedure

The following statements can be used with the NLMIXED procedure:

PROC NLMIXED < *options* > ;
ARRAY *array specification* ;
BOUNDS *boundary constraints* ;
BY *variables* ;
CONTRAST *'label' expression* < *,expression* >< *options* > ;
ESTIMATE *'label' expression* < *options* > ;
ID *names* ;
MODEL *model specification* ;
PARMS *parameters and starting values* ;
PREDICT *expression* **OUT=***SAS-data-set* < *options* > ;
RANDOM *random effects specification* ;
REPLICATE *variable* ;
Program statements ;

The following sections provide a detailed description of each of these statements.

PROC NLMIXED Statement

PROC NLMIXED < *options* > ;

This statement invokes the NLMIXED procedure. A large number of options are available in the PROC NLMIXED statement, and Table 63.1 categorizes them according to function.

Table 63.1 PROC NLMIXED Statement Options

Option	Description
Basic Options	
DATA=	input data set
METHOD=	integration method
Displayed Output Specifications	
START	gradient at starting values
HESS	Hessian matrix
ITDETAILS	iteration details
CORR	correlation matrix
COV	covariance matrix
ECORR	correlation matrix of additional estimates
ECOV	covariance matrix of additional estimates
EDER	derivatives of additional estimates
EMPIRICAL	empirical ("sandwich") estimator of covariance matrix
ALPHA=	alpha for confidence limits
DF=	degrees of freedom for p-values and confidence limits
Debugging Output	
LIST	model program, variables
LISTCODE	compiled model program
LISTDEP	model dependency listing
LISTDER	model derivatives
XREF	model cross references
FLOW	model execution messages
TRACE	detailed model execution messages
Quadrature Options	
NOAD	no adaptive centering
NOADSCALE	no adaptive scaling
OUTQ=	output data set
QFAC=	search factor
QMAX=	maximum points
QPOINTS=	number of points
QSCALEFAC=	scale factor
QTOL=	tolerance
Empirical Bayes Options	
EBSTEPS=	number of Newton steps
EBSUBSTEPS=	number of substeps
EBSSFRAC=	step-shortening fraction
EBSSTOL=	step-shortening tolerance
EBTOL=	convergence tolerance
EBOPT	comprehensive optimization
EBZSTART	zero starting values

Table 63.1 *continued*

Option	Description
Optimization Specifications	
TECHNIQUE=	minimization technique
UPDATE=	update technique
LINESEARCH=	line-search method
LSPRECISION=	line-search precision
HESCAL=	type of Hessian scaling
INHESSIAN<=>	start for approximated Hessian
RESTART=	iteration number for update restart
OPTCHECK<=>	check optimality in neighborhood
Derivatives Specifications	
FD<=>	finite-difference derivatives
FDHESSIAN<=>	finite-difference second derivatives
DIAHES	use only diagonal of Hessian
Constraint Specifications	
LCEPSILON=	range for active constraints
LCDEACT=	LM tolerance for deactivating
LCSINGULAR=	tolerance for dependent constraints
Termination Criteria Specifications	
MAXFUNC=	maximum number of function calls
MAXITER=	maximum number of iterations
MINITER=	minimum number of iterations
MAXTIME=	upper limit seconds of CPU time
ABSCONV=	absolute function convergence criterion
ABSFCONV=	absolute function convergence criterion
ABSGCONV=	absolute gradient convergence criterion
ABSXCONV=	absolute parameter convergence criterion
FCONV=	relative function convergence criterion
FCONV2=	relative function convergence criterion
GCONV=	relative gradient convergence criterion
XCONV=	relative parameter convergence criterion
FDIGITS=	number accurate digits in objective function
FSIZE=	used in FCONV, GCONV criterion
XSIZE=	used in XCONV criterion
Step Length Specifications	
DAMPSTEP<=>	damped steps in line search
MAXSTEP=	maximum trust-region radius
INSTEP=	initial trust-region radius
Singularity Tolerances	
SINGCHOL=	tolerance for Cholesky roots
SINGHESS=	tolerance for Hessian

Table 63.1 *continued*

Option	Description
SINGSWEEP=	tolerance for sweep
SINGVAR=	tolerance for variances
Covariance Matrix Tolerances	
ASINGULAR=	absolute singularity for inertia
MSINGULAR=	relative M singularity for inertia
VSINGULAR=	relative V singularity for inertia
G4=	threshold for Moore-Penrose inverse
COVSING=	tolerance for singular COV matrix
CFACTOR=	multiplication factor for COV matrix

These options are described in alphabetical order. For a description of the mathematical notation used in the following sections, see the section "Modeling Assumptions and Notation" on page 5217.

ABSCONV=*r*

ABSTOL=*r*

specifies an absolute function convergence criterion. For minimization, termination requires $f(\boldsymbol{\theta}^{(k)}) \leq r$. The default value of r is the negative square root of the largest double-precision value, which serves only as a protection against overflows.

ABSFCONV=*r* **< [***n***] >**

ABSFTOL=*r* **< [***n***] >**

specifies an absolute function convergence criterion. For all techniques except NMSIMP, termination requires a small change of the function value in successive iterations:

$$|f(\boldsymbol{\theta}^{(k-1)}) - f(\boldsymbol{\theta}^{(k)})| \leq r$$

The same formula is used for the NMSIMP technique, but $\boldsymbol{\theta}^{(k)}$ is defined as the vertex with the lowest function value, and $\boldsymbol{\theta}^{(k-1)}$ is defined as the vertex with the highest function value in the simplex. The default value is $r = 0$. The optional integer value n specifies the number of successive iterations for which the criterion must be satisfied before the process can be terminated.

ABSGCONV=*r* **< [***n***] >**

ABSGTOL=*r* **< [***n***] >**

specifies an absolute gradient convergence criterion. Termination requires the maximum absolute gradient element to be small:

$$\max_j |g_j(\boldsymbol{\theta}^{(k)})| \leq r$$

This criterion is not used by the NMSIMP technique. The default value is $r = 1\text{E}{-5}$. The optional integer value n specifies the number of successive iterations for which the criterion must be satisfied before the process can be terminated.

ABSXCONV=*r*< [*n*] >

ABSXTOL=*r*< [*n*] >

specifies an absolute parameter convergence criterion. For all techniques except NMSIMP, termination requires a small Euclidean distance between successive parameter vectors,

$$\| \boldsymbol{\theta}^{(k)} - \boldsymbol{\theta}^{(k-1)} \|_2 \leq r$$

For the NMSIMP technique, termination requires either a small length $\alpha^{(k)}$ of the vertices of a restart simplex,

$$\alpha^{(k)} \leq r$$

or a small simplex size,

$$\delta^{(k)} \leq r$$

where the simplex size $\delta^{(k)}$ is defined as the L1 distance from the simplex vertex $\boldsymbol{\xi}^{(k)}$ with the smallest function value to the other n simplex points $\boldsymbol{\theta}_l^{(k)} \neq \boldsymbol{\xi}^{(k)}$:

$$\delta^{(k)} = \sum_{\boldsymbol{\theta}_l \neq y} \| \boldsymbol{\theta}_l^{(k)} - \boldsymbol{\xi}^{(k)} \|_1$$

The default is $r = 1\text{E}{-8}$ for the NMSIMP technique and $r = 0$ otherwise. The optional integer value n specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate.

ALPHA=α

specifies the alpha level to be used in computing confidence limits. The default value is 0.05.

ASINGULAR=*r*

ASING=*r*

specifies an absolute singularity criterion for the computation of the inertia (number of positive, negative, and zero eigenvalues) of the Hessian and its projected forms. The default value is the square root of the smallest positive double-precision value.

CFACTOR=*f*

specifies a multiplication factor f for the estimated covariance matrix of the parameter estimates.

COV

requests the approximate covariance matrix for the parameter estimates.

CORR

requests the approximate correlation matrix for the parameter estimates.

COVSING=*r*> 0

specifies a nonnegative threshold that determines whether the eigenvalues of a singular Hessian matrix are considered to be zero.

DAMPSTEP<=*r*>

DS<=*r*>

specifies that the initial step-size value $\alpha^{(0)}$ for each line search (used by the QUANEW, CONGRA, or NEWRAP technique) cannot be larger than r times the step-size value used in the former iteration. If you specify the DAMPSTEP option without factor r, the default value is $r = 2$. The DAMPSTEP=r option can prevent the line-search algorithm from repeatedly stepping into regions where some objective functions are difficult to compute or where they could lead to floating-point overflows during the computation of objective functions and their derivatives. The DAMPSTEP=r option can save time-costly function calls that result in very small step sizes α. For more details on setting the start values of each line search, see the section "Restricting the Step Length" on page 5232.

DATA=*SAS-data-set*

specifies the input data set. Observations in this data set are used to compute the log likelihood function that you specify with PROC NLMIXED statements.

NOTE: If you are using a RANDOM statement, the input data set must be clustered according to the SUBJECT= variable. One easy way to accomplish this is to sort your data by the SUBJECT= variable prior to calling PROC NLMIXED. PROC NLMIXED does not sort the input data set for you.

DF=*d*

specifies the degrees of freedom to be used in computing p values and confidence limits. The default value is the number of subjects minus the number of random effects for random effects models, and the number of observations otherwise.

DIAHES

specifies that only the diagonal of the Hessian is used.

EBOPT

requests that a more comprehensive optimization be carried out if the default empirical Bayes optimization fails to converge.

EBSSFRAC=*r* > 0

specifies the step-shortening fraction to be used while computing empirical Bayes estimates of the random effects. The default value is 0.8.

EBSSTOL=*r* ≥ 0

specifies the objective function tolerance for determining the cessation of step-shortening while computing empirical Bayes estimates of the random effects. The default value is $r = 1\text{E}{-8}$.

EBSTEPS=*n* ≥ 0

specifies the maximum number of Newton steps for computing empirical Bayes estimates of random effects. The default value is $n = 50$.

EBSUBSTEPS=*n* ≥ 0

specifies the maximum number of step-shortenings for computing empirical Bayes estimates of random effects. The default value is $n = 20$.

EBTOL=*r* ≥ 0

specifies the convergence tolerance for empirical Bayes estimation. The default value is $r = \epsilon\text{E}4$, where ϵ is the machine precision. This default value equals approximately $1\text{E}{-12}$ on most machines.

EBZSTART

requests that a zero be used as starting values during empirical Bayes estimation. By default, the starting values are set equal to the estimates from the previous iteration (or zero for the first iteration).

ECOV

requests the approximate covariance matrix for all expressions specified in ESTIMATE statements.

ECORR

requests the approximate correlation matrix for all expressions specified in ESTIMATE statements.

EDER

requests the derivatives of all expressions specified in ESTIMATE statements with respect to each of the model parameters.

EMPIRICAL

requests that the covariance matrix of the parameter estimates be computed as a likelihood-based empirical ("sandwich") estimator (White 1982). If $f(\boldsymbol{\theta}) = -\log\{m(\boldsymbol{\theta})\}$ is the objective function for the optimization and $m(\boldsymbol{\theta})$ denotes the marginal log likelihood (see the section "Modeling Assumptions and Notation" on page 5217 for notation and further definitions) the empirical estimator is computed as

$$\mathbf{H}(\hat{\boldsymbol{\theta}})^{-1}\left(\sum_{i=1}^{s}\mathbf{g}_i(\hat{\boldsymbol{\theta}})\mathbf{g}_i(\hat{\boldsymbol{\theta}})'\right)\mathbf{H}(\hat{\boldsymbol{\theta}})^{-1}$$

where $\mathbf{H}$ is the second derivative matrix of f and $\mathbf{g}_i$ is the first derivative of the contribution to f by the ith subject. If you choose the EMPIRICAL option, this estimator of the covariance matrix of the parameter estimates replaces the model-based estimator $\mathbf{H}(\hat{\boldsymbol{\theta}})^{-1}$ in subsequent calculations. You can output the subject-specific gradients $\mathbf{g}_i$ to a SAS data set with the SUBGRADIENT option in the PROC NLMIXED statement.

The EMPIRICAL option requires the presence of a RANDOM statement and is available for METHOD=GAUSS and METHOD=ISAMP only.

FCONV=*r*<[*n*]>

FTOL=*r*<[*n*]>

specifies a relative function convergence criterion. For all techniques except NMSIMP, termination requires a small relative change of the function value in successive iterations,

$$\frac{|f(\boldsymbol{\theta}^{(k)}) - f(\boldsymbol{\theta}^{(k-1)})|}{\max(|f(\boldsymbol{\theta}^{(k-1)})|, \text{FSIZE})} \leq r$$

where FSIZE is defined by the FSIZE= option. The same formula is used for the NMSIMP technique, but $\boldsymbol{\theta}^{(k)}$ is defined as the vertex with the lowest function value, and $\boldsymbol{\theta}^{(k-1)}$ is defined as the vertex with the highest function value in the simplex. The default is $r = 10^{-\text{FDIGITS}}$, where FDIGITS is the value of the FDIGITS= option. The optional integer value n specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate.

FCONV2=*r*< [*n*] >

FTOL2=*r*< [*n*] >

specifies another function convergence criterion. For all techniques except NMSIMP, termination requires a small predicted reduction

$$df^{(k)} \approx f(\boldsymbol{\theta}^{(k)}) - f(\boldsymbol{\theta}^{(k)} + \mathbf{s}^{(k)})$$

of the objective function. The predicted reduction

$$\begin{aligned} df^{(k)} &= -\mathbf{g}^{(k)\prime}\mathbf{s}^{(k)} - \frac{1}{2}\mathbf{s}^{(k)\prime}\mathbf{H}^{(k)}\mathbf{s}^{(k)} \\ &= -\frac{1}{2}\mathbf{s}^{(k)\prime}\mathbf{g}^{(k)} \\ &\leq r \end{aligned}$$

is computed by approximating the objective function f by the first two terms of the Taylor series and substituting the Newton step:

$$\mathbf{s}^{(k)} = -[\mathbf{H}^{(k)}]^{-1}\mathbf{g}^{(k)}$$

For the NMSIMP technique, termination requires a small standard deviation of the function values of the $n+1$ simplex vertices $\boldsymbol{\theta}_l^{(k)}$, $l = 0, \ldots, n$,

$$\sqrt{\frac{1}{n+1}\sum_l \left[f(\boldsymbol{\theta}_l^{(k)}) - \overline{f}(\boldsymbol{\theta}^{(k)})\right]^2} \leq r$$

where $\overline{f}(\boldsymbol{\theta}^{(k)}) = \frac{1}{n+1}\sum_l f(\boldsymbol{\theta}_l^{(k)})$. If there are n_{act} boundary constraints active at $\boldsymbol{\theta}^{(k)}$, the mean and standard deviation are computed only for the $n + 1 - n_{act}$ unconstrained vertices. The default value is $r = 1\text{E}{-6}$ for the NMSIMP technique and $r = 0$ otherwise. The optional integer value n specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate.

FD < = FORWARD | CENTRAL |*r* >

specifies that all derivatives be computed using finite difference approximations. The following specifications are permitted:

FD — is equivalent to FD=100.

FD=CENTRAL — uses central differences.

FD=FORWARD — uses forward differences.

FD=*r* — uses central differences for the initial and final evaluations of the gradient and for the Hessian. During iteration, start with forward differences and switch to a corresponding central-difference formula during the iteration process when one of the following two criteria is satisfied:

- The absolute maximum gradient element is less than or equal to r times the ABSGCONV= threshold.
- The normalized predicted function reduction (see the GTOL option) is less than or equal to $\max(1\text{E}-6,\ r \times \text{GTOL})$. The 1E−6 ensures that the switch is done, even if you set the GTOL threshold to zero.

Note that the FD and FDHESSIAN options cannot apply at the same time. The FDHESSIAN option is ignored when only first-order derivatives are used. See the section "Finite-Difference Approximations of Derivatives" on page 5228 for more information.

FDHESSIAN< =FORWARD | CENTRAL >
FDHES< =FORWARD | CENTRAL >
FDH< =FORWARD | CENTRAL >
specifies that second-order derivatives be computed using finite difference approximations based on evaluations of the gradients.

FDHESSIAN=FORWARD uses forward differences.

FDHESSIAN=CENTRAL uses central differences.

FDHESSIAN uses forward differences for the Hessian except for the initial and final output.

Note that the FD and FDHESSIAN options cannot apply at the same time. See the section "Finite-Difference Approximations of Derivatives" on page 5228 for more information.

FDIGITS=*r*
specifies the number of accurate digits in evaluations of the objective function. Fractional values such as FDIGITS=4.7 are allowed. The default value is $r = -\log_{10}\epsilon$, where ϵ is the machine precision. The value of r is used to compute the interval size h for the computation of finite-difference approximations of the derivatives of the objective function and for the default value of the FCONV= option.

FLOW
displays a message for each statement in the model program as it is executed. This debugging option is very rarely needed and produces voluminous output.

FSIZE=*r*
specifies the FSIZE parameter of the relative function and relative gradient termination criteria. The default value is $r = 0$. For more details, see the FCONV= and GCONV= options.

G4=*n* > 0
specifies a dimension to determine the type of generalized inverse to use when the approximate covariance matrix of the parameter estimates is singular. The default value of n is 60. See the section "Covariance Matrix" on page 5237 for more information.

GCONV=*r***< [***n***] >**
GTOL=*r***< [***n***] >**
specifies a relative gradient convergence criterion. For all techniques except CONGRA and NMSIMP, termination requires that the normalized predicted function reduction is small,

$$\frac{\mathbf{g}(\boldsymbol{\theta}^{(k)})'[\mathbf{H}^{(k)}]^{-1}\mathbf{g}(\boldsymbol{\theta}^{(k)})}{\max(|f(\boldsymbol{\theta}^{(k)})|, \text{FSIZE})} \leq r$$

where FSIZE is defined by the FSIZE= option. For the CONGRA technique (where a reliable Hessian estimate H is not available), the following criterion is used:

$$\frac{\| \mathbf{g}(\boldsymbol{\theta}^{(k)}) \|_2^2 \quad \| \mathbf{s}(\boldsymbol{\theta}^{(k)}) \|_2}{\| \mathbf{g}(\boldsymbol{\theta}^{(k)}) - \mathbf{g}(\boldsymbol{\theta}^{(k-1)}) \|_2 \max(|f(\boldsymbol{\theta}^{(k)})|, \text{FSIZE})} \leq r$$

This criterion is not used by the NMSIMP technique.

The default value is $r = 1E{-}8$. The optional integer value n specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate.

HESCAL=0|1|2|3

HS=0|1|2|3

specifies the scaling version of the Hessian matrix used in NRRIDG, TRUREG, NEWRAP, or DBLDOG optimization.

If HS is not equal to 0, the first iteration and each restart iteration sets the diagonal scaling matrix $\mathbf{D}^{(0)} = \text{diag}(d_i^{(0)})$:

$$d_i^{(0)} = \sqrt{\max(|H_{i,i}^{(0)}|, \epsilon)}$$

where $H_{i,i}^{(0)}$ are the diagonal elements of the Hessian. In every other iteration, the diagonal scaling matrix $\mathbf{D}^{(0)} = \text{diag}(d_i^{(0)})$ is updated depending on the HS option:

HS=0 specifies that no scaling is done.

HS=1 specifies the Moré (1978) scaling update:

$$d_i^{(k+1)} = \max\left[d_i^{(k)}, \sqrt{\max(|H_{i,i}^{(k)}|, \epsilon)}\right]$$

HS=2 specifies the Dennis, Gay, and Welsch (1981) scaling update:

$$d_i^{(k+1)} = \max\left[0.6 * d_i^{(k)}, \sqrt{\max(|H_{i,i}^{(k)}|, \epsilon)}\right]$$

HS=3 specifies that d_i is reset in each iteration:

$$d_i^{(k+1)} = \sqrt{\max(|H_{i,i}^{(k)}|, \epsilon)}$$

In each scaling update, ϵ is the relative machine precision. The default value is HS=0. Scaling of the Hessian can be time-consuming in the case where general linear constraints are active.

HESS

requests the display of the final Hessian matrix after optimization. If you also specify the START option, then the Hessian at the starting values is also printed.

INHESSIAN<=*r*>

INHESS<=*r*>

specifies how the initial estimate of the approximate Hessian is defined for the quasi-Newton techniques QUANEW and DBLDOG. There are two alternatives:

- If you do not use the r specification, the initial estimate of the approximate Hessian is set to the Hessian at $\boldsymbol{\theta}^{(0)}$.
- If you do use the r specification, the initial estimate of the approximate Hessian is set to the multiple of the identity matrix, $r\mathbf{I}$.

By default, if you do not specify the option INHESSIAN=r, the initial estimate of the approximate Hessian is set to the multiple of the identity matrix $r\mathbf{I}$, where the scalar r is computed from the magnitude of the initial gradient.

INSTEP=r

reduces the length of the first trial step during the line search of the first iterations. For highly nonlinear objective functions, such as the EXP function, the default initial radius of the trust-region algorithm TRUREG or DBLDOG or the default step length of the line-search algorithms can result in arithmetic overflows. If this occurs, you should specify decreasing values of $0 < r < 1$ such as INSTEP=1E−1, INSTEP=1E−2, INSTEP=1E−4, and so on, until the iteration starts successfully.

- For trust-region algorithms (TRUREG, DBLDOG), the INSTEP= option specifies a factor $r > 0$ for the initial radius $\Delta^{(0)}$ of the trust region. The default initial trust-region radius is the length of the scaled gradient. This step corresponds to the default radius factor of $r = 1$.
- For line-search algorithms (NEWRAP, CONGRA, QUANEW), the INSTEP= option specifies an upper bound for the initial step length for the line search during the first five iterations. The default initial step length is $r = 1$.
- For the Nelder-Mead simplex algorithm, using TECH=NMSIMP, the INSTEP=r option defines the size of the start simplex.

For more details, see the section "Computational Problems" on page 5234.

ITDETAILS

requests a more complete iteration history, including the current values of the parameter estimates, their gradients, and additional optimization statistics. For further details, see the section "Iterations" on page 5240.

LCDEACT=r

LCD=r

specifies a threshold r for the Lagrange multiplier that determines whether an active inequality constraint remains active or can be deactivated. During minimization, an active inequality constraint can be deactivated only if its Lagrange multiplier is less than the threshold value $r < 0$. The default value is

$$r = -\min(0.01, \max(0.1 \times \text{ABSGCONV}, 0.001 \times \text{gmax}^{(k)}))$$

where ABSGCONV is the value of the absolute gradient criterion, and $\text{gmax}^{(k)}$ is the maximum absolute element of the (projected) gradient $\mathbf{g}^{(k)}$ or $\mathbf{Z}'\mathbf{g}^{(k)}$. (See the section "Active Set Methods" for a definition of $\mathbf{Z}$.)

LCEPSILON=$r > 0$

LCEPS=$r > 0$

LCE=$r > 0$

specifies the range for active and violated boundary constraints. The default value is $r = 1\text{E}{-8}$. During the optimization process, the introduction of rounding errors can force PROC NLMIXED to increase the value of r by a factor of $10, 100, \ldots$. If this happens, it is indicated by a message displayed in the log.

LCSINGULAR=*r* > 0

LCSING=*r* > 0

LCS=*r* > 0

specifies a criterion r, used in the update of the QR decomposition, that determines whether an active constraint is linearly dependent on a set of other active constraints. The default value is $r = 1\text{E}{-8}$. The larger r becomes, the more the active constraints are recognized as being linearly dependent. If the value of r is larger than 0.1, it is reset to 0.1.

LINESEARCH=*i*

LIS=*i*

specifies the line-search method for the CONGRA, QUANEW, and NEWRAP optimization techniques. See Fletcher (1987) for an introduction to line-search techniques. The value of i can be $1, \ldots, 8$. For CONGRA, QUANEW and NEWRAP, the default value is $i = 2$.

LIS=1 specifies a line-search method that needs the same number of function and gradient calls for cubic interpolation and cubic extrapolation; this method is similar to one used by the Harwell subroutine library.

LIS=2 specifies a line-search method that needs more function than gradient calls for quadratic and cubic interpolation and cubic extrapolation; this method is implemented as shown in Fletcher (1987) and can be modified to an exact line search by using the LSPRECISION= option.

LIS=3 specifies a line-search method that needs the same number of function and gradient calls for cubic interpolation and cubic extrapolation; this method is implemented as shown in Fletcher (1987) and can be modified to an exact line search by using the LSPRECISION= option.

LIS=4 specifies a line-search method that needs the same number of function and gradient calls for stepwise extrapolation and cubic interpolation.

LIS=5 specifies a line-search method that is a modified version of LIS=4.

LIS=6 specifies golden section line search (Polak 1971), which uses only function values for linear approximation.

LIS=7 specifies bisection line search (Polak 1971), which uses only function values for linear approximation.

LIS=8 specifies the Armijo line-search technique (Polak 1971), which uses only function values for linear approximation.

LIST

displays the model program and variable lists. The LIST option is a debugging feature and is not normally needed.

LISTCODE

displays the derivative tables and the compiled program code. The LISTCODE option is a debugging feature and is not normally needed.

LISTDEP

produces a report that lists, for each variable in the program, the variables that depend on it and on which it depends. The LISTDEP option is a debugging feature and is not normally needed.

LISTDER

displays a table of derivatives. This table lists each nonzero derivative computed for the problem. The LISTDER option is a debugging feature and is not normally needed.

LOGNOTE<=*n*>

writes periodic notes to the log that describe the current status of computations. It is designed for use with analyses requiring extensive CPU resources. The optional integer value n specifies the desired level of reporting detail. The default is $n = 1$. Choosing $n = 2$ adds information about the objective function values at the end of each iteration. The most detail is obtained with $n = 3$, which also reports the results of function evaluations within iterations.

LSPRECISION=*r*

LSP=*r*

specifies the degree of accuracy that should be obtained by the line-search algorithms LIS=2 and LIS=3. Usually an imprecise line search is inexpensive and successful. For more difficult optimization problems, a more precise and expensive line search might be necessary (Fletcher 1987). The second line-search method (which is the default for the NEWRAP, QUANEW, and CONGRA techniques) and the third line-search method approach exact line search for small LSPRECISION= values. If you have numerical problems, you should try to decrease the LSPRECISION= value to obtain a more precise line search. The default values are shown in the following table.

TECH=	UPDATE=	LSP default
QUANEW	DBFGS, BFGS	$r = 0.4$
QUANEW	DDFP, DFP	$r = 0.06$
CONGRA	all	$r = 0.1$
NEWRAP	no update	$r = 0.9$

For more details, see Fletcher (1987).

MAXFUNC=*i*

MAXFU=*i*

specifies the maximum number i of function calls in the optimization process. The default values are as follows:

- TRUREG, NRRIDG, NEWRAP: 125
- QUANEW, DBLDOG: 500
- CONGRA: 1000
- NMSIMP: 3000

Note that the optimization can terminate only after completing a full iteration. Therefore, the number of function calls that is actually performed can exceed the number that is specified by the MAXFUNC= option.

MAXITER=*i*

MAXIT=*i*

specifies the maximum number i of iterations in the optimization process. The default values are as follows:

- TRUREG, NRRIDG, NEWRAP: 50
- QUANEW, DBLDOG: 200
- CONGRA: 400
- NMSIMP: 1000

These default values are also valid when *i* is specified as a missing value.

MAXSTEP=*r*<**[***n***]**>
specifies an upper bound for the step length of the line-search algorithms during the first *n* iterations. By default, *r* is the largest double-precision value and *n* is the largest integer available. Setting this option can improve the speed of convergence for the CONGRA, QUANEW, and NEWRAP techniques.

MAXTIME=*r*
specifies an upper limit of *r* seconds of CPU time for the optimization process. The default value is the largest floating-point double representation of your computer. Note that the time specified by the MAXTIME= option is checked only once at the end of each iteration. Therefore, the actual running time can be much longer than that specified by the MAXTIME= option. The actual running time includes the rest of the time needed to finish the iteration and the time needed to generate the output of the results.

METHOD=*value*
specifies the method for approximating the integral of the likelihood over the random effects. Valid values are as follows:

FIRO
specifies the first-order method of Beal and Sheiner (1982). When using METHOD=FIRO, you must specify the NORMAL distribution in the MODEL statement and you must also specify a RANDOM statement.

GAUSS
specifies adaptive Gauss-Hermite quadrature (Pinheiro and Bates 1995). You can prevent the adaptation with the NOAD option or prevent adaptive scaling with the NOADSCALE option. This is the default integration method.

HARDY
specifies Hardy quadrature based on an adaptive trapezoidal rule. This method is available only for one-dimensional integrals; that is, you must specify only one random effect.

ISAMP
specifies adaptive importance sampling (Pinheiro and Bates 1995). You can prevent the adaptation with the NOAD option or prevent adaptive scaling with the NOADSCALE option. You can use the SEED= option to specify a starting seed for the random number generation used in the importance sampling. If you do not specify a seed, or if you specify a value less than or equal to zero, the seed is generated from reading the time of day from the computer clock.

MINITER=*i*

MINIT=*i*

specifies the minimum number of iterations. The default value is 0. If you request more iterations than are actually needed for convergence to a stationary point, the optimization algorithms can behave strangely. For example, the effect of rounding errors can prevent the algorithm from continuing for the required number of iterations.

MSINGULAR=*r* > 0

MSING=*r* > 0

specifies a relative singularity criterion for the computation of the inertia (number of positive, negative, and zero eigenvalues) of the Hessian and its projected forms. The default value is 1E−12 if you do not specify the SINGHESS= option; otherwise, the default value is $\max(10\epsilon, (1\text{E} - 4) \times$ SINGHESS). See the section "Covariance Matrix" on page 5237 for more information.

NOAD

requests that the Gaussian quadrature be nonadaptive; that is, the quadrature points are centered at zero for each of the random effects and the current random-effects variance matrix is used as the scale matrix.

NOADSCALE

requests nonadaptive scaling for adaptive Gaussian quadrature; that is, the quadrature points are centered at the empirical Bayes estimates for the random effects, but the current random-effects variance matrix is used as the scale matrix. By default, the observed Hessian from the current empirical Bayes estimates is used as the scale matrix.

OPTCHECK<=*r* > 0**>**

computes the function values $f(\boldsymbol{\theta}_l)$ of a grid of points $\boldsymbol{\theta}_l$ in a ball of radius of r about $\boldsymbol{\theta}^*$. If you specify the OPTCHECK option without factor r, the default value is $r = 0.1$ at the starting point and $r = 0.01$ at the terminating point. If a point $\boldsymbol{\theta}_l^*$ is found with a better function value than $f(\boldsymbol{\theta}^*)$, then optimization is restarted at $\boldsymbol{\theta}_l^*$.

OUTQ=*SAS-data-set*

specifies an output data set containing the quadrature points used for numerical integration.

QFAC=*r* > 0

specifies the additive factor used to adaptively search for the number of quadrature points. For METHOD=GAUSS, the search sequence is 1, 3, 5, 7, 9, 11, 11 + r, 11 + $2r$, ..., where the default value of r is 10. For METHOD=ISAMP, the search sequence is 10, 10 + r, 10 + $2r$, ..., where the default value of r is 50.

QMAX=*r* > 0

specifies the maximum number of quadrature points permitted before the adaptive search is aborted. The default values are 31 for adaptive Gaussian quadrature, 61 for nonadaptive Gaussian quadrature, 160 for adaptive importance sampling, and 310 for nonadaptive importance sampling.

QPOINTS=*n* > 0

specifies the number of quadrature points to be used during evaluation of integrals. For METHOD=GAUSS, n equals the number of points used in each dimension of the random effects, resulting in a total of n^r points, where r is the number of dimensions. For METHOD=ISAMP,

n specifies the total number of quadrature points regardless of the dimension of the random effects. By default, the number of quadrature points is selected adaptively, and this option disables the adaptive search.

QSCALEFAC=$r > 0$

specifies a multiplier for the scale matrix used during quadrature calculations. The default value is 1.0.

QTOL=$r > 0$

specifies the tolerance used to adaptively select the number of quadrature points. When the relative difference between two successive likelihood calculations is less than r, then the search terminates and the lesser number of quadrature points is used during the subsequent optimization process. The default value is 1E−4.

RESTART=$i > 0$

REST=$i > 0$

specifies that the QUANEW or CONGRA algorithm is restarted with a steepest descent/ascent search direction after, at most, i iterations. Default values are as follows:

- CONGRA: UPDATE=PB: restart is performed automatically, i is not used.
- CONGRA: UPDATE≠PB: $i = \min(10n, 80)$, where n is the number of parameters.
- QUANEW: i is the largest integer available.

SEED=i

specifies the random number seed for METHOD=ISAMP. If you do not specify a seed, or if you specify a value less than or equal to zero, the seed is generated from reading the time of day from the computer clock. The value must be less than $2^{31} - 1$.

SINGCHOL=$r > 0$

specifies the singularity criterion r for Cholesky roots of the random-effects variance matrix and scale matrix for adaptive Gaussian quadrature. The default value is 1E4 times the machine epsilon; this product is approximately 1E−12 on most computers.

SINGHESS=$r > 0$

specifies the singularity criterion r for the inversion of the Hessian matrix. The default value is 1E−8. See the ASINGULAR, MSINGULAR=, and VSINGULAR= options for more information.

SINGSWEEP=$r > 0$

specifies the singularity criterion r for inverting the variance matrix in the first-order method and the empirical Bayes Hessian matrix. The default value is 1E4 times the machine epsilon; this product is approximately 1E−12 on most computers.

SINGVAR=$r > 0$

specifies the singularity criterion r below which statistical variances are considered to equal zero. The default value is 1E4 times the machine epsilon; this product is approximately 1E−12 on most computers.

START

requests that the gradient of the log likelihood at the starting values be displayed. If you also specify the HESS option, then the starting Hessian is displayed as well.

SUBGRADIENT=*SAS-data-set*

SUBGRAD=*SAS-data-set*

specifies a SAS data set to save in models with RANDOM statement the subject-specific gradients of the integrated, marginal log-likelihood with respect to all parameters. The sum of the subject-specific gradients equals the gradient reported in the "Parameter Estimates" table. The data set contains a variable identifying the subjects.

In models without RANDOM statement the SUBGRADIENT= data set contains the observation-wise gradient. The variable identifying the SUBJECT= is then replaced with the Observation. This observation counter includes observations not used in the analysis and is reset in each BY-group.

Saving disaggregated gradient information with the SUBGRADIENT= option requires METHOD=GAUSS or METHOD=ISAMP.

TECHNIQUE=*value*

TECH=*value*

specifies the optimization technique. Valid values are as follows:

- CONGRA
  performs a conjugate-gradient optimization, which can be more precisely specified with the UPDATE= option and modified with the LINESEARCH= option. When you specify this option, UPDATE=PB by default.
- DBLDOG
  performs a version of double-dogleg optimization, which can be more precisely specified with the UPDATE= option. When you specify this option, UPDATE=DBFGS by default.
- NMSIMP
  performs a Nelder-Mead simplex optimization.
- NONE
  does not perform any optimization. This option can be used as follows:
  - to perform a grid search without optimization
  - to compute estimates and predictions that cannot be obtained efficiently with any of the optimization techniques
- NEWRAP
  performs a Newton-Raphson optimization combining a line-search algorithm with ridging. The line-search algorithm LIS=2 is the default method.
- NRRIDG
  performs a Newton-Raphson optimization with ridging.
- QUANEW
  performs a quasi-Newton optimization, which can be defined more precisely with the UPDATE= option and modified with the LINESEARCH= option. This is the default estimation method.
- TRUREG
  performs a trust region optimization.

TRACE

displays the result of each operation in each statement in the model program as it is executed. This debugging option is very rarely needed, and it produces voluminous output.

UPDATE=*method*

UPD=*method*

specifies the update method for the quasi-Newton, double-dogleg, or conjugate-gradient optimization technique. Not every update method can be used with each optimizer. See the section "Optimization Algorithms" on page 5222 for more information.

Valid methods are as follows:

- BFGS
  performs the original Broyden, Fletcher, Goldfarb, and Shanno (BFGS) update of the inverse Hessian matrix.
- DBFGS
  performs the dual BFGS update of the Cholesky factor of the Hessian matrix. This is the default update method.
- DDFP
  performs the dual Davidon, Fletcher, and Powell (DFP) update of the Cholesky factor of the Hessian matrix.
- DFP
  performs the original DFP update of the inverse Hessian matrix.
- PB
  performs the automatic restart update method of Powell (1977) and Beale (1972).
- FR
  performs the Fletcher-Reeves update (Fletcher 1987).
- PR
  performs the Polak-Ribiere update (Fletcher 1987).
- CD
  performs a conjugate-descent update of Fletcher (1987).

VSINGULAR=*r* > 0

VSING=*r* > 0

specifies a relative singularity criterion for the computation of the inertia (number of positive, negative, and zero eigenvalues) of the Hessian and its projected forms. The default value is $r = 1\text{E}{-8}$ if the SINGHESS= option is not specified, and it is the value of SINGHESS= option otherwise. See the section "Covariance Matrix" on page 5237 for more information.

XCONV=*r* **< [***n***] >**

XTOL=*r* **< [***n***] >**

specifies the relative parameter convergence criterion. For all techniques except NMSIMP, termination requires a small relative parameter change in subsequent iterations:

$$\frac{\max_j |\theta_j^{(k)} - \theta_j^{(k-1)}|}{\max(|\theta_j^{(k)}|, |\theta_j^{(k-1)}|, \text{XSIZE})} \leq r$$

For the NMSIMP technique, the same formula is used, but $\boldsymbol{\theta}^{(k)}$ is defined as the vertex with the lowest function value and $\boldsymbol{\theta}^{(k-1)}$ is defined as the vertex with the highest function value in the simplex.

The default value is $r = 1E{-}8$ for the NMSIMP technique and $r = 0$ otherwise. The optional integer value n specifies the number of successive iterations for which the criterion must be satisfied before the process can be terminated.

XREF

displays a cross-reference of the variables in the program showing where each variable is referenced or given a value. The XREF listing does not include derivative variables. This option is a debugging feature and is not normally needed.

XSIZE=*r* > 0

specifies the XSIZE parameter of the relative parameter termination criterion. The default value is $r = 0$. For more details, see the XCONV= option.

ARRAY Statement

ARRAY *arrayname* **[{** *dimensions* **}] [$] [***variables and constants***] ;**

The ARRAY statement is similar to, but not exactly the same as, the ARRAY statement in the SAS DATA step, and it is exactly the same as the ARRAY statements in the NLIN, NLP, and MODEL procedures. The ARRAY statement is used to associate a name (of no more than eight characters) with a list of variables and constants. The array name is used with subscripts in the program to refer to the array elements. The following statements illustrate this:

```
array r[8] r1-r8;

do i = 1 to 8;
   r[i] = 0;
end;
```

The ARRAY statement does not support all the features of the ARRAY statement in the DATA step. It cannot be used to assign initial values to array elements. Implicit indexing of variables cannot be used; all array references must have explicit subscript expressions. Only exact array dimensions are allowed; lower-bound specifications are not supported. A maximum of six dimensions is allowed.

On the other hand, the ARRAY statement does allow both variables and constants to be used as array elements. (Constant array elements cannot have values assigned to them.) Both dimension specification and the list of elements are optional, but at least one must be specified. When the list of elements is not specified or fewer elements than the size of the array are listed, array variables are created by suffixing element numbers to the array name to complete the element list.

BOUNDS Statement

BOUNDS *b_con [, b_con. . .]* **;**

where	*b_con* :=	number *operator* parameter_list *operator* number
or	*b_con* :=	number *operator* parameter_list
or	*b_con* :=	parameter_list *operator* number
and	*operator* :=	<=, <, >=, or >

Boundary constraints are specified with a BOUNDS statement. One- or two-sided boundary constraints are allowed. The list of boundary constraints are separated by commas. For example:

```
bounds 0 <= a1-a9 X <= 1, -1 <= c2-c5;
bounds b1-b10 y >= 0;
```

You can specify more than one BOUNDS statement. If you specify more than one lower (upper) bound for the same parameter, the maximum (minimum) of these is taken.

If the maximum l_j of all lower bounds is larger than the minimum of all upper bounds u_j for the same parameter θ_j, the boundary constraint is replaced by $\theta_j := l_j := \min(u_j)$ defined by the minimum of all upper bounds specified for θ_j.

BY Statement

BY *variables* **;**

You can use a BY statement with the NLMIXED procedure to obtain separate analyses on DATA= data set observations in groups defined by the BY variables. This means that, unless TECH=NONE, an optimization problem is solved for each BY group separately. When a BY statement appears, the procedure expects the input DATA= data set to be sorted in the order of the BY variables. If your input data set is not sorted in ascending order, use one of the following alternatives:

- Use the SORT procedure with a similar BY statement to sort the data.
- Use the BY statement option NOTSORTED or DESCENDING in the BY statement for the NLMIXED procedure. As a cautionary note, the NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Use the DATASETS procedure (in Base SAS software) to create an index on the BY variables.

For more information about the BY statement, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the *Base SAS Procedures Guide*.

CONTRAST Statement

CONTRAST *'label' expression* < *, expression* > < *options* > **;**

The CONTRAST statement enables you to conduct a statistical test that several expressions simultaneously equal zero. The expressions are typically contrasts—that is, differences whose expected values equal zero under the hypothesis of interest.

In the CONTRAST statement you must provide a quoted string to identify the contrast and then a list of valid SAS expressions separated by commas. Multiple CONTRAST statements are permitted, and results from all statements are listed in a common table. PROC NLMIXED constructs approximate F tests for each statement using the delta method (Cox 1998) to approximate the variance-covariance matrix of the constituent expressions.

The following option is available in the CONTRAST statement:

DF=*d*

specifies the denominator degrees of freedom to be used in computing p values for the F statistics. The default value corresponds to the DF= option in the PROC NLMIXED statement.

ESTIMATE Statement

ESTIMATE *'label' expression* < *options* > **;**

The ESTIMATE statement enables you to compute an additional estimate that is a function of the parameter values. You must provide a quoted string to identify the estimate and then a valid SAS expression. Multiple ESTIMATE statements are permitted, and results from all statements are listed in a common table. PROC NLMIXED computes approximate standard errors for the estimates using the delta method (Billingsley 1986). It uses these standard errors to compute corresponding t statistics, p-values, and confidence limits.

The ECOV option in the PROC NLMIXED statement produces a table containing the approximate covariance matrix of all the additional estimates you specify. The ECORR option produces the corresponding correlation matrix. The EDER option produces a table of the derivatives of the additional estimates with respect to each of the model parameters.

The following options are available in the ESTIMATE statement:

ALPHA=*α*

specifies the alpha level to be used in computing confidence limits. The default value corresponds to the ALPHA= option in the PROC NLMIXED statement.

DF=*d*

specifies the degrees of freedom to be used in computing p-values and confidence limits. The default value corresponds to the DF= option in the PROC NLMIXED statement.

ID Statement

ID *names* **;**

The ID statement identifies additional quantities to be included in the OUT= data set of the PREDICT statement. These can be any symbols you have defined with SAS programming statements.

MODEL Statement

MODEL *dependent-variable* ∼ *distribution* **;**

The MODEL statement is the mechanism for specifying the conditional distribution of the data given the random effects. You must specify a single dependent variable from the input data set, a tilde (∼), and then a distribution with its parameters. Valid distributions are as follows.

- *normal(m,v)* specifies a normal (Gaussian) distribution with mean m and variance v.
- *binary(p)* specifies a binary (Bernoulli) distribution with probability p.
- *binomial(n,p)* specifies a binomial distribution with count n and probability p.
- *gamma(a,b)* specifies a gamma distribution with shape a and scale b.
- *negbin(n,p)* specifies a negative binomial distribution with count n and probability p.
- *poisson(m)* specifies a Poisson distribution with mean m.
- *general(ll)* specifies a general log likelihood function that you construct using SAS programming statements.

The MODEL statement must follow any SAS programming statements you specify for computing parameters of the preceding distributions. See the section "Built-in Log-Likelihood Functions" on page 5220 for expressions of the built-in conditional log-likelihood functions.

PARMS Statement

PARMS *<name_list [=numbers] [, name_list [=numbers] ...]>*
</ options> **;**

The PARMS statement lists names of parameters and specifies initial values, possibly over a grid. You can specify the parameters and values directly in a list, or you can provide the name of a SAS data set that contains them by using the DATA= option.

While the PARMS statement is not required, you are encouraged to use it to provide PROC NLMIXED with accurate starting values. Parameters not listed in the PARMS statement are assigned an initial value of 1.

PROC NLMIXED considers all symbols not assigned values to be parameters, so you should specify your modeling statements carefully and check the output from the "Parameters" table to make sure the proper parameters are identified.

A list of parameter names in the PARMS statement is not separated by commas and is followed by an equal sign and a list of numbers. If the number list consists of only one number, this number defines the initial value for all the parameters listed to the left of the equal sign.

If the number list consists of more than one number, these numbers specify the grid locations for each of the parameters listed to the left of the equal sign. You can use the TO and BY keywords to specify a number list for a grid search. If you specify a grid of points in a PARMS statement, PROC NLMIXED computes the objective function value at each grid point and chooses the best (feasible) grid point as an initial point for the optimization process. You can use the BEST= option to save memory for the storing and sorting of all grid point information.

The following options are available in the PARMS statement after a slash (/):

BEST=*i* > 0
specifies the maximum number of points displayed in the "Parameters" table, selected as the points with the maximum likelihood values. By default, all grid values are displayed.

BYDATA
enables you to assign different starting values for each BY group by using the DATA=*SAS-data-set* option during BY processing. By default, BY groups are ignored in the PARMS data set. For the BYDATA option to be effective, the DATA= data set must contain the BY variables and the same BY groups as the primary input data set. When you supply a grid of starting values with the DATA= data set and the BYDATA option is in effect, the size of the grid is determined by the first BY group.

DATA=*SAS-data-set*
specifies a SAS data set containing parameter names and starting values. The data set should be in one of two forms: narrow or wide. The narrow-form data set contains the variables Parameter and Estimate, with parameters and values listed as distinct observations. The wide-form data set has the parameters themselves as variables, and each observation provides a different set of starting values. By default, BY groups are ignored in this data set, so the same starting grid is evaluated for each BY group. You can vary the starting values for BY groups by using the BYDATA option.

PREDICT Statement

PREDICT *expression OUT=SAS-data-set* < *options* > **;**

The PREDICT statement enables you to construct predictions of an expression across all of the observations in the input data set. Any valid SAS programming expression involving the input data set variables, parameters, and random effects is valid. Predicted values are computed using the parameter estimates and empirical Bayes estimates of the random effects. Standard errors of prediction are computed using the delta method (Billingsley 1986, Cox 1998). Results are placed in an output data set that you specify with the OUT= option. Besides all variables from the input data set, the OUT= data set contains the following variables: Pred, StdErrPred, DF, tValue, Probt, Alpha, Lower, Upper. You can also add other computed quantities to this data set with the ID statement.

The following options are available in the PREDICT statement:

ALPHA=α

specifies the alpha level to be used in computing t statistics and intervals. The default value corresponds to the ALPHA= option in the PROC NLMIXED statement.

DER

requests that derivatives of the predicted expression with respect to all parameters be included in the OUT= data set. The variable names for the derivatives are the same as the parameter names with the prefix "Der_" appended. All of the derivatives are evaluated at the final estimates of the parameters and the empirical Bayes estimates of the random effects.

DF=d

specifies the degrees of freedom to be used in computing t statistics and intervals in the OUT= data set. The default value corresponds to the DF= option in the PROC NLMIXED statement.

RANDOM Statement

RANDOM *random-effects* ~ *distribution* **SUBJECT**=*variable* < *options* > **;**

The RANDOM statement defines the random effects and their distribution. The random effects must be represented by symbols that appear in your SAS programming statements. They typically influence the mean value of the distribution specified in the MODEL statement. The RANDOM statement consists of a list of the random effects (usually just one or two symbols), a tilde (~), the distribution for the random effects, and then a SUBJECT= variable.

NOTE: The input data set must be clustered according to the SUBJECT= variable. One easy way to accomplish this is to sort your data by the SUBJECT= variable prior to calling PROC NLMIXED. PROC NLMIXED does not sort the input data set for you; rather, it processes the data sequentially and considers an observation to be from a new subject whenever the value of its SUBJECT= variable changes from the previous observation.

The only distribution available for the random effects is normal(m,v) with mean m and variance v.

This syntax is illustrated as follows for one effect:

```
random u ~ normal(0,s2u) subject=clinic;
```

For multiple effects, you should specify bracketed vectors for m and v, the latter consisting of the lower triangle of the random-effects variance matrix listed in row order. This is illustrated for two and three random effects as follows:

```
random b1 b2 ~ normal([0,0],[g11,g21,g22]) subject=person;
random b1 b2 b3 ~ normal([0,0,0],[g11,g21,g22,g31,g32,g33])
   subject=person;
```

The SUBJECT= variable determines when new realizations of the random effects are assumed to occur. PROC NLMIXED assumes that a new realization occurs whenever the value of the SUBJECT= variable changes from the previous observation, so your input data set should be clustered according to this variable.

One easy way to accomplish this is to run PROC SORT prior to calling PROC NLMIXED by using the SUBJECT= variable as the BY variable.

Only one RANDOM statement is permitted, so multilevel nonlinear mixed models are not accommodated. However, you can specify certain nested random effects structure with a single RANDOM statement (see Chapter 15 of Littell et al. (2006) for an example).

The following options are available in the RANDOM statement:

ALPHA=α

specifies the alpha level to be used in computing t statistics and intervals. The default value corresponds to the ALPHA= option in the PROC NLMIXED statement.

DF=d

specifies the degrees of freedom to be used in computing t statistics and intervals in the OUT= data set. The default value corresponds to the DF= option in the PROC NLMIXED statement.

OUT=*SAS-data-set*

requests an output data set containing empirical Bayes estimates of the random effects and their approximate standard errors of prediction.

REPLICATE Statement

REPLICATE *variable* **;**

The REPLICATE statement provides a way to accommodate models in which different subjects have identical data. This occurs most commonly when the dependent variable is binary. When you specify a REPLICATE variable, PROC NLMIXED assumes that its value indicates the number of subjects having data identical to those for the current value of the SUBJECT= variable (specified in the RANDOM statement). Only the last observation of the REPLICATE variable for each subject is used, and the replicate variable must have only positive integer values.

Note that the REPLICATE mechanism is different from using a FREQ statement in other statistical modeling procedures, such as PROC GLM, GENMOD, GLIMMIX, and LOGISTIC. A FREQ variable is used to identify grouped values for observations, essentially multiplying the log likelihood or sum of squares contribution for the observation. A REPLICATE variable is used to multiply the contribution of a subject that comprises one or more observations.

Programming Statements

This section lists the programming statements used to code the log-likelihood function in PROC NLMIXED. It also documents the differences between programming statements in PROC NLMIXED and programming statements in the SAS DATA step. The syntax of programming statements used in PROC NLMIXED is identical to that used in the CALIS and GENMOD procedures (see Chapter 26 and Chapter 39, respectively), and the MODEL procedure (see the *SAS/ETS User's Guide*). Most of the programming statements that can

be used in the SAS DATA step can also be used in the NLMIXED procedure. See *SAS Language Reference: Dictionary* for a description of SAS programming statements. The following are valid statements:

ABORT;
CALL *name [(expression [, expression . . .])]*;
DELETE;
DO *[variable = expression*
*[***TO** *expression] [***BY** *expression]*
[, expression [**TO** *expression] [* **BY** *expression] . . .]*
]
[**WHILE** *expression] [* **UNTIL** *expression]*;
END;
GOTO *statement_label*;
IF *expression*;
IF *expression* **THEN** *program_statement*;
ELSE *program_statement*;
variable = expression;
variable + expression;
LINK *statement_label*;
PUT *[variable] [=] [...]*;
RETURN;
SELECT[(*expression* **)];**
STOP;
SUBSTR(*variable, index, length* **)=** *expression*;
WHEN *(expression) program_statement*;
OTHERWISE *program_statement*;

For the most part, the SAS programming statements work the same as they do in the SAS DATA step, as documented in *SAS Language Reference: Concepts*; however, there are the following differences:

- The ABORT statement does not allow any arguments.
- The DO statement does not allow a character index variable. Thus

```
do i = 1,2,3;
```

  is supported, but the following statement is not supported:

```
do i = 'A','B','C';
```

- The LAG function does work appropriately with PROC NLMIXED, but you can use the ZLAG function instead.
- The PUT statement, used mostly for program debugging in PROC NLMIXED, supports only some of the features of the DATA step PUT statement, and it has some new features that the DATA step PUT statement does not.
  - The PROC NLMIXED PUT statement does not support line pointers, factored lists, iteration factors, overprinting, _INFILE_, the colon (:) format modifier, or "$".

  - The PROC NLMIXED PUT statement does support expressions, but the expression must be enclosed in parentheses. For example, the following statement displays the square root of x:

    ```
    put  (sqrt(x));
    ```

  - The PROC NLMIXED PUT statement supports the item _PDV_ to display a formatted listing of all variables in the program. For example, the following statement displays a much more readable listing of the variables than the _ALL_ print item:

    ```
    put  _pdv_;
    ```

- The WHEN and OTHERWISE statements enable you to specify more than one target statement. That is, DO/END groups are not necessary for multiple statement WHENs. For example, the following syntax is valid:

```
select;
   when (exp1) stmt1;
               stmt2;
   when (exp2) stmt3;
               stmt4;
end;
```

When coding your programming statements, you should avoid defining variables that begin with an underscore (_), because they might conflict with internal variables created by PROC NLMIXED. The MODEL statement must come after any SAS programming statements that define or modify terms used in the construction of the log-likelihood.

Details: NLMIXED Procedure

This section contains details about the underlying theory and computations of PROC NLMIXED.

Modeling Assumptions and Notation

PROC NLMIXED operates under the following general framework for nonlinear mixed models. Assume that you have an observed data vector $\mathbf{y}_i$ for each of i subjects, $i = 1, \ldots, s$. The $\mathbf{y}_i$ are assumed to be independent across i, but within-subject covariance is likely to exist because each of the elements of $\mathbf{y}_i$ is measured on the same subject. As a statistical mechanism for modeling this within-subject covariance, assume that there exist latent random-effect vectors $\mathbf{u}_i$ of small dimension (typically one or two) that are also independent across i. Assume also that an appropriate model linking $\mathbf{y}_i$ and $\mathbf{u}_i$ exists, leading to the joint probability density function

$$p(\mathbf{y}_i|\mathbf{X}_i, \boldsymbol{\phi}, \mathbf{u}_i)q(\mathbf{u}_i|\boldsymbol{\xi})$$

where $\mathbf{X}_i$ is a matrix of observed explanatory variables and $\boldsymbol{\phi}$ and $\boldsymbol{\xi}$ are vectors of unknown parameters.

Let $\boldsymbol{\theta} = [\boldsymbol{\phi}, \boldsymbol{\xi}]$ and assume that it is of dimension n. Then inferences about $\boldsymbol{\theta}$ are based on the marginal likelihood function

$$m(\boldsymbol{\theta}) = \prod_{i=1}^{s} \int p(\mathbf{y}_i|\mathbf{X}_i, \boldsymbol{\phi}, \mathbf{u}_i) q(\mathbf{u}_i|\boldsymbol{\xi}) d\mathbf{u}_i$$

In particular, the function

$$f(\boldsymbol{\theta}) = -\log m(\boldsymbol{\theta})$$

is minimized over $\boldsymbol{\theta}$ numerically in order to estimate $\boldsymbol{\theta}$, and the inverse Hessian (second derivative) matrix at the estimates provides an approximate variance-covariance matrix for the estimate of $\boldsymbol{\theta}$. The function $f(\boldsymbol{\theta})$ is referred to both as the negative log likelihood function and as the objective function for optimization.

As an example of the preceding general framework, consider the nonlinear growth curve example in the section "Getting Started: NLMIXED Procedure" on page 5184. Here, the conditional distribution $p(\mathbf{y}_i|\mathbf{X}_i, \boldsymbol{\phi}, u_i)$ is normal with mean

$$\frac{b_1 + u_{i1}}{1 + \exp[-(d_{ij} - b_2)/b_3]}$$

and variance σ_e^2; thus $\boldsymbol{\phi} = [b_1, b_2, b_3, \sigma_e^2]$. Also, u_i is a scalar and $q(u_i|\xi)$ is normal with mean 0 and variance σ_u^2; thus $\xi = \sigma_u^2$.

The following additional notation is also found in this chapter. The quantity $\boldsymbol{\theta}^{(k)}$ refers to the parameter vector at the kth iteration, the vector $\mathbf{g}(\boldsymbol{\theta})$ refers to the gradient vector $\nabla f(\boldsymbol{\theta})$, and the matrix $\mathbf{H}(\boldsymbol{\theta})$ refers to the Hessian $\nabla^2 f(\boldsymbol{\theta})$. Other symbols are used to denote various constants or option values.

Integral Approximations

An important part of the marginal maximum likelihood method described previously is the computation of the integral over the random effects. The default method in PROC NLMIXED for computing this integral is adaptive Gaussian quadrature as described in Pinheiro and Bates (1995). Another approximation method is the first-order method of Beal and Sheiner (1982, 1988). A description of these two methods follows.

Adaptive Gaussian Quadrature

A quadrature method approximates a given integral by a weighted sum over predefined abscissas for the random effects. A good approximation can usually be obtained with an adequate number of quadrature points as well as appropriate centering and scaling of the abscissas. Adaptive Gaussian quadrature for the integral over $\mathbf{u}_i$ centers the integral at the empirical Bayes estimate of $\mathbf{u}_i$, defined as the vector $\widehat{\mathbf{u}}_i$ that minimizes

$$-\log\left[p(\mathbf{y}_i|\mathbf{X}_i, \boldsymbol{\phi}, \mathbf{u}_i) q(\mathbf{u}_i|\boldsymbol{\xi})\right]$$

with $\boldsymbol{\phi}$ and $\boldsymbol{\xi}$ set equal to their current estimates. The final Hessian matrix from this optimization can be used to scale the quadrature abscissas.

Suppose $(z_j, w_j; j = 1, \ldots, p)$ denote the standard Gauss-Hermite abscissas and weights (Golub and Welsch 1969, or Table 25.10 of Abramowitz and Stegun 1972). The adaptive Gaussian quadrature integral approximation is as follows:

$$\int p(\mathbf{y}_i|\mathbf{X}_i, \boldsymbol{\phi}, \mathbf{u}_i) q(\mathbf{u}_i|\boldsymbol{\xi}) d\mathbf{u}_i \approx$$

$$2^{r/2} |\boldsymbol{\Gamma}(\mathbf{X}_i, \boldsymbol{\theta})|^{-1/2} \sum_{j_1=1}^{p} \cdots \sum_{j_r=1}^{p} \left[p(\mathbf{y}_i|\mathbf{X}_i, \boldsymbol{\phi}, \mathbf{a}_{j_1,\ldots,j_r}) q(\mathbf{a}_{j_1,\ldots,j_r}|\boldsymbol{\xi}) \prod_{k=1}^{r} w_{j_k} \exp z_{j_k}^2 \right]$$

where r is the dimension of u_i, $\boldsymbol{\Gamma}(\mathbf{X}_i, \boldsymbol{\theta})$ is the Hessian matrix from the empirical Bayes minimization, $\mathbf{z}_{j_1,\ldots,j_r}$ is a vector with elements $(z_{j_1}, \ldots, z_{j_r})$, and

$$\mathbf{a}_{j_1,\ldots,j_r} = \widehat{\mathbf{u}}_i + 2^{1/2} \boldsymbol{\Gamma}(\mathbf{X}_i, \boldsymbol{\theta})^{-1/2} \mathbf{z}_{j_1,\ldots,j_r}$$

PROC NLMIXED selects the number of quadrature points adaptively by evaluating the log-likelihood function at the starting values of the parameters until two successive evaluations have a relative difference less than the value of the QTOL= option. The specific search sequence is described under the QFAC= option. Using the QPOINTS= option, you can adjust the number of quadrature points p to obtain different levels of accuracy. Setting $p = 1$ results in the Laplacian approximation as described in Beal and Sheiner (1992), Wolfinger (1993), Vonesh (1992, 1996), Vonesh and Chinchilli (1997), and Wolfinger and Lin (1997).

The NOAD option in the PROC NLMIXED statement requests nonadaptive Gaussian quadrature. Here all $\widehat{\mathbf{u}}_i$ are set equal to zero, and the Cholesky root of the estimated variance matrix of the random effects is substituted for $\boldsymbol{\Gamma}(\mathbf{X}_i, \boldsymbol{\theta})^{-1/2}$ in the preceding expression for $\mathbf{a}_{j_1,\ldots,j_r}$. In this case derivatives are computed using the algorithm of Smith (1995). The NOADSCALE option requests the same scaling substitution but with the empirical Bayes $\widehat{\mathbf{u}}_i$.

PROC NLMIXED computes the derivatives of the adaptive Gaussian quadrature approximation when carrying out the default dual quasi-Newton optimization.

First-Order Method

Another integral approximation available in PROC NLMIXED is the first-order method of Beal and Sheiner (1982, 1988) and Sheiner and Beal (1985). This approximation is used only in the case where $p(\mathbf{y}_i|\mathbf{X}_i, \boldsymbol{\phi}, \mathbf{u}_i)$ is normal—that is,

$$p(\mathbf{y}_i|\mathbf{X}_i, \boldsymbol{\phi}, \mathbf{u}_i) = (2\pi)^{-n_i/2} |\mathbf{R}_i(\mathbf{X}_i, \boldsymbol{\phi})|^{-1/2}$$
$$\exp\left\{-(1/2)\left[\mathbf{y}_i - \mathbf{m}_i(\mathbf{X}_i, \boldsymbol{\phi}, \mathbf{u}_i)\right]' \mathbf{R}_i(\mathbf{X}_i, \boldsymbol{\phi})^{-1} \left[\mathbf{y}_i - \mathbf{m}_i(\mathbf{X}_i, \boldsymbol{\phi}, \mathbf{u}_i)\right]\right\}$$

where n_i is the dimension of $\mathbf{y}_i$, $\mathbf{R}_i$ is a diagonal variance matrix, and $\mathbf{m}_i$ is the conditional mean vector of $\mathbf{y}_i$.

The first-order approximation is obtained by expanding $\mathbf{m}_i(\mathbf{X}_i, \boldsymbol{\phi}, \mathbf{u}_i)$ with a one-term Taylor series expansion about $\mathbf{u}_i = \mathbf{0}$, resulting in the approximation

$$p(\mathbf{y}_i|\mathbf{X}_i, \boldsymbol{\phi}, \mathbf{u}_i) \approx (2\pi)^{-n_i/2} |\mathbf{R}_i(\mathbf{X}_i, \boldsymbol{\phi})|^{-1/2}$$
$$\exp\big(-(1/2)\left[\mathbf{y}_i - \mathbf{m}_i(\mathbf{X}_i, \boldsymbol{\phi}, \mathbf{0}) - \mathbf{Z}_i(\mathbf{X}_i, \boldsymbol{\phi})\mathbf{u}_i\right]'$$
$$\mathbf{R}_i(\mathbf{X}_i, \boldsymbol{\phi})^{-1} \left[\mathbf{y}_i - \mathbf{m}_i(\mathbf{X}_i, \boldsymbol{\phi}, \mathbf{0}) - \mathbf{Z}_i(\mathbf{X}_i, \boldsymbol{\phi})\mathbf{u}_i\right]\big)$$

where $\mathbf{Z}_i(\mathbf{X}_i, \boldsymbol{\phi})$ is the Jacobian matrix $\partial \mathbf{m}_i(\mathbf{X}_i, \boldsymbol{\phi}, \mathbf{u}_i)/\partial \mathbf{u}_i$ evaluated at $\mathbf{u}_i = \mathbf{0}$.

Assuming that $q(\mathbf{u}_i|\boldsymbol{\xi})$ is normal with mean $\mathbf{0}$ and variance matrix $\mathbf{G}(\boldsymbol{\xi})$, the first-order integral approximation is computable in closed form after completing the square:

$$\int p(\mathbf{y}_i|\mathbf{X}_i, \boldsymbol{\phi}, \mathbf{u}_i) q(\mathbf{u}_i|\boldsymbol{\xi})\, d\mathbf{u}_i \approx (2\pi)^{-n_i/2} |\mathbf{V}_i(\mathbf{X}_i, \boldsymbol{\theta})|^{-1/2} \exp\left(-(1/2)\left[\mathbf{y}_i - \mathbf{m}_i(\mathbf{X}_i, \boldsymbol{\phi}, \mathbf{0})\right]' \mathbf{V}_i(\mathbf{X}_i, \boldsymbol{\theta})^{-1} \left[\mathbf{y}_i - \mathbf{m}_i(\mathbf{X}_i, \boldsymbol{\phi}, \mathbf{0})\right]\right)$$

where $\mathbf{V}_i(\mathbf{X}_i, \boldsymbol{\theta}) = \mathbf{Z}_i(\mathbf{X}_i, \boldsymbol{\phi})\mathbf{G}(\boldsymbol{\xi})\mathbf{Z}_i(\mathbf{X}_i, \boldsymbol{\phi})' + \mathbf{R}_i(\mathbf{X}_i, \boldsymbol{\phi})$. The resulting approximation for $f(\boldsymbol{\theta})$ is then minimized over $\boldsymbol{\theta} = [\boldsymbol{\phi}, \boldsymbol{\xi}]$ to obtain the first-order estimates. PROC NLMIXED uses finite-difference derivatives of the first-order integral approximation when carrying out the default dual quasi-Newton optimization.

Built-in Log-Likelihood Functions

This section displays the basic formulas used by the NLMIXED procedure to compute the conditional log-likelihood functions of the data given the random effects. Note, however, that in addition to these basic equations, the NLMIXED procedure employs a number of checks for missing values and floating-point arithmetic. You can see the entire program used by the NLMIXED procedure to compute the conditional log-likelihood functions $l(\boldsymbol{\phi}; y)$ by adding the LIST debugging option to the PROC NLMIXED statement.

$Y \sim \text{normal}(m, v)$

$$\begin{aligned} l(m, v; y) &= -\frac{1}{2}\left(\log\{2\pi\} + \frac{(y-m)^2}{v} + \log\{v\}\right) \\ \mathrm{E}[Y] &= m \\ \mathrm{Var}[Y] &= v \\ v &> 0 \end{aligned}$$

$Y \sim \text{binary}(p)$

$$\begin{aligned} l_1(p; y) &= \begin{cases} y\ \log\{p\} & y > 0 \\ 0 & \text{otherwise} \end{cases} \\ l_2(p; y) &= \begin{cases} (1-y)\ \log\{1-p\} & y < 1 \\ 0 & \text{otherwise} \end{cases} \\ l(p; y) &= l_1(p; y) + l_2(p; y) \\ \mathrm{E}[Y] &= p \\ \mathrm{Var}[Y] &= p\,(1-p) \\ 0 &< p < 1 \end{aligned}$$

$Y \sim \text{binomial}(n, p)$

$$
\begin{aligned}
l_c &= \log\{\Gamma(n+1)\} - \log\{\Gamma(y+1)\} - \log\{\Gamma(n-y+1)\} \\
l_1(n,p;y) &= \begin{cases} y \ \log\{p\} & y > 0 \\ 0 & \text{otherwise} \end{cases} \\
l_2(n,p;y) &= \begin{cases} (n-y) \ \log\{1-p\} & n-y > 0 \\ 0 & \text{otherwise} \end{cases} \\
l(n,p;y) &= l_c + l_1(n,p;y) + l_2(n,p;y) \\
\mathrm{E}[Y] &= n\,p \\
\mathrm{Var}[Y] &= n\,p\,(1-p) \\
0 &< p < 1
\end{aligned}
$$

$Y \sim \text{gamma}(a, b)$

$$
\begin{aligned}
l(a,b;y) &= -a\log\{b\} - \log\{\Gamma(a)\} + (a-1)\log\{y\} - y/b \\
\mathrm{E}[Y] &= ab \\
\mathrm{Var}[Y] &= ab^2 \\
a &> 0 \\
b &> 0
\end{aligned}
$$

This parameterization of the gamma distribution differs from the parameterization used in the GLIMMIX and GENMOD procedures. The following statements show the equivalent reparameterization in the NLMIXED procedure that fits a generalized linear model for gamma-distributed data in the parameterization of the GLIMMIX procedure:

```
proc glimmix;
   model y = x / dist=gamma s;
run;

proc nlmixed;
   parms b0=1 b1=0 scale=14;
   linp = b0 + b1*x;
   mu   = exp(linp);
   b    = mu/scale;
   model y ~ gamma(scale,b);
run;
```

$Y \sim \text{negbin}(n, p)$

$$
\begin{aligned}
l(n,p;y) &= \log\{\Gamma(n+y)\} - \log\{\Gamma(n)\} - \log\{\Gamma(y+1)\} \\
&\quad + n\log\{p\} + y\log\{1-p\} \\
\mathrm{E}[Y] &= nP = n\left(\frac{1-p}{p}\right) \\
\mathrm{Var}[Y] &= nP(1-P) = n\left(\frac{1-p}{p}\right)\frac{1}{p} \\
n &\geq 0 \\
0 &< p < 1
\end{aligned}
$$

This form of the negative binomial distribution is one of the many parameterizations in which the mass function or log-likelihood function appears. Another common parameterization uses

$$l(n, p; y) = \log\{\Gamma(n + y)\} - \log\{\Gamma(n)\} - \log\{\Gamma(y + 1)\} \\ + n \log\{1 - P/(1 + P)\} + y \log\{P/(1 + P)\}$$

with $P = (1 - p)/p$, $P > 0$.

Note that the parameter n can be real-numbered; it does not have to be integer-valued. The parameterization of the negative binomial distribution in the NLMIXED procedure differs from that in the GLIMMIX and GENMOD procedures. The following statements show the equivalent formulations for maximum likelihood estimation in the GLIMMIX and NLMIXED procedures in a negative binomial regression model:

```
proc glimmix;
  model y = x / dist=negbin s;
run;
```

```
proc nlmixed;
   parms b0=3, b1=1, k=0.8;
   linp = b0 + b1*x;
   mu = exp(linp);
   p  = 1/(1+mu*k);
   model y ~ negbin(1/k,p);
run;
```

$Y \sim \text{Poisson}(m)$

$$l(m; y) = y \log\{m\} - m - \log\{\Gamma(y + 1)\}$$
$$\text{E}[Y] = m$$
$$\text{Var}[Y] = m$$
$$m > 0$$

Optimization Algorithms

There are several optimization techniques available in PROC NLMIXED. You can choose a particular optimizer with the TECH= option in the PROC NLMIXED statement.

Algorithm	TECH=
trust region method	TRUREG
Newton-Raphson method with line search	NEWRAP
Newton-Raphson method with ridging	NRRIDG
quasi-Newton methods (DBFGS, DDFP, BFGS, DFP)	QUANEW
double-dogleg method (DBFGS, DDFP)	DBLDOG
conjugate gradient methods (PB, FR, PR, CD)	CONGRA
Nelder-Mead simplex method	NMSIMP

No algorithm for optimizing general nonlinear functions exists that always finds the global optimum for a general nonlinear minimization problem in a reasonable amount of time. Since no single optimization technique is invariably superior to others, PROC NLMIXED provides a variety of optimization techniques that work well in various circumstances. However, you can devise problems for which none of the techniques in PROC NLMIXED can find the correct solution. Moreover, nonlinear optimization can be computationally expensive in terms of time and memory, so you must be careful when matching an algorithm to a problem.

All optimization techniques in PROC NLMIXED use $O(n^2)$ memory except the conjugate gradient methods, which use only $O(n)$ of memory and are designed to optimize problems with many parameters. Since the techniques are iterative, they require the repeated computation of the following:

- the function value (optimization criterion)
- the gradient vector (first-order partial derivatives)
- for some techniques, the (approximate) Hessian matrix (second-order partial derivatives)

However, since each of the optimizers requires different derivatives, some computational efficiencies can be gained. The following table shows, for each optimization technique, which derivatives are required (FOD: first-order derivatives; SOD: second-order derivatives).

Algorithm	FOD	SOD
TRUREG	x	x
NEWRAP	x	x
NRRIDG	x	x
QUANEW	x	-
DBLDOG	x	-
CONGRA	x	-
NMSIMP	-	-

Each optimization method employs one or more convergence criteria that determine when it has converged. The various termination criteria are listed and described in the "PROC NLMIXED Statement" section. An algorithm is considered to have converged when any one of the convergence criteria is satisfied. For example, under the default settings, the QUANEW algorithm will converge if ABSGCONV$<$ 1E$-$5, FCONV$<$ $10^{-FDIGITS}$, or GCONV$<$ 1E$-$8.

Choosing an Optimization Algorithm

The factors that go into choosing a particular optimization technique for a particular problem are complex and can involve trial and error.

For many optimization problems, computing the gradient takes more computer time than computing the function value, and computing the Hessian sometimes takes *much* more computer time and memory than computing the gradient, especially when there are many decision variables. Unfortunately, optimization techniques that do not use some kind of Hessian approximation usually require many more iterations than techniques that do use a Hessian matrix, and as a result the total run time of these techniques is often longer.

Techniques that do not use the Hessian also tend to be less reliable. For example, they can more easily terminate at stationary points rather than at global optima.

A few general remarks about the various optimization techniques follow:

- The second-derivative methods TRUREG, NEWRAP, and NRRIDG are best for small problems where the Hessian matrix is not expensive to compute. Sometimes the NRRIDG algorithm can be faster than the TRUREG algorithm, but TRUREG can be more stable. The NRRIDG algorithm requires only one matrix with $n(n+1)/2$ double words; TRUREG and NEWRAP require two such matrices.
- The first-derivative methods QUANEW and DBLDOG are best for medium-sized problems where the objective function and the gradient are much faster to evaluate than the Hessian. The QUANEW and DBLDOG algorithms, in general, require more iterations than TRUREG, NRRIDG, and NEWRAP, but each iteration can be much faster. The QUANEW and DBLDOG algorithms require only the gradient to update an approximate Hessian, and they require slightly less memory than TRUREG or NEWRAP (essentially one matrix with $n(n+1)/2$ double words). QUANEW is the default optimization method.
- The first-derivative method CONGRA is best for large problems where the objective function and the gradient can be computed much faster than the Hessian and where too much memory is required to store the (approximate) Hessian. The CONGRA algorithm, in general, requires more iterations than QUANEW or DBLDOG, but each iteration can be much faster. Since CONGRA requires only a factor of n double-word memory, many large applications of PROC NLMIXED can be solved only by CONGRA.
- The no-derivative method NMSIMP is best for small problems where derivatives are not continuous or are very difficult to compute.

Algorithm Descriptions

Some details about the optimization techniques follow.

Trust Region Optimization (TRUREG)

The trust region method uses the gradient $\mathbf{g}(\boldsymbol{\theta}^{(k)})$ and the Hessian matrix $\mathbf{H}(\boldsymbol{\theta}^{(k)})$; thus, it requires that the objective function $f(\boldsymbol{\theta})$ have continuous first- and second-order derivatives inside the feasible region.

The trust region method iteratively optimizes a quadratic approximation to the nonlinear objective function within a hyperelliptic trust region with radius Δ that constrains the step size corresponding to the quality of the quadratic approximation. The trust region method is implemented using Dennis, Gay, and Welsch (1981), Gay (1983), and Moré and Sorensen (1983).

The trust region method performs well for small- to medium-sized problems, and it does not need many function, gradient, and Hessian calls. However, if the computation of the Hessian matrix is computationally expensive, one of the (dual) quasi-Newton or conjugate gradient algorithms might be more efficient.

Newton-Raphson Optimization with Line Search (NEWRAP)

The NEWRAP technique uses the gradient $\mathbf{g}(\boldsymbol{\theta}^{(k)})$ and the Hessian matrix $\mathbf{H}(\boldsymbol{\theta}^{(k)})$; thus, it requires that the objective function have continuous first- and second-order derivatives inside the feasible region. If second-order derivatives are computed efficiently and precisely, the NEWRAP method can perform well for medium-sized to large problems, and it does not need many function, gradient, and Hessian calls.

This algorithm uses a pure Newton step when the Hessian is positive definite and when the Newton step reduces the value of the objective function successfully. Otherwise, a combination of ridging and line search is performed to compute successful steps. If the Hessian is not positive definite, a multiple of the identity matrix is added to the Hessian matrix to make it positive definite (Eskow and Schnabel 1991).

In each iteration, a line search is performed along the search direction to find an approximate optimum of the objective function. The default line-search method uses quadratic interpolation and cubic extrapolation (LINESEARCH=2).

Newton-Raphson Ridge Optimization (NRRIDG)

The NRRIDG technique uses the gradient $\mathbf{g}(\boldsymbol{\theta}^{(k)})$ and the Hessian matrix $\mathbf{H}(\boldsymbol{\theta}^{(k)})$; thus, it requires that the objective function have continuous first- and second-order derivatives inside the feasible region.

This algorithm uses a pure Newton step when the Hessian is positive definite and when the Newton step reduces the value of the objective function successfully. If at least one of these two conditions is not satisfied, a multiple of the identity matrix is added to the Hessian matrix.

The NRRIDG method performs well for small- to medium-sized problems, and it does not require many function, gradient, and Hessian calls. However, if the computation of the Hessian matrix is computationally expensive, one of the (dual) quasi-Newton or conjugate gradient algorithms might be more efficient.

Since the NRRIDG technique uses an orthogonal decomposition of the approximate Hessian, each iteration of NRRIDG can be slower than that of the NEWRAP technique, which works with Cholesky decomposition. Usually, however, NRRIDG requires fewer iterations than NEWRAP.

Quasi-Newton Optimization (QUANEW)

The (dual) quasi-Newton method uses the gradient $\mathbf{g}(\boldsymbol{\theta}^{(k)})$, and it does not need to compute second-order derivatives since they are approximated. It works well for medium to moderately large optimization problems where the objective function and the gradient are much faster to compute than the Hessian; but, in general, it requires more iterations than the TRUREG, NEWRAP, and NRRIDG techniques, which compute second-order derivatives. QUANEW is the default optimization algorithm because it provides an appropriate balance between the speed and stability required for most nonlinear mixed model applications.

The QUANEW technique is one of the following, depending on the value of the UPDATE= option.

- the original quasi-Newton algorithm, which updates an approximation of the inverse Hessian
- the dual quasi-Newton algorithm, which updates the Cholesky factor of an approximate Hessian (default)

You can specify four update formulas with the UPDATE= option:

- DBFGS performs the dual Broyden, Fletcher, Goldfarb, and Shanno (BFGS) update of the Cholesky factor of the Hessian matrix. This is the default.
- DDFP performs the dual Davidon, Fletcher, and Powell (DFP) update of the Cholesky factor of the Hessian matrix.
- BFGS performs the original BFGS update of the inverse Hessian matrix.
- DFP performs the original DFP update of the inverse Hessian matrix.

In each iteration, a line search is performed along the search direction to find an approximate optimum. The default line-search method uses quadratic interpolation and cubic extrapolation to obtain a step size α satisfying the Goldstein conditions. One of the Goldstein conditions can be violated if the feasible region defines an upper limit of the step size. Violating the left-side Goldstein condition can affect the positive definiteness of the quasi-Newton update. In that case, either the update is skipped or the iterations are restarted with an identity matrix, resulting in the steepest descent or ascent search direction. You can specify line-search algorithms other than the default with the LINESEARCH= option.

The QUANEW algorithm uses its own line-search technique. No options and parameters (except the INSTEP= option) controlling the line search in the other algorithms apply here. In several applications, large steps in the first iterations are troublesome. You can use the INSTEP= option to impose an upper bound for the step size α during the first five iterations. You can also use the INHESSIAN=r option to specify a different starting approximation for the Hessian. If you specify only the INHESSIAN option, the Cholesky factor of a (possibly ridged) finite difference approximation of the Hessian is used to initialize the quasi-Newton update process. The values of the LCSINGULAR=, LCEPSILON=, and LCDEACT= options, which control the processing of linear and boundary constraints, are valid only for the quadratic programming subroutine used in each iteration of the QUANEW algorithm.

Double-Dogleg Optimization (DBLDOG)

The double-dogleg optimization method combines the ideas of the quasi-Newton and trust region methods. In each iteration, the double-dogleg algorithm computes the step $\mathbf{s}^{(k)}$ as the linear combination of the steepest descent or ascent search direction $\mathbf{s}_1^{(k)}$ and a quasi-Newton search direction $\mathbf{s}_2^{(k)}$:

$$\mathbf{s}^{(k)} = \alpha_1 \mathbf{s}_1^{(k)} + \alpha_2 \mathbf{s}_2^{(k)}$$

The step is requested to remain within a prespecified trust region radius; see Fletcher (1987, p. 107). Thus, the DBLDOG subroutine uses the dual quasi-Newton update but does not perform a line search. You can specify two update formulas with the UPDATE= option:

- DBFGS performs the dual Broyden, Fletcher, Goldfarb, and Shanno update of the Cholesky factor of the Hessian matrix. This is the default.
- DDFP performs the dual Davidon, Fletcher, and Powell update of the Cholesky factor of the Hessian matrix.

The double-dogleg optimization technique works well for medium to moderately large optimization problems where the objective function and the gradient are much faster to compute than the Hessian. The implementation is based on Dennis and Mei (1979) and Gay (1983), but it is extended for dealing with boundary and linear constraints. The DBLDOG technique generally requires more iterations than the TRUREG, NEWRAP, and NRRIDG techniques, which require second-order derivatives; however, each of the DBLDOG iterations is computationally cheap. Furthermore, the DBLDOG technique requires only gradient calls for the update of the Cholesky factor of an approximate Hessian.

Conjugate Gradient Optimization (CONGRA)

Second-order derivatives are not required by the CONGRA algorithm and are not even approximated. The CONGRA algorithm can be expensive in function and gradient calls, but it requires only $O(n)$ memory for unconstrained optimization. In general, many iterations are required to obtain a precise solution, but each of the CONGRA iterations is computationally cheap. You can specify four different update formulas for generating the conjugate directions by using the UPDATE= option:

- PB performs the automatic restart update method of Powell (1977) and Beale (1972). This is the default.
- FR performs the Fletcher-Reeves update (Fletcher 1987).
- PR performs the Polak-Ribiere update (Fletcher 1987).
- CD performs a conjugate-descent update of Fletcher (1987).

The default, UPDATE=PB, behaved best in most test examples. You are advised to avoid the option UPDATE=CD, which behaved worst in most test examples.

The CONGRA subroutine should be used for optimization problems with large n. For the unconstrained or boundary constrained case, CONGRA requires only $O(n)$ bytes of working memory, whereas all other optimization methods require order $O(n^2)$ bytes of working memory. During n successive iterations, uninterrupted by restarts or changes in the working set, the conjugate gradient algorithm computes a cycle of n conjugate search directions. In each iteration, a line search is performed along the search direction to find an approximate optimum of the objective function. The default line-search method uses quadratic interpolation and cubic extrapolation to obtain a step size α satisfying the Goldstein conditions. One of the Goldstein conditions can be violated if the feasible region defines an upper limit for the step size. Other line-search algorithms can be specified with the LINESEARCH= option.

Nelder-Mead Simplex Optimization (NMSIMP)

The Nelder-Mead simplex method does not use any derivatives and does not assume that the objective function has continuous derivatives. The objective function itself needs to be continuous. This technique is quite expensive in the number of function calls, and it might be unable to generate precise results for $n \gg 40$.

The original Nelder-Mead simplex algorithm is implemented and extended to boundary constraints. This algorithm does not compute the objective for infeasible points, but it changes the shape of the simplex adapting to the nonlinearities of the objective function, which contributes to an increased speed of convergence. It uses a special termination criterion.

Finite-Difference Approximations of Derivatives

The FD= and FDHESSIAN= options specify the use of finite-difference approximations of the derivatives. The FD= option specifies that all derivatives are approximated using function evaluations, and the FDHESSIAN= option specifies that second-order derivatives are approximated using gradient evaluations.

Computing derivatives by finite-difference approximations can be very time-consuming, especially for second-order derivatives based only on values of the objective function (FD= option). If analytical derivatives are difficult to obtain (for example, if a function is computed by an iterative process), you might consider one of the optimization techniques that use first-order derivatives only (QUANEW, DBLDOG, or CONGRA). In the expressions that follow, $\boldsymbol{\theta}$ denotes the parameter vector, h_i denotes the step size for the ith parameter, and $\mathbf{e}_i$ is a vector of zeros with a 1 in the ith position.

Forward-Difference Approximations

The forward-difference derivative approximations consume less computer time, but they are usually not as precise as approximations that use central-difference formulas.

- For first-order derivatives, n additional function calls are required:

$$g_i = \frac{\partial f}{\partial \theta_i} \approx \frac{f(\boldsymbol{\theta} + h_i \mathbf{e}_i) - f(\boldsymbol{\theta})}{h_i}$$

- For second-order derivatives based on function calls only (Dennis and Schnabel 1983, p. 80), $n+n^2/2$ additional function calls are required for dense Hessian:

$$\frac{\partial^2 f}{\partial \theta_i \partial \theta_j} \approx \frac{f(\boldsymbol{\theta} + h_i \mathbf{e}_i + h_j \mathbf{e}_j) - f(\boldsymbol{\theta} + h_i \mathbf{e}_i) - f(\boldsymbol{\theta} + h_j \mathbf{e}_j) + f(\boldsymbol{\theta})}{h_i h_j}$$

- For second-order derivatives based on gradient calls (Dennis and Schnabel 1983, p. 103), n additional gradient calls are required:

$$\frac{\partial^2 f}{\partial \theta_i \partial \theta_j} \approx \frac{g_i(\boldsymbol{\theta} + h_j \mathbf{e}_j) - g_i(\boldsymbol{\theta})}{2h_j} + \frac{g_j(\boldsymbol{\theta} + h_i \mathbf{e}_i) - g_j(\boldsymbol{\theta})}{2h_i}$$

Central-Difference Approximations

Central-difference approximations are usually more precise, but they consume more computer time than approximations that use forward-difference derivative formulas.

- For first-order derivatives, $2n$ additional function calls are required:

$$g_i = \frac{\partial f}{\partial \theta_i} \approx \frac{f(\boldsymbol{\theta} + h_i \mathbf{e}_i) - f(\boldsymbol{\theta} - h_i \mathbf{e}_i)}{2h_i}$$

- For second-order derivatives based on function calls only (Abramowitz and Stegun 1972, p. 884), $2n + 4n^2/2$ additional function calls are required.

$$\frac{\partial^2 f}{\partial \theta_i^2} \approx \frac{-f(\boldsymbol{\theta} + 2h_i\mathbf{e}_i) + 16f(\boldsymbol{\theta} + h_i\mathbf{e}_i) - 30f(\boldsymbol{\theta}) + 16f(\boldsymbol{\theta} - h_{\mathbf{i}}e_i) - f(\boldsymbol{\theta} - 2h_i\mathbf{e}_i)}{12h_i^2}$$

$$\frac{\partial^2 f}{\partial \theta_i \partial \theta_j} \approx \frac{f(\boldsymbol{\theta} + h_i\mathbf{e}_i + h_j\mathbf{e}_j) - f(\boldsymbol{\theta} + h_i\mathbf{e}_i - h_j\mathbf{e}_j) - f(\boldsymbol{\theta} - h_i\mathbf{e}_i + h_j\mathbf{e}_j) + f(\boldsymbol{\theta} - h_i\mathbf{e}_i - h_j\mathbf{e}_j)}{4h_i h_j}$$

- For second-order derivatives based on gradient calls, $2n$ additional gradient calls are required:

$$\frac{\partial^2 f}{\partial \theta_i \partial \theta_j} \approx \frac{g_i(\boldsymbol{\theta} + h_j\mathbf{e}_j) - g_i(\boldsymbol{\theta} - h_j\mathbf{e}_j)}{4h_j} + \frac{g_j(\boldsymbol{\theta} + h_i\mathbf{e}_i) - g_j(\boldsymbol{\theta} - h_i\mathbf{e}_i)}{4h_i}$$

You can use the FDIGITS= option to specify the number of accurate digits in the evaluation of the objective function. This specification is helpful in determining an appropriate interval size h to be used in the finite-difference formulas.

The step sizes h_j, $j = 1, \ldots, n$ are defined as follows:

- For the forward-difference approximation of first-order derivatives that use function calls and second-order derivatives that use gradient calls, $h_j = \sqrt[2]{\eta}(1 + |\theta_j|)$.
- For the forward-difference approximation of second-order derivatives that use only function calls and all central-difference formulas, $h_j = \sqrt[3]{\eta}(1 + |\theta_j|)$.

The value of η is defined by the FDIGITS= option:

- If you specify the number of accurate digits by using FDIGITS=r, η is set to 10^{-r}.
- If you do not specify the FDIGITS= option, η is set to the machine precision ϵ.

Hessian Scaling

The rows and columns of the Hessian matrix can be scaled when you use the trust region, Newton-Raphson, and double-dogleg optimization techniques. Each element $H_{i,j}$, $i, j = 1, \ldots, n$ is divided by the scaling factor $d_i d_j$, where the scaling vector $d = (d_1, \ldots, d_n)$ is iteratively updated in a way specified by the HESCAL=i option, as follows:

$i = 0$: No scaling is done (equivalent to $d_i = 1$).

$i \neq 0$: First iteration and each restart iteration sets:

$$d_i^{(0)} = \sqrt{\max(|H_{i,i}^{(0)}|, \epsilon)}$$

$i = 1$: Refer to Moré (1978):

$$d_i^{(k+1)} = \max\left[d_i^{(k)}, \sqrt{\max(|H_{i,i}^{(k)}|, \epsilon)}\right]$$

$i = 2$: Refer to Dennis, Gay, and Welsch (1981):

$$d_i^{(k+1)} = \max\left[0.6d_i^{(k)}, \sqrt{\max(|H_{i,i}^{(k)}|, \epsilon)}\right]$$

$i = 3$: d_i is reset in each iteration:

$$d_i^{(k+1)} = \sqrt{\max(|H_{i,i}^{(k)}|, \epsilon)}$$

In the preceding equations, ϵ is the relative machine precision or, equivalently, the largest double-precision value that, when added to 1, results in 1.

Active Set Methods

The parameter vector $\boldsymbol{\theta} \in \mathcal{R}^n$ can be subject to a set of m linear equality and inequality constraints:

$$\sum_{j=1}^{n} a_{ij}\theta_j = b_i \qquad i = 1, \ldots, m_e$$
$$\sum_{j=1}^{n} a_{ij}\theta_j \geq b_i \qquad i = m_e + 1, \ldots, m$$

The coefficients a_{ij} and right-hand sides b_i of the equality and inequality constraints are collected in the $m \times n$ matrix $\mathbf{A}$ and the m vector $\mathbf{b}$.

The m linear constraints define a feasible region $\mathcal{G}$ in $\mathcal{R}^n$ that must contain the point $\boldsymbol{\theta}_*$ that minimizes the problem. If the feasible region $\mathcal{G}$ is empty, no solution to the optimization problem exists.

In PROC NLMIXED, all optimization techniques use *active set methods*. The iteration starts with a feasible point $\boldsymbol{\theta}^{(0)}$, which you can provide or which can be computed by the Schittkowski and Stoer (1979) algorithm implemented in PROC NLMIXED. The algorithm then moves from one feasible point $\boldsymbol{\theta}^{(k-1)}$ to a better feasible point $\boldsymbol{\theta}^{(k)}$ along a feasible search direction $\mathbf{s}^{(k)}$,

$$\boldsymbol{\theta}^{(k)} = \boldsymbol{\theta}^{(k-1)} + \alpha^{(k)}\mathbf{s}^{(k)} \quad , \quad \alpha^{(k)} > 0$$

Theoretically, the path of points $\boldsymbol{\theta}^{(k)}$ never leaves the feasible region $\mathcal{G}$ of the optimization problem, but it can reach its boundaries. The active set $\mathcal{A}^{(k)}$ of point $\boldsymbol{\theta}^{(k)}$ is defined as the index set of all linear equality constraints and those inequality constraints that are satisfied at $\boldsymbol{\theta}^{(k)}$. If no constraint is active $\boldsymbol{\theta}^{(k)}$, the point is located in the interior of $\mathcal{G}$, and the active set $\mathcal{A}^{(k)} = \emptyset$ is empty. If the point $\boldsymbol{\theta}^{(k)}$ in iteration k hits the boundary of inequality constraint i, this constraint i becomes active and is added to $\mathcal{A}^{(k)}$. Each equality constraint and each active inequality constraint reduce the dimension (degrees of freedom) of the optimization problem.

In practice, the active constraints can be satisfied only with finite precision. The LCEPSILON=*r* option specifies the range for active and violated linear constraints. If the point $\boldsymbol{\theta}^{(k)}$ satisfies the condition

$$\left| \sum_{j=1}^{n} a_{ij}\theta_j^{(k)} - b_i \right| \leq t$$

where $t = r(|b_i| + 1)$, the constraint i is recognized as an active constraint. Otherwise, the constraint i is either an inactive inequality or a violated inequality or equality constraint. Due to rounding errors in computing the projected search direction, error can be accumulated so that an iterate $\boldsymbol{\theta}^{(k)}$ steps out of the feasible region.

In those cases, PROC NLMIXED might try to pull the iterate $\boldsymbol{\theta}^{(k)}$ back into the feasible region. However, in some cases the algorithm needs to increase the feasible region by increasing the LCEPSILON=*r* value. If this happens, a message is displayed in the log output.

If the algorithm cannot improve the value of the objective function by moving from an active constraint back into the interior of the feasible region, it makes this inequality constraint an equality constraint in the next iteration. This means that the active set $\mathcal{A}^{(k+1)}$ still contains the constraint i. Otherwise, it releases the active inequality constraint and increases the dimension of the optimization problem in the next iteration.

A serious numerical problem can arise when some of the active constraints become (nearly) linearly dependent. PROC NLMIXED removes linearly dependent equality constraints before starting optimization. You can use the LCSINGULAR= option to specify a criterion r used in the update of the QR decomposition that determines whether an active constraint is linearly dependent relative to a set of other active constraints.

If the solution $\boldsymbol{\theta}^*$ is subjected to n_{act} linear equality or active inequality constraints, the QR decomposition of the $n \times n_{act}$ matrix $\hat{\mathbf{A}}'$ of the linear constraints is computed by $\hat{\mathbf{A}}' = \mathbf{QR}$, where $\mathbf{Q}$ is an $n \times n$ orthogonal matrix and $\mathbf{R}$ is an $n \times n_{act}$ upper triangular matrix. The n columns of matrix $\mathbf{Q}$ can be separated into two matrices, $\mathbf{Q} = [\mathbf{Y}, \mathbf{Z}]$, where $\mathbf{Y}$ contains the first n_{act} orthogonal columns of $\mathbf{Q}$ and $\mathbf{Z}$ contains the last $n - n_{act}$ orthogonal columns of $\mathbf{Q}$. The $n \times (n - n_{act})$ column-orthogonal matrix $\mathbf{Z}$ is also called the *null-space matrix* of the active linear constraints $\hat{\mathbf{A}}'$. The $n - n_{act}$ columns of the $n \times (n - n_{act})$ matrix $\mathbf{Z}$ form a basis orthogonal to the rows of the $n_{act} \times n$ matrix $\hat{\mathbf{A}}$.

At the end of the iterating, PROC NLMIXED computes the *projected gradient* $\mathbf{g}_Z$,

$$\mathbf{g}_Z = \mathbf{Z}'\mathbf{g}$$

In the case of boundary-constrained optimization, the elements of the projected gradient correspond to the gradient elements of the free parameters. A necessary condition for $\boldsymbol{\theta}^*$ to be a local minimum of the optimization problem is

$$\mathbf{g}_Z(\boldsymbol{\theta}^*) = \mathbf{Z}'\mathbf{g}(\boldsymbol{\theta}^*) = \mathbf{0}$$

The symmetric $n_{act} \times n_{act}$ matrix $\mathbf{G}_Z$,

$$\mathbf{G}_Z = \mathbf{Z}'\mathbf{G}\mathbf{Z}$$

is called a *projected Hessian matrix*. A second-order necessary condition for $\boldsymbol{\theta}^*$ to be a local minimizer requires that the projected Hessian matrix is positive semidefinite.

Those elements of the n_{act} vector of first-order estimates of *Lagrange multipliers*,

$$\lambda = (\hat{\mathbf{A}}\hat{\mathbf{A}}')^{-1}\hat{\mathbf{A}}\mathbf{Z}\mathbf{Z}'\mathbf{g}$$

that correspond to active inequality constraints indicate whether an improvement of the objective function can be obtained by releasing this active constraint. For minimization, a significant negative Lagrange multiplier indicates that a possible reduction of the objective function can be achieved by releasing this active linear constraint. The LCDEACT=r option specifies a threshold r for the Lagrange multiplier that determines whether an active inequality constraint remains active or can be deactivated. (In the case of boundary-constrained optimization, the Lagrange multipliers for active lower (upper) constraints are the negative (positive) gradient elements corresponding to the active parameters.)

Line-Search Methods

In each iteration k, the (dual) quasi-Newton, conjugate gradient, and Newton-Raphson minimization techniques use iterative line-search algorithms that try to optimize a linear, quadratic, or cubic approximation of f along a feasible descent search direction $\mathbf{s}^{(k)}$,

$$\boldsymbol{\theta}^{(k+1)} = \boldsymbol{\theta}^{(k)} + \alpha^{(k)}\mathbf{s}^{(k)}, \quad \alpha^{(k)} > 0$$

by computing an approximately optimal scalar $\alpha^{(k)}$.

Therefore, a line-search algorithm is an iterative process that optimizes a nonlinear function $f(\alpha)$ of one parameter (α) within each iteration k of the optimization technique. Since the outside iteration process is based only on the approximation of the objective function, the inside iteration of the line-search algorithm does not have to be perfect. Usually, it is satisfactory that the choice of α significantly reduces (in a minimization) the objective function. Criteria often used for termination of line-search algorithms are the Goldstein conditions (see Fletcher 1987).

You can select various line-search algorithms by specifying the LINESEARCH= option. The line-search method LINESEARCH=2 seems to be superior when function evaluation consumes significantly less computation time than gradient evaluation. Therefore, LINESEARCH=2 is the default method for Newton-Raphson, (dual) quasi-Newton, and conjugate gradient optimizations.

You can modify the line-search methods LINESEARCH=2 and LINESEARCH=3 to be exact line searches by using the LSPRECISION= option and specifying the σ parameter described in Fletcher (1987). The line-search methods LINESEARCH=1, LINESEARCH=2, and LINESEARCH=3 satisfy the left-side and right-side Goldstein conditions (see Fletcher 1987). When derivatives are available, the line-search methods LINESEARCH=6, LINESEARCH=7, and LINESEARCH=8 try to satisfy the right-side Goldstein condition; if derivatives are not available, these line-search algorithms use only function calls.

Restricting the Step Length

Almost all line-search algorithms use iterative extrapolation techniques that can easily lead them to (feasible) points where the objective function f is no longer defined or is difficult to compute. Therefore, PROC NLMIXED provides options restricting the step length α or trust region radius Δ, especially during the first main iterations.

The inner product $\mathbf{g}'\mathbf{s}$ of the gradient $\mathbf{g}$ and the search direction $\mathbf{s}$ is the slope of $f(\alpha) = f(\boldsymbol{\theta} + \alpha\mathbf{s})$ along the search direction $\mathbf{s}$. The default starting value $\alpha^{(0)} = \alpha^{(k,0)}$ in each line-search algorithm ($\min_{\alpha>0} f(\boldsymbol{\theta} + \alpha\mathbf{s})$) during the main iteration k is computed in three steps:

1. The first step uses either the difference $df = |f^{(k)} - f^{(k-1)}|$ of the function values during the last two consecutive iterations or the final step-size value α^- of the last iteration $k-1$ to compute a first value of $\alpha_1^{(0)}$.
   - If the DAMPSTEP option is not used,

     $$\alpha_1^{(0)} = \begin{cases} step & \text{if } 0.1 \leq step \leq 10 \\ 10 & \text{if } step > 10 \\ 0.1 & \text{if } step < 0.1 \end{cases}$$

     with

     $$step = \begin{cases} df/|\mathbf{g}'\mathbf{s}| & \text{if } |\mathbf{g}'\mathbf{s}| \geq \epsilon \max(100df, 1) \\ 1 & \text{otherwise} \end{cases}$$

     This value of $\alpha_1^{(0)}$ can be too large and can lead to a difficult or impossible function evaluation, especially for highly nonlinear functions such as the EXP function.
   - If the DAMPSTEP=r option is used,

     $$\alpha_1^{(0)} = \min(1, r\alpha^-)$$

     The initial value for the new step length can be no larger than r times the final step length α^- of the former iteration. The default value is $r = 2$.
2. During the first five iterations, the second step enables you to reduce $\alpha_1^{(0)}$ to a smaller starting value $\alpha_2^{(0)}$ by using the INSTEP=r option:

   $$\alpha_2^{(0)} = \min(\alpha_1^{(0)}, r)$$

   After more than five iterations, $\alpha_2^{(0)}$ is set to $\alpha_1^{(0)}$.
3. The third step can further reduce the step length by

   $$\alpha_3^{(0)} = \min(\alpha_2^{(0)}, \min(10, u))$$

   where u is the maximum length of a step inside the feasible region.

The INSTEP=r option enables you to specify a smaller or larger radius Δ of the trust region used in the first iteration of the trust region and double-dogleg algorithms. The default initial trust region radius $\Delta^{(0)}$ is the length of the scaled gradient (Moré 1978). This step corresponds to the default radius factor of $r = 1$. In most practical applications of the TRUREG and DBLDOG algorithms, this choice is successful. However, for bad initial values and highly nonlinear objective functions (such as the EXP function), the default start radius can result in arithmetic overflows. If this happens, you can try decreasing values of INSTEP=r, $0 < r < 1$, until the iteration starts successfully. A small factor r also affects the trust region radius $\Delta^{(k+1)}$ of the next steps because the radius is changed in each iteration by a factor $0 < c \leq 4$, depending on the ratio ρ expressing the goodness of quadratic function approximation. Reducing the radius Δ corresponds to increasing the ridge parameter λ, producing smaller steps aimed more closely toward the (negative) gradient direction.

Computational Problems

Floating-Point Errors and Overflows

Numerical optimization of a numerically integrated function is a difficult task, and the computation of the objective function and its derivatives can lead to arithmetic exceptions and overflows. A typical cause of these problems is parameters with widely varying scales. If the scaling of your parameters varies by more than a few orders of magnitude, the numerical stability of the optimization problem can be seriously reduced and can result in computational difficulties. A simple remedy is to rescale each parameter so that its final estimated value has a magnitude near 1.

If parameter rescaling does not help, consider the following actions:

- Specify the ITDETAILS option in the PROC NLMIXED statement to obtain more detailed information about when and where the problem is occurring.
- Provide different initial values or try a grid search of values.
- Use boundary constraints to avoid the region where overflows can happen.
- Delete outlying observations or subjects from the input data, if this is reasonable.
- Change the algorithm (specified in programming statements) that computes the objective function.

The line-search algorithms that work with cubic extrapolation are especially sensitive to arithmetic overflows. If an overflow occurs during a line search, you can use the INSTEP= option to reduce the length of the first trial step during the first five iterations, or you can use the DAMPSTEP or MAXSTEP option to restrict the step length of the initial α in subsequent iterations. If an arithmetic overflow occurs in the first iteration of the trust region or double-dogleg algorithm, you can use the INSTEP= option to reduce the default trust region radius of the first iteration. You can also change the optimization technique or the line-search method.

Long Run Times

PROC NLMIXED can take a long time to run for problems involving complex models, many parameters, or large input data sets. Although the optimization techniques used by PROC NLMIXED are some of the best ones available, they are not guaranteed to converge quickly for all problems. Ill-posed or misspecified models can cause the algorithms to use more extensive calculations designed to achieve convergence, and this can result in longer run times. So first make sure that your model is specified correctly, that your parameters are scaled to be of the same order of magnitude, and that your data reasonably match the model you are contemplating.

If you are using the default adaptive Gaussian quadrature algorithm and no iteration history is printing at all, then PROC NLMIXED might be bogged down trying to determine the number of quadrature points at the first set of starting values. Specifying the QPOINTS= option will bypass this stage and proceed directly to iterations; however, be aware that the likelihood approximation might not be accurate if there are too few quadrature points.

PROC NLMIXED can also have difficulty determining the number of quadrature points if the initial starting values are far from the optimum values. To obtain more accurate starting values for the model parameters, one easy method is to fit a model with no RANDOM statement. You can then use these estimates as starting values, although you will still need to specify values for the random-effects distribution. For normal-normal models, another strategy is to use METHOD=FIRO. If you can obtain estimates by using this approximate method, then they can be used as starting values for more accurate likelihood approximations.

If you are running PROC NLMIXED multiple times, you will probably want to include a statement like the following in your program:

```
ods output ParameterEstimates=pe;
```

This statement creates a SAS data set named PE upon completion of the run. In your next invocation of PROC NLMIXED, you can then specify

```
parms / data=pe;
```

to read in the previous estimates as starting values.

To speed general computations, you should double-check your programming statements to minimize the number of floating-point operations. Using auxiliary variables and factoring amenable expressions can be useful changes in this regard.

Problems Evaluating Code for Objective Function

The starting point $\boldsymbol{\theta}^{(0)}$ must be a point for which the programming statements can be evaluated. However, during optimization, the optimizer might iterate to a point $\boldsymbol{\theta}^{(k)}$ where the objective function or its derivatives cannot be evaluated. In some cases, the specification of boundary for parameters can avoid such situations. In many other cases, you can indicate that the point $\boldsymbol{\theta}^{(0)}$ is a bad point simply by returning an extremely large value for the objective function. In these cases, the optimization algorithm reduces the step length and stays closer to the point that has been evaluated successfully in the former iteration.

No Convergence

There are a number of things to try if the optimizer fails to converge.

- Change the initial values by using a grid search specification to obtain a set of good feasible starting values.
- Change or modify the update technique or the line-search algorithm.

  This method applies only to TECH=QUANEW and TECH=CONGRA. For example, if you use the default update formula and the default line-search algorithm, you can do the following:

  – change the update formula with the UPDATE= option
  – change the line-search algorithm with the LINESEARCH= option
  – specify a more precise line search with the LSPRECISION= option, if you use LINESEARCH=2 or LINESEARCH=3

- Change the optimization technique.

  For example, if you use the default option, TECH=QUANEW, you can try one of the second-derivative methods if your problem is small or the conjugate gradient method if it is large.

- Adjust finite-difference derivatives.

  The forward-difference derivatives specified with the FD= or FDHESSIAN= option might not be precise enough to satisfy strong gradient termination criteria. You might need to specify the more expensive central-difference formulas. The finite-difference intervals might be too small or too big, and the finite-difference derivatives might be erroneous.

- Double-check the data entry and program specification.

Convergence to Stationary Point

The gradient at a stationary point is the null vector, which always leads to a zero search direction. This point satisfies the first-order termination criterion. Search directions that are based on the gradient are zero, so the algorithm terminates. There are two ways to avoid this situation:

- Use the PARMS statement to specify a grid of feasible initial points.
- Use the OPTCHECK=*r* option to avoid terminating at the stationary point.

The signs of the eigenvalues of the (reduced) Hessian matrix contain the following information regarding a stationary point:

- If all of the eigenvalues are positive, the Hessian matrix is positive definite, and the point is a minimum point.
- If some of the eigenvalues are positive and all remaining eigenvalues are zero, the Hessian matrix is positive semidefinite, and the point is a minimum or saddle point.
- If all of the eigenvalues are negative, the Hessian matrix is negative definite, and the point is a maximum point.
- If some of the eigenvalues are negative and all remaining eigenvalues are zero, the Hessian matrix is negative semidefinite, and the point is a maximum or saddle point.
- If all of the eigenvalues are zero, the point can be a minimum, maximum, or saddle point.

Precision of Solution

In some applications, PROC NLMIXED can result in parameter values that are not precise enough. Usually, this means that the procedure terminated at a point too far from the optimal point. The termination criteria define the size of the termination region around the optimal point. Any point inside this region can be accepted for terminating the optimization process. The default values of the termination criteria are set to satisfy a reasonable compromise between the computational effort (computer time) and the precision of the

computed estimates for the most common applications. However, there are a number of circumstances in which the default values of the termination criteria specify a region that is either too large or too small.

If the termination region is too large, then it can contain points with low precision. In such cases, you should determine which termination criterion stopped the optimization process. In many applications, you can obtain a solution with higher precision simply by using the old parameter estimates as starting values in a subsequent run in which you specify a smaller value for the termination criterion that was satisfied at the former run.

If the termination region is too small, the optimization process might take longer to find a point inside such a region, or it might not even find such a point due to rounding errors in function values and derivatives. This can easily happen in applications in which finite-difference approximations of derivatives are used and the GCONV and ABSGCONV termination criteria are too small to respect rounding errors in the gradient values.

Covariance Matrix

The estimated covariance matrix of the parameter estimates is computed as the inverse Hessian matrix, and for unconstrained problems it should be positive definite. If the final parameter estimates are subjected to $n_{act} > 0$ active linear inequality constraints, the formulas of the covariance matrices are modified similar to Gallant (1987) and Cramer (1986, p. 38) and additionally generalized for applications with singular matrices.

There are several steps available that enable you to tune the rank calculations of the covariance matrix.

1. You can use the ASINGULAR=, MSINGULAR=, and VSINGULAR= options to set three singularity criteria for the inversion of the Hessian matrix $\mathbf{H}$. The singularity criterion used for the inversion is

$$|d_{j,j}| \leq \max(\text{ASING}, \text{VSING} * |H_{j,j}|, \text{MSING} * max(|H_{1,1}|, \ldots, |H_{n,n}|))$$

   where $d_{j,j}$ is the diagonal pivot of the matrix $\mathbf{H}$, and ASING, VSING, and MSING are the specified values of the ASINGULAR=, VSINGULAR=, and MSINGULAR= options, respectively. The default values are as follows:

   - ASING: the square root of the smallest positive double-precision value
   - MSING: 1E−12 if you do not specify the SINGHESS= option and $\max(10\epsilon, 1\text{E} - 4 \times \text{SINGHESS})$ otherwise, where ϵ is the machine precision
   - VSING: 1E−8 if you do not specify the SINGHESS= option and the value of SINGHESS otherwise

   Note that, in many cases, a normalized matrix $\mathbf{D}^{-1}\mathbf{A}\mathbf{D}^{-1}$ is decomposed, and the singularity criteria are modified correspondingly.

2. If the matrix $\mathbf{H}$ is found to be singular in the first step, a generalized inverse is computed. Depending on the G4= option, either a generalized inverse satisfying all four Moore-Penrose conditions is computed (a g_4-inverse) or a generalized inverse satisfying only two Moore-Penrose conditions is computed (a g_2-inverse, Pringle and Rayner, 1971). If the number of parameters n of the application

is less than or equal to G4=i, a g_4-inverse is computed; otherwise, only a g_2-inverse is computed. The g_4-inverse is computed by the (computationally very expensive but numerically stable) eigenvalue decomposition, and the g_2-inverse is computed by Gauss transformation. The g_4-inverse is computed using the eigenvalue decomposition $\mathbf{A} = \mathbf{Z}\mathbf{\Lambda}\mathbf{Z}'$, where $\mathbf{Z}$ is the orthogonal matrix of eigenvectors and $\mathbf{\Lambda}$ is the diagonal matrix of eigenvalues, $\mathbf{\Lambda} = diag(\lambda_1, \ldots, \lambda_n)$. The g_4-inverse of $\mathbf{H}$ is set to

$$\mathbf{A}^- = \mathbf{Z}\mathbf{\Lambda}^-\mathbf{Z}'$$

where the diagonal matrix $\mathbf{\Lambda}^- = diag(\lambda_1^-, \ldots, \lambda_n^-)$ is defined using the COVSING= option:

$$\lambda_i^- = \begin{cases} 1/\lambda_i & \text{if } |\lambda_i| > \text{COVSING} \\ 0 & \text{if } |\lambda_i| \leq \text{COVSING} \end{cases}$$

If you do not specify the COVSING= option, the nr smallest eigenvalues are set to zero, where nr is the number of rank deficiencies found in the first step.

For optimization techniques that do not use second-order derivatives, the covariance matrix is computed using finite-difference approximations of the derivatives.

Prediction

The nonlinear mixed model is a useful tool for statistical prediction. Assuming a prediction is to be made regarding the ith subject, suppose that $f(\boldsymbol{\theta}, \mathbf{u}_i)$ is a differentiable function predicting some quantity of interest. Recall that $\boldsymbol{\theta}$ denotes the vector of unknown parameters and $\mathbf{u}_i$ denotes the vector of random effects for the ith subject. A natural point prediction is $f(\widehat{\boldsymbol{\theta}}, \widehat{\mathbf{u}}_i)$, where $\widehat{\boldsymbol{\theta}}$ is the maximum likelihood estimate of $\boldsymbol{\theta}$ and $\widehat{\mathbf{u}}_i$ is the empirical Bayes estimate of $\mathbf{u}_i$ described previously in the section "Integral Approximations" on page 5218.

An approximate prediction variance matrix for $(\widehat{\boldsymbol{\theta}}, \widehat{\mathbf{u}}_i)$ is

$$\mathbf{P} = \begin{bmatrix} \widehat{\mathbf{H}}^{-1} & \widehat{\mathbf{H}}^{-1}\left(\frac{\partial \widehat{\mathbf{u}}_i}{\partial \boldsymbol{\theta}}\right)' \\ \left(\frac{\partial \widehat{\mathbf{u}}_i}{\partial \boldsymbol{\theta}}\right)\widehat{\mathbf{H}}^{-1} & \widehat{\mathbf{\Gamma}}^{-1} + \left(\frac{\partial \widehat{\mathbf{u}}_i}{\partial \boldsymbol{\theta}}\right)\widehat{\mathbf{H}}^{-1}\left(\frac{\partial \widehat{\mathbf{u}}_i}{\partial \boldsymbol{\theta}}\right)' \end{bmatrix}$$

where $\widehat{\mathbf{H}}$ is the approximate Hessian matrix from the optimization for $\widehat{\boldsymbol{\theta}}$, $\widehat{\mathbf{\Gamma}}$ is the approximate Hessian matrix from the optimization for $\widehat{\mathbf{u}}_i$, and $(\partial \widehat{\mathbf{u}}_i / \partial \boldsymbol{\theta})$ is the derivative of $\widehat{\mathbf{u}}_i$ with respect to $\boldsymbol{\theta}$, evaluated at $(\widehat{\boldsymbol{\theta}}, \widehat{\mathbf{u}}_i)$. The approximate variance matrix for $\widehat{\boldsymbol{\theta}}$ is the standard one discussed in the previous section, and that for $\widehat{\mathbf{u}}_i$ is an approximation to the conditional mean squared error of prediction described by Booth and Hobert (1998).

The prediction variance for a general scalar function $f(\boldsymbol{\theta}, \mathbf{u}_i)$ is defined as the expected squared difference $E[f(\widehat{\boldsymbol{\theta}}, \widehat{\mathbf{u}}_i) - f(\boldsymbol{\theta}, \mathbf{u}_i)]^2$. PROC NLMIXED computes an approximation to it as follows. The derivative of $f(\boldsymbol{\theta}, \mathbf{u}_i)$ is computed with respect to each element of $(\boldsymbol{\theta}, \mathbf{u}_i)$ and evaluated at $(\widehat{\boldsymbol{\theta}}, \widehat{\mathbf{u}}_i)$. If $\mathbf{a}_i$ is the resulting vector, then the approximate prediction variance is $\mathbf{a}_i'\mathbf{P}\mathbf{a}_i$. This approximation is known as the delta method (Billingsley 1986, Cox 1998).

Computational Resources

Since nonlinear optimization is an iterative process that depends on many factors, it is difficult to estimate how much computer time is necessary to find an optimal solution satisfying one of the termination criteria. You can use the MAXTIME=, MAXITER=, and MAXFUNC= options to restrict the amount of CPU time, the number of iterations, and the number of function calls in a single run of PROC NLMIXED.

In each iteration k, the NRRIDG technique uses a symmetric Householder transformation to decompose the $n \times n$ Hessian matrix $\mathbf{H}$,

$$\mathbf{H} = \mathbf{V}'\mathbf{T}\mathbf{V}, \qquad \mathbf{V}\text{: orthogonal}, \quad \mathbf{T}\text{: tridiagonal}$$

to compute the (Newton) search direction $\mathbf{s}$,

$$\mathbf{s}^{(k)} = -[\mathbf{H}^{(k)}]^{-1}\mathbf{g}^{(k)} \qquad k = 1, 2, 3, \ldots$$

The TRUREG and NEWRAP techniques use the Cholesky decomposition to solve the same linear system while computing the search direction. The QUANEW, DBLDOG, CONGRA, and NMSIMP techniques do not need to invert or decompose a Hessian matrix; thus, they require less computational resources than the other techniques.

The larger the problem, the more time is needed to compute function values and derivatives. Therefore, you might want to compare optimization techniques by counting and comparing the respective numbers of function, gradient, and Hessian evaluations.

Finite-difference approximations of the derivatives are expensive because they require additional function or gradient calls:

- forward-difference formulas
  - For first-order derivatives, n additional function calls are required.
  - For second-order derivatives based on function calls only, for a dense Hessian, $n + n^2/2$ additional function calls are required.
  - For second-order derivatives based on gradient calls, n additional gradient calls are required.
- central-difference formulas
  - For first-order derivatives, $2n$ additional function calls are required.
  - For second-order derivatives based on function calls only, for a dense Hessian, $2n + 2n^2$ additional function calls are required.
  - For second-order derivatives based on gradient calls, $2n$ additional gradient calls are required.

Many applications need considerably more time for computing second-order derivatives (Hessian matrix) than for computing first-order derivatives (gradient). In such cases, a dual quasi-Newton technique is recommended, which does not require second-order derivatives.

Displayed Output

This section describes the displayed output from PROC NLMIXED. See the section "ODS Table Names" on page 5242 for details about how this output interfaces with the Output Delivery System.

Specifications

The NLMIXED procedure first displays the "Specifications" table, listing basic information about the nonlinear mixed model that you have specified. It includes the principal variables and estimation methods.

Dimensions

The "Dimensions" table lists counts of important quantities in your nonlinear mixed model, including the number of observations, subjects, parameters, and quadrature points.

Parameters

The "Parameters" table displays the information you provided with the PARMS statement and the value of the negative log-likelihood function evaluated at the starting values.

Starting Gradient and Hessian

The START option in the PROC NLMIXED statement displays the gradient of the negative log-likelihood function at the starting values of the parameters. If you also specify the HESS option, then the starting Hessian is displayed as well.

Iterations

The iteration history consists of one line of output for each iteration in the optimization process. The iteration history is displayed by default because it is important that you check for possible convergence problems. The default iteration history includes the following variables:

- Iter, the iteration number
- Calls, the number of function calls
- NegLogLike, the value of the objective function
- Diff, the difference between adjacent function values
- MaxGrad, the maximum of the absolute (projected) gradient components (except NMSIMP)
- Slope, the slope $\mathbf{g}'\mathbf{s}$ of the search direction $\mathbf{s}$ at the current parameter iterate $\boldsymbol{\theta}^{(k)}$ (QUANEW only)
- Rho, the ratio between the achieved and predicted values of Diff (NRRIDG only)
- Radius, the radius of the trust region (TRUREG only)

- StdDev, the standard deviation of the simplex values (NMSIMP only)
- Delta, the vertex length of the simplex (NMSIMP only)
- Size, the size of the simplex (NMSIMP only)

For the QUANEW method, the value of Slope should be significantly negative. Otherwise, the line-search algorithm has difficulty reducing the function value sufficiently. If this difficulty is encountered, an asterisk (*) appears after the iteration number. If there is a tilde (~) after the iteration number, the BFGS update is skipped, and very high values of the Lagrange function are produced. A backslash (\ ) after the iteration number indicates that Powell's correction for the BFGS update is used.

For methods using second derivatives, an asterisk (*) after the iteration number means that the computed Hessian approximation was singular and had to be ridged with a positive value.

For the NMSIMP method, only one line is displayed for several internal iterations. This technique skips the output for some iterations because some of the termination tests (StdDev and Size) are rather time-consuming compared to the simplex operations, and they are performed only every five simplex operations.

The ITDETAILS option in the PROC NLMIXED statement provides a more detailed iteration history. Besides listing the current values of the parameters and their gradients, the ITDETAILS option provides the following values in addition to the default output:

- Restart, the number of iteration restarts
- Active, the number of active constraints
- Lambda, the value of the Lagrange multiplier (TRUREG and DBLDOG only)
- Ridge, the ridge value (NRRIDG only)
- Alpha, the line-search step size (QUANEW only)

An apostrophe (') trailing the number of active constraints indicates that at least one of the active constraints was released from the active set due to a significant Lagrange multiplier.

Convergence Status

The "Convergence Status" table contains a status message describing the reason for termination of the optimization. For ODS purposes, the name of this table is "ConvergenceStatus," and you can query the nonprinting numeric variable Status to check for a successful optimization. This is useful in batch processing, or when processing BY groups, for example, in simulations. Successful convergence is indicated by Status$= 0$.

Fitting Information

The "Fitting Information" table lists the final minimized value of -2 times the log likelihood as well as the information criteria of Akaike (AIC) and Schwarz (BIC), as well as a finite-sample corrected version of AIC

(AICC). The criteria are computed as follows:

$$
\begin{aligned}
AIC &= 2f(\widehat{\boldsymbol{\theta}}) + 2p \\
AICC &= 2f(\widehat{\boldsymbol{\theta}}) + 2pn/(n-p-1) \\
BIC &= 2f(\widehat{\boldsymbol{\theta}}) + p\log(s)
\end{aligned}
$$

where $f()$ is the negative of the marginal log-likelihood function, $\widehat{\boldsymbol{\theta}}$ is the vector of parameter estimates, p is the number of parameters, n is the number of observations, and s is the number of subjects. Refer to Hurvich and Tsai (1989) and Burnham and Anderson (1998) for additional details.

Parameter Estimates

The "Parameter Estimates" table lists the estimates of the parameter values after successful convergence of the optimization problem or the final values of the parameters under nonconvergence. If the problem did converge, standard errors are computed from the final Hessian matrix. The ratio of the estimate with its standard error produces a t value, with approximate degrees of freedom computed as the number of subjects minus the number of random effects. A p-value and confidence limits based on this t distribution are also provided. Finally, the gradient of the negative log-likelihood function is displayed for each parameter, and you should verify that they each are sufficiently small for nonconstrained parameters.

Covariance and Correlation Matrices

Following standard maximum likelihood theory (for example, Serfling 1980), the asymptotic variance-covariance matrix of the parameter estimates equals the inverse of the Hessian matrix. You can display this matrix with the COV option in the PROC NLMIXED statement. The corresponding correlation form is available with the CORR option.

Additional Estimates

The "Additional Estimates" table displays the results of all ESTIMATE statements that you specify, with the same columns as the "Parameter Estimates" table. The ECOV and ECORR options in the PROC NLMIXED statement produce tables displaying the approximate covariance and correlation matrices of the additional estimates. They are computed using the delta method (Billingsley 1986; Cox 1998). The EDER option in the PROC NLMIXED statement produces a table that displays the derivatives of the additional estimates with respect to the model parameters evaluated at their final estimated values.

ODS Table Names

PROC NLMIXED assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 63.2. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 63.2 ODS Tables Produced by PROC NLMIXED

ODS Table Name	Description	Statement or Option
AdditionalEstimates	Results from ESTIMATE statements	ESTIMATE
Contrasts	Results from CONTRAST statements	CONTRAST
ConvergenceStatus	Convergence status	default
CorrMatAddEst	Correlation matrix of additional estimates	ECORR
CorrMatParmEst	Correlation matrix of parameter estimates	CORR
CovMatAddEst	Covariance matrix of additional estimates	ECOV
CovMatParmEst	Covariance matrix of parameter estimates	COV
DerAddEst	Derivatives of additional estimates	EDER
Dimensions	Dimensions of the problem	default

StartingValues	Starting values and gradient	START

Examples: NLMIXED Procedure

Example 63.1: One-Compartment Model with Pharmacokinetic Data

A popular application of nonlinear mixed models is in the field of pharmacokinetics, which studies how a drug disperses through a living individual. This example considers the theophylline data from Pinheiro and Bates (1995). Serum concentrations of the drug theophylline are measured in 12 subjects over a 25-hour period after oral administration. The data are as follows.

```
data theoph;
  input subject time conc dose wt;
  datalines;
 1  0.00  0.74 4.02 79.6
 1  0.25  2.84 4.02 79.6
 1  0.57  6.57 4.02 79.6
 1  1.12 10.50 4.02 79.6
 1  2.02  9.66 4.02 79.6
 1  3.82  8.58 4.02 79.6
 1  5.10  8.36 4.02 79.6

   ... more lines ...

12 24.15  1.17 5.30 60.5
;
```

Pinheiro and Bates (1995) consider the following first-order compartment model for these data:

$$C_{it} = \frac{Dk_{e_i}k_{a_i}}{Cl_i(k_{a_i} - k_{e_i})}[\exp(-k_{e_i}t) - \exp(-k_{a_i}t)] + e_{it}$$

where C_{it} is the observed concentration of the ith subject at time t, D is the dose of theophylline, k_{e_i} is the elimination rate constant for subject i, k_{a_i} is the absorption rate constant for subject i, Cl_i is the clearance for subject i, and e_{it} are normal errors. To allow for random variability between subjects, they assume

$$\begin{aligned} Cl_i &= \exp(\beta_1 + b_{i1}) \\ k_{a_i} &= \exp(\beta_2 + b_{i2}) \\ k_{e_i} &= \exp(\beta_3) \end{aligned}$$

where the βs denote fixed-effects parameters and the b_is denote random-effects parameters with an unknown covariance matrix.

The PROC NLMIXED statements to fit this model are as follows:

```
proc nlmixed data=theoph;
   parms beta1=-3.22 beta2=0.47 beta3=-2.45
         s2b1 =0.03  cb12 =0    s2b2 =0.4 s2=0.5;
   cl   = exp(beta1 + b1);
   ka   = exp(beta2 + b2);
   ke   = exp(beta3);
   pred = dose*ke*ka*(exp(-ke*time)-exp(-ka*time))/cl/(ka-ke);
   model conc ~ normal(pred,s2);
   random b1 b2 ~ normal([0,0],[s2b1,cb12,s2b2]) subject=subject;
run;
```

The PARMS statement specifies starting values for the three βs and four variance-covariance parameters. The clearance and rate constants are defined using SAS programming statements, and the conditional model for the data is defined to be normal with mean pred and variance s2. The two random effects are b1 and b2, and their joint distribution is defined in the RANDOM statement. Brackets are used in defining their mean vector (two zeros) and the lower triangle of their variance-covariance matrix (a general 2×2 matrix). The SUBJECT= variable is subject.

The results from this analysis are as follows.

Output 63.1.1 Model Specification for One-Compartment Model

The NLMIXED Procedure

Specifications

Data Set	WORK.THEOPH
Dependent Variable	conc
Distribution for Dependent Variable	Normal
Random Effects	b1 b2
Distribution for Random Effects	Normal
Subject Variable	subject
Optimization Technique	Dual Quasi-Newton
Integration Method	Adaptive Gaussian Quadrature

The "Specifications" table lists the setup of the model (Output 63.1.1). The "Dimensions" table indicates that there are 132 observations, 12 subjects, and 7 parameters. PROC NLMIXED selects 5 quadrature points for each random effect, producing a total grid of 25 points over which quadrature is performed (Output 63.1.2).

Output 63.1.2 Dimensions Table for One-Compartment Model

Dimensions

Observations Used	132
Observations Not Used	0
Total Observations	132
Subjects	12
Max Obs Per Subject	11
Parameters	7
Quadrature Points	5

The "Parameters" table lists the 7 parameters, their starting values, and the initial evaluation of the negative log likelihood using adaptive Gaussian quadrature (Output 63.1.3). The "Iteration History" table indicates that 10 steps are required for the dual quasi-Newton algorithm to achieve convergence.

Output 63.1.3 Starting Values and Iteration History

Parameters

beta1	beta2	beta3	s2b1	cb12	s2b2	s2	NegLogLike
-3.22	0.47	-2.45	0.03	0	0.4	0.5	177.789945

beta2	0.9238	3.645E-7
beta3	-2.3449	0.000039
s2b1	0.05523	-0.00014
cb12	0.07458	-0.00007
s2b2	0.8798	-6.98E-6
s2	0.6540	6.133E-6

The "Parameter Estimates" table contains the maximum likelihood estimates of the parameters (Output 63.1.5). Both s2b1 and s2b2 are marginally significant, indicating between-subject variability in the clearances and absorption rate constants, respectively. There does not appear to be a significant covariance between them, as seen by the estimate of cb12.

The estimates of β_1, β_2, and β_3 are close to the adaptive quadrature estimates listed in Table 3 of Pinheiro and Bates (1995). However, Pinheiro and Bates use a Cholesky-root parameterization for the random-effects variance matrix and a logarithmic parameterization for the residual variance. The PROC NLMIXED statements using their parameterization are as follows, and results are similar.

```
proc nlmixed data=theoph;
   parms l11=-1.5 l2=0 l13=-0.1 beta1=-3 beta2=0.5 beta3=-2.5 ls2=-0.7;
   s2   = exp(ls2);
```

```
   l1   = exp(ll1);
   l3   = exp(ll3);
   s2b1 = l1*l1*s2;
   cb12 = l2*l1*s2;
   s2b2 = (l2*l2 + l3*l3)*s2;
   cl   = exp(beta1 + b1);
   ka   = exp(beta2 + b2);
   ke   = exp(beta3);
   pred = dose*ke*ka*(exp(-ke*time)-exp(-ka*time))/cl/(ka-ke);
   model conc   ~ normal(pred,s2);
   random b1 b2 ~ normal([0,0],[s2b1,cb12,s2b2]) subject=subject;
run;
```

Example 63.2: Probit-Normal Model with Binomial Data

For this example, consider the data from Weil (1970), also studied by Williams (1975), Ochi and Prentice (1984), and McCulloch (1994). In this experiment 16 pregnant rats receive a control diet and 16 receive a chemically treated diet, and the litter size for each rat is recorded after 4 and 21 days. The SAS data set follows:

```
data rats;
  input trt $ m x @@;
  if (trt='c') then do;
     x1 = 1;
     x2 = 0;
  end;
  else do;
     x1 = 0;
     x2 = 1;
  end;
  litter = _n_;
  datalines;
c 13 13   c 12 12   c  9  9   c  9  9   c  8  8   c  8  8   c 13 12   c 12 11
c 10  9   c 10  9   c  9  8   c 13 11   c  5  4   c  7  5   c 10  7   c 10  7
t 12 12   t 11 11   t 10 10   t  9  9   t 11 10   t 10  9   t 10  9   t  9  8
t  9  8   t  5  4   t  9  7   t  7  4   t 10  5   t  6  3   t 10  3   t  7  0
;
```

Here, m represents the size of the litter after 4 days, and x represents the size of the litter after 21 days. Also, indicator variables x1 and x2 are constructed for the two treatment levels.

Following McCulloch (1994), assume a latent survival model of the form

$$y_{ijk} = t_i + \alpha_{ij} + e_{ijk}$$

where i indexes treatment, j indexes litter, and k indexes newborn rats within a litter. The t_i represent treatment means, the α_{ij} represent random litter effects assumed to be iid $N(0, s_i^2)$, and the e_{ijk} represent iid residual errors, all on the latent scale.

Instead of observing the survival times y_{ijk}, assume that only the binary variable indicating whether y_{ijk} exceeds 0 is observed. If x_{ij} denotes the sum of these binary variables for the ith treatment and the jth

litter, then the preceding assumptions lead to the following generalized linear mixed model:

$$x_{ij}|\alpha_{ij} \sim \text{Binomial}(m_{ij}, p_{ij})$$

where m_{ij} is the size of each litter after 4 days and

$$p_{ij} = \Phi(t_i + \alpha_{ij})$$

The PROC NLMIXED statements to fit this model are as follows:

```
proc nlmixed data=rats;
   parms t1=1 t2=1 s1=.05 s2=1;
   eta = x1*t1 + x2*t2 + alpha;
   p   = probnorm(eta);
   model x ~ binomial(m,p);
   random alpha ~ normal(0,x1*s1*s1+x2*s2*s2) subject=litter;
   estimate 'gamma2' t2/sqrt(1+s2*s2);
   predict p out=p;
run;
```

As in Example 63.1, the PROC NLMIXED statement invokes the procedure and the PARMS statement defines the parameters. The parameters for this example are the two treatment means, t1 and t2, and the two random-effect standard deviations, s1 and s2.

The indicator variables x1 and x2 are used in the program to assign the proper mean to each observation in the input data set as well as the proper variance to the random effects. Note that programming expressions are permitted inside the distributional specifications, as illustrated by the random-effects variance specified here.

The ESTIMATE statement requests an estimate of $\gamma_2 = t_2/\sqrt{1+s_2^2}$, which is a location-scale parameter from Ochi and Prentice (1984).

The PREDICT statement constructs predictions for each observation in the input data set. For this example, predictions of p and approximate standard errors of prediction are output to a SAS data set named P. These predictions are functions of the parameter estimates and the empirical Bayes estimates of the random effects α_i.

The output for this model is as follows.

Output 63.2.1 Specifications, Dimensions, and Starting Values

The NLMIXED Procedure

Specifications

Data Set	WORK.RATS
Dependent Variable	x
Distribution for Dependent Variable	Binomial
Random Effects	alpha
Distribution for Random Effects	Normal
Subject Variable	litter
Optimization Technique	Dual Quasi-Newton
Integration Method	Adaptive Gaussian Quadrature

Output 63.2.1 *continued*

Dimensions

Observations Used	32
Observations Not Used	0
Total Observations	32
Subjects	32
Max Obs Per Subject	1
Parameters	4
Quadrature Points	7

Parameters

t1	t2	s1	s2	NegLogLike
1	1	0.05	1	54.9362323

The "Specifications" table provides basic information about this nonlinear mixed model (Output 63.2.1). The "Dimensions" table provides counts of various variables. Note that each observation in the data comprises a separate subject. Using the starting values in the "Parameters" table, PROC NLMIXED determines that the log-likelihood function can be approximated with sufficient accuracy with a seven-point quadrature rule.

Output 63.2.2 Iteration History for Probit-Normal Model

Iteration History

Iter	Calls	NegLogLike	Diff	MaxGrad	Slope
1	2	53.9933934	0.942839	11.03261	-81.9428
2	3	52.875353	1.11804	2.148952	-2.86277
3	5	52.6350386	0.240314	0.329957	-1.05049
4	6	52.6319939	0.003045	0.122926	-0.00672
5	8	52.6313583	0.000636	0.028246	-0.00352

7	13	52.6313115	5.839E-6	0.000603	-0.00001
8	15	52.6313115	9.45E-9	0.000022	-1.68E-8

NOTE: GCONV convergence criterion satisfied.

The "Iteration History" table indicates successful convergence in 8 iterations (Output 63.2.2).

Output 63.2.3 Fit Statistics for Probit-Normal Model

Fit Statistics

-2 Log Likelihood	105.3
AIC (smaller is better)	113.3
AICC (smaller is better)	114.7
BIC (smaller is better)	119.1

The "Fit Statistics" table lists useful statistics based on the maximized value of the log likelihood (Output 63.2.3).

Output 63.2.4 Parameter Estimates for Probit-Normal Model

Parameter Estimates

Parameter	Estimate	Standard Error	DF	t Value	Pr > |t|	Alpha	Lower
t1	1.3063	0.1685	31	7.75	<.0001	0.05	0.9626
t2	0.9475	0.3055	31	3.10	0.0041	0.05	0.3244
s1	0.2403	0.3015	31	0.80	0.4315	0.05	−0.3746
s2	1.0292	0.2988	31	3.44	0.0017	0.05	0.4198

Parameter Estimates

Parameter	Upper	Gradient
t1	1.6499	−0.00002
t2	1.5705	9.283E−6
s1	0.8552	0.000014
s2	1.6385	−3.16E−6

The "Parameter Estimates" table indicates significance of all the parameters except S1 (Output 63.2.4).

Output 63.2.5 Additional Estimates

Additional Estimates

Label	Estimate	Standard Error	DF	t Value	Pr > |t|	Alpha	Lower	Upper
gamma2	0.6603	0.2165	31	3.05	0.0047	0.05	0.2186	1.1019

The "Additional Estimates" table displays results from the ESTIMATE statement (Output 63.2.5). The estimate of γ_2 equals 0.66, agreeing with that obtained by McCulloch (1994). The standard error 0.22 is computed using the delta method (Billingsley 1986; Cox, 1998).

Not shown is the P data set, which contains the original 32 observations and predictions of the p_{ij}.

Example 63.3: Probit-Normal Model with Ordinal Data

The data for this example are from Ezzet and Whitehead (1991), who describe a crossover experiment on two groups of patients using two different inhaler devices (A and B). Patients from group 1 used device A for one week and then device B for another week. Patients from group 2 used the devices in reverse order. The data entered as a SAS data set are as follows:

```
data inhaler;
   input clarity group time freq @@;
   gt = group*time;
   sub = floor((_n_+1)/2);
   datalines;
1 0 0 59   1 0 1 59   1 0 0 35   2 0 1 35   1 0 0  3   3 0 1  3   1 0 0  2
4 0 1  2   2 0 0 11   1 0 1 11   2 0 0 27   2 0 1 27   2 0 0  2   3 0 1  2
2 0 0  1   4 0 1  1   4 0 0  1   1 0 1  1   4 0 0  1   2 0 1  1   1 1 0 63
1 1 1 63   1 1 0 13   2 1 1 13   2 1 0 40   1 1 1 40   2 1 0 15   2 1 1 15
3 1 0  7   1 1 1  7   3 1 0  2   2 1 1  2   3 1 0  1   3 1 1  1   4 1 0  2
1 1 1  2   4 1 0  1   3 1 1  1
;
```

The response measurement, clarity, is the patients' assessment on the clarity of the leaflet instructions for the devices. The clarity variable is on an ordinal scale, with 1=easy, 2=only clear after rereading, 3=not very clear, and 4=confusing. The group variable indicates the treatment group, and the time variable indicates the time of measurement. The freq variable indicates the number of patients with exactly the same responses. A variable gt is created to indicate a group-by-time interaction, and a variable sub is created to indicate patients.

As in the previous example and in Hedeker and Gibbons (1994), assume an underlying latent continuous variable, here with the form

$$y_{ij} = \beta_0 + \beta_1 g_i + \beta_2 t_j + \beta_3 g_i t_j + u_i + e_{ij}$$

where i indexes patient and j indexes the time period, g_i indicates groups, t_j indicates time, u_i is a patient-level normal random effect, and e_{ij} are iid normal errors. The βs are unknown coefficients to be estimated.

Instead of observing y_{ij}, however, you observe only whether it falls in one of the four intervals: $(-\infty, 0)$, $(0, I1)$, $(I1, I1 + I2)$, or $(I1 + I2, \infty)$, where $I1$ and $I2$ are both positive. The resulting category is the value assigned to the clarity variable.

The following code sets up and fits this ordinal probit model:

```
proc nlmixed data=inhaler corr ecorr;
   parms b0=0 b1=0 b2=0 b3=0 sd=1 i1=1 i2=1;
   bounds i1 > 0, i2 > 0;
   eta = b0 + b1*group + b2*time + b3*gt + u;
   if (clarity=1) then p = probnorm(-eta);
   else if (clarity=2) then
      p = probnorm(i1-eta) - probnorm(-eta);
   else if (clarity=3) then
      p = probnorm(i1+i2-eta) - probnorm(i1-eta);
   else p = 1 - probnorm(i1+i2-eta);
   if (p > 1e-8) then ll = log(p);
   else ll = -1e20;
   model clarity ~ general(ll);
   random u ~ normal(0,sd*sd) subject=sub;
   replicate freq;
   estimate 'thresh2' i1;
   estimate 'thresh3' i1 + i2;
   estimate 'icc' sd*sd/(1+sd*sd);
run;
```

The PROC NLMIXED statement specifies the input data set and requests correlations both for the parameter estimates (CORR option) and for the additional estimates specified with ESTIMATE statements (ECORR option).

The parameters as defined in the PARMS statement are as follows: b0 (overall intercept), b1 (group main effect), B2 (time main effect), b3 (group-by-time interaction), sd (standard deviation of the random effect), i1 (increment between first and second thresholds), and i2 (increment between second and third thresholds). The BOUNDS statement restricts i1 and i2 to be positive.

The SAS programming statements begin by defining the linear predictor eta, which is a linear combination of the b parameters and a single random effect u. The next statements define the ordinal likelihood according to the clarity variable, eta, and the increment variables. An error trap is included in case the likelihood becomes too small.

A general log-likelihood specification is used in the MODEL statement, and the RANDOM statement defines the random effect u to have standard deviation sd and subject variable sub. The REPLICATE statement indicates that data for each subject should be replicated according to the freq variable.

The ESTIMATE statements specify the second and third thresholds in terms of the increment variables (the first threshold is assumed to equal zero for model identifiability). Also computed is the intraclass correlation.

The output is as follows.

Output 63.3.1 Specifications for Ordinal Data Model

The NLMIXED Procedure

Specifications

Data Set	WORK.INHALER
Dependent Variable	clarity
Distribution for Dependent Variable	General
Random Effects	u
Distribution for Random Effects	Normal
Subject Variable	sub
Replicate Variable	freq
Optimization Technique	Dual Quasi-Newton
Integration Method	Adaptive Gaussian Quadrature

The "Specifications" table echoes some primary information specified for this nonlinear mixed model (Output 63.3.1). Because the log-likelihood function was expressed with SAS programming statements, the distribution is displayed as *General* in the "Specifications" table.

The "Dimensions" table reveals a total of 286 subjects, which is the sum of the values of the FREQ variable for the second time point. Five quadrature points are selected for log-likelihood evaluation (Output 63.3.2).

Output 63.3.2 Dimensions Table for Ordinal Data Model

Dimensions

Observations Used	38
Observations Not Used	0
Total Observations	38
Subjects	286
Max Obs Per Subject	2

The "Additional Estimates" table displays results from the ESTIMATE statements (Output 63.3.7).

Example 63.4: Poisson-Normal Model with Count Data

This example uses the pump failure data of Gaver and O'Muircheartaigh (1987). The number of failures and the time of operation are recorded for 10 pumps. Each of the pumps is classified into one of two groups corresponding to either continuous or intermittent operation. The data are as follows:

```
data pump;
  input y t group;
  pump = _n_;
  logtstd = log(t) - 2.4564900;
  datalines;
 5  94.320 1
 1  15.720 2
 5  62.880 1
14 125.760 1
 3   5.240 2
19  31.440 1
 1   1.048 2
 1   1.048 2
 4   2.096 2
22  10.480 2
;
```

Each row denotes data for a single pump, and the variable logtstd contains the centered operation times.

Letting y_{ij} denote the number of failures for the jth pump in the ith group, Draper (1996) considers the following hierarchical model for these data:

$$
\begin{aligned}
y_{ij}|\lambda_{ij} &\sim \text{Poisson}(\lambda_{ij}) \\
\log \lambda_{ij} &= \alpha_i + \beta_i(\log t_{ij} - \overline{\log t}) + e_{ij} \\
e_{ij}|\sigma^2 &\sim \text{Normal}(0, \sigma^2)
\end{aligned}
$$

The model specifies different intercepts and slopes for each group, and the random effect is a mechanism for accounting for overdispersion.

The corresponding PROC NLMIXED statements are as follows:

```
proc nlmixed data=pump;
   parms logsig 0 beta1 1 beta2 1 alpha1 1 alpha2 1;
   if (group = 1) then eta = alpha1 + beta1*logtstd + e;
   else eta = alpha2 + beta2*logtstd + e;
   lambda = exp(eta);
   model y ~ poisson(lambda);
   random e ~ normal(0,exp(2*logsig)) subject=pump;
   estimate 'alpha1-alpha2' alpha1-alpha2;
   estimate 'beta1-beta2' beta1-beta2;
run;
```

The selected output is as follows.

Output 63.4.1 Dimensions Table for Poisson-Normal Model

The NLMIXED Procedure

Dimensions

Observations Used	10
Observations Not Used	0
Total Observations	10

beta1−beta2	0.8623

The "Parameter Estimates" and "Additional Estimates" tables list the maximum likelihood estimates for each of the parameters and two differences (Output 63.4.4). The point estimates for the mean parameters agree fairly closely with the Bayesian posterior means reported by Draper (1996); however, the likelihood-based standard errors are roughly half the Bayesian posterior standard deviations. This is most likely due to the fact that the Bayesian standard deviations account for the uncertainty in estimating σ^2, whereas the likelihood values plug in its estimated value. This downward bias can be corrected somewhat by using the t_9 distribution shown here.

Example 63.5: Failure Time and Frailty Model

In this example an accelerated failure time model with proportional hazard is fitted with and without random effects. The data are from the "Getting Started" example of PROC LIFEREG; see Chapter 50, "The LIFEREG Procedure." Thirty-eight patients are divided into two groups of equal size, and different pain relievers are assigned to each group. The outcome reported is the time in minutes until headache relief. The variable censor indicates whether relief was observed during the course of the observation period (censor = 0) or whether the observation is censored (censor = 1). The SAS DATA step for these data is as follows:

```
data headache;
  input minutes group censor @@;
  patient = _n_;
  datalines;
11  1  0    12  1  0    19  1  0    19  1  0
19  1  0    19  1  0    21  1  0    20  1  0
21  1  0    21  1  0    20  1  0    21  1  0
20  1  0    21  1  0    25  1  0    27  1  0
30  1  0    21  1  1    24  1  1    14  2  0
16  2  0    16  2  0    21  2  0    21  2  0
23  2  0    23  2  0    23  2  0    23  2  0
25  2  1    23  2  0    24  2  0    24  2  0
26  2  1    32  2  1    30  2  1    30  2  0
32  2  1    20  2  1
;
```

In modeling survival data, censoring of observations must be taken into account carefully. In this example, only right censoring occurs. If $g(t,\boldsymbol{\beta})$, $h(t,\boldsymbol{\beta})$, and $G(t,\boldsymbol{\beta})$ denote the density of failure, the hazard function, and the survival distribution function at time t, respectively, then the log likelihood can be written as

$$\begin{aligned} l(\boldsymbol{\beta};\mathbf{t}) &= \sum_{i\in U_u} \log g(t_i,\boldsymbol{\beta}) + \sum_{i\in U_c} \log G(t_i,\boldsymbol{\beta}) \\ &= \sum_{i\in U_u} \log h(t_i,\boldsymbol{\beta}) + \sum_{i=1}^{n} \log G(t_i,\boldsymbol{\beta}) \end{aligned}$$

(See Cox and Oakes 1984, Ch. 3.) In these expressions U_u is the set of uncensored observations, U_c is the set of censored observations, and n denotes the total sample size.

The proportional hazards specification expresses the hazard in terms of a baseline hazard, multiplied by a constant. In this example the hazard is that of a Weibull model and is parameterized as $h(t,\boldsymbol{\beta}) = \gamma\alpha(\alpha t)^{\gamma-1}$ and $\alpha = \exp\{-\mathbf{x}'\boldsymbol{\beta}\}$.

The linear predictor is set equal to the intercept in the reference group (group = 2); this defines the baseline hazard. The corresponding distribution of survival past time t is $G(t,\boldsymbol{\beta}) = \exp\{-(\alpha t)^{\gamma}\}$. See Cox and Oakes (1984, Table 2.1) and the section "Supported Distributions" in Chapter 50, "The LIFEREG Procedure," for this and other survival distribution models and various parameterizations.

The following NLMIXED statements fit this accelerated failure time model and estimate the cumulative distribution function of time to headache relief:

```
proc nlmixed data=headache;
    bounds gamma > 0;
    linp  = b0 - b1*(group-2);
    alpha = exp(-linp);
    G_t   = exp(-(alpha*minutes)**gamma);
    g     = gamma*alpha*((alpha*minutes)**(gamma-1))*G_t;
    ll    = (censor=0)*log(g) + (censor=1)*log(G_t);
    model minutes ~ general(ll);
    predict 1-G_t out=cdf;
run;
```

Output 63.5.1 Specifications Table for Fixed-Effects Failure Time Model

The NLMIXED Procedure

Specifications

Data Set	WORK.HEADACHE
Dependent Variable	minutes
Distribution for Dependent Variable	General
Optimization Technique	Dual Quasi-Newton
Integration Method	None

The "Specifications" table shows that no integration is required, since the model does not contain random effects (Output 63.5.1).

Output 63.5.2 Negative Log Likelihood with Default Starting Values

Parameters

gamma	b0	b1	NegLogLike
1	1	1	263.990327

No starting values were given for the three parameters. The NLMIXED procedure assigns the default value of 1.0 in this case. The negative log likelihood based on these starting values is shown in Output 63.5.2.

Output 63.5.3 Iteration History for Fixed-Effects Failure Time Model

Iteration History

Iter	Calls	NegLogLike	Diff	MaxGrad	Slope

16	32	99.8736351	4.071E−6	0.000705	−6.9E−6
17	34	99.8736351	6.1E−10	4.768E−6	−1.23E−9

NOTE: GCONV convergence criterion satisfied.

The "Iteration History" table shows that the procedure converges after 17 iterations and 34 evaluations of the objective function (Output 63.5.3).

Output 63.5.4 Fit Statistics and Parameter Estimates

Fit Statistics

−2 Log Likelihood	199.7
AIC (smaller is better)	205.7
AICC (smaller is better)	206.5
BIC (smaller is better)	210.7

Parameter Estimates

Parameter	Estimate	Standard Error	DF	t Value	Pr > |t|	Alpha	Lower
gamma	4.7128	0.6742	38	6.99	<.0001	0.05	3.3479
b0	3.3091	0.05885	38	56.23	<.0001	0.05	3.1900
b1	−0.1933	0.07856	38	−2.46	0.0185	0.05	−0.3523

Parameter Estimates

Parameter	Upper	Gradient
gamma	6.0777	5.327E−8
b0	3.4283	−4.77E−6
b1	−0.03426	−1.22E−6

The parameter estimates and their standard errors shown in Output 63.5.4 are identical to those obtained with the LIFEREG procedure and the following statements:

```
proc lifereg data=headache;
   class group;
   model minutes*censor(1) = group / dist=weibull;
   output out=new cdf=prob;
run;
```

The t statistic and confidence limits are based on 38 degrees of freedom. The LIFEREG procedure computes z intervals for the parameter estimates.

For the two groups you obtain

$$\widehat{\alpha}(\text{group} = 1) = \exp\{-3.3091 + 0.1933\} = 0.04434$$
$$\widehat{\alpha}(\text{group} = 2) = \exp\{-3.3091\} = 0.03655$$

The probabilities of headache relief by t minutes are estimated as

$$1 - G(t, \text{group} = 1) = 1 - \exp\{-(0.04434 * t)^{4.7128}\}$$
$$1 - G(t, \text{group} = 2) = 1 - \exp\{-(0.03655 * t)^{4.7128}\}$$

These probabilities, calculated at the observed times, are shown for the two groups in Output 63.5.5 and printed with the following statements:

```
proc print data=cdf;
   var group censor patient minutes pred;
run;
```

Since the slope estimate is negative with p-value of 0.0185, you can infer that pain reliever 1 leads to overall significantly faster relief, but the estimated probabilities give no information about patient-to-patient variation within and between groups. For example, while pain reliever 1 provides faster relief overall, some patients in group 2 might respond more quickly than some patients in group 1. A frailty model enables you to accommodate and estimate patient-to-patient variation in health status by introducing random effects into a subject's hazard function.

The following statements model the hazard for patient i in terms of $\alpha_i = \exp\{-\mathbf{x}_i'\boldsymbol{\beta} - z_i\}$, where z_i is a (normal) random patient effect. Notice that the only difference from the previous NLMIXED statements are the RANDOM statement and the addition of z in the linear predictor. The empirical Bayes estimates of the random effect (RANDOM statement), the parameter estimates (ODS OUTPUT statement), and the estimated cumulative distribution function (PREDICT statement) are saved to subsequently graph the patient-specific distribution functions.

```
ods output ParameterEstimates=est;
proc nlmixed data=headache;
    bounds gamma > 0;
    linp  = b0 - b1*(group-2) + z;
    alpha = exp(-linp);
```

```
    G_t   = exp(-(alpha*minutes)**gamma);
    g     = gamma*alpha*((alpha*minutes)**(gamma-1))*G_t;
    ll = (censor=0)*log(g) + (censor=1)*log(G_t);
    model minutes ~ general(ll);
    random z ~ normal(0,exp(2*logsig)) subject=patient out=EB;
    predict 1-G_t out=cdf;
run;
```

Output 63.5.6 Specifications for Random Frailty Model

The NLMIXED Procedure

Specifications

Data Set	WORK.HEADACHE
Dependent Variable	minutes
Distribution for Dependent Variable	General
Random Effects	z
Distribution for Random Effects	Normal
Subject Variable	patient
Optimization Technique	Dual Quasi-Newton
Integration Method	Adaptive Gaussian Quadrature

The "Specifications" table shows that the objective function is computed by adaptive Gaussian quadrature because of the presence of random effects (compare Output 63.5.6 and Output 63.5.1). The "Dimensions" table reports that nine quadrature points are being used to integrate over the random effects (Output 63.5.7).

15	31	99.2444957	9.147E-8	0.000271	-1.84E-7

NOTE: GCONV convergence criterion satisfied.

The procedure converges after 15 iterations (Output 63.5.8). The achieved -2 log likelihood is only 1.2 less than that in the model without random effects (compare Output 63.5.9 and Output 63.5.4). Compared to a chi-square distribution with one degree of freedom, the addition of the random effect appears not to improve the model significantly. You must exercise care, however, in interpreting likelihood ratio tests when the value under the null hypothesis falls on the boundary of the parameter space (see, for example, Self and Liang 1987).

Output 63.5.9 Fit Statistics for Random Frailty Model

Fit Statistics

-2 Log Likelihood	198.5

           markerattrs=(symbol=CircleFilled size=9);
   scatter x=minutes2 y=pcdf2  /
           markerattrs=(symbol=Circle       size=9);
run;
```

The separation of the distribution functions by groups is evident in Output 63.5.12. Most of the distributions of patients in the first group are to the left of the distributions in the second group. The separation is not complete, however. Several patients who are assigned the second pain reliever experience headache relief more quickly than patients assigned to the first group.

Output 63.5.12 Patient-Specific CDFs and Predicted Values. Pain Reliever 1: Solid Lines, Closed Circles; Pain Reliever 2: Dashed Lines, Open Circles.

Chapter 64

The NPAR1WAY Procedure

Contents

Overview: NPAR1WAY Procedure

The NPAR1WAY procedure performs nonparametric tests for location and scale differences across a one-way classification. PROC NPAR1WAY also provides a standard analysis of variance on the raw data and tests based on the empirical distribution function.

PROC NPAR1WAY performs tests for location and scale differences based on the following scores of a response variable: Wilcoxon, median, Van der Waerden (normal), Savage, Siegel-Tukey, Ansari-Bradley, Klotz, Mood, and Conover. Additionally, PROC NPAR1WAY provides tests that use the raw input data as scores. When the data are classified into two samples, tests are based on simple linear rank statistics. When the data are classified into more than two samples, tests are based on one-way ANOVA statistics. Both asymptotic and exact *p*-values are available for these tests. PROC NPAR1WAY also provides Hodges-Lehmann estimation, including exact confidence limits for the location shift.

PROC NPAR1WAY computes empirical distribution function (EDF) statistics, which test whether the distribution of a variable is the same across different groups. These include the Kolmogorov-Smirnov test, the Cramer-von Mises test, and, when the data are classified into only two samples, the Kuiper test. Exact *p*-values are available for the two-sample Kolmogorov-Smirnov test.

PROC NPAR1WAY uses the Output Delivery System (ODS), a SAS subsystem that provides capabilities for displaying and controlling the output from SAS procedures. ODS enables you to convert any of the output from PROC NPAR1WAY into a SAS data set. See the section "ODS Table Names" on page 5321 for more information.

PROC NPAR1WAY uses ODS Graphics to create graphs as part of its output. For general information about ODS Graphics, see Chapter 21, "Statistical Graphics Using ODS." For specific information about the statistical graphics available with the NPAR1WAY procedure, see the PLOTS= option in the PROC NPAR1WAY statement and the section "ODS Graphics" on page 5323.

Getting Started: NPAR1WAY Procedure

This example illustrates how you can use PROC NPAR1WAY to perform a one-way nonparametric analysis. The data from Halverson and Sherwood (1930) consist of weight gain measurements for five different levels of gossypol additive in animal feed. Gossypol is a substance contained in cottonseed shells, and these data were collected to study the effect of gossypol on animal nutrition.

The following DATA step statements create the SAS data set Gossypol:

```
data Gossypol;
   input Dose n;
   do i=1 to n;
      input Gain @@;
      output;
   end;
   datalines;
0 16
228 229 218 216 224 208 235 229 233 219 224 220 232 200 208 232
.04 11
186 229 220 208 228 198 222 273 216 198 213
.07 12
179 193 183 180 143 204 114 188 178 134 208 196
.10 17
130 87 135 116 118 165 151 59 126 64 78 94 150 160 122 110 178
.13 11
154 130 130 118 118 104 112 134 98 100 104
;
```

The data set Gossypol contains the variable Dose, which represents the amount of gossypol additive, and the variable Gain, which represents the weight gain.

Researchers are interested in whether there is a difference in weight gain among animals receiving the different dose levels of gossypol. The following statements invoke the NPAR1WAY procedure to perform a nonparametric analysis of this problem:

```
proc npar1way data=Gossypol;
   class Dose;
   var Gain;
run;
```

The variable Dose is the CLASS variable, and the VAR statement specifies the variable Gain is the response variable. The CLASS statement is required, and you must name only one CLASS variable. You can name one or more analysis variables in the VAR statement. If you omit the VAR statement, PROC NPAR1WAY analyzes all numeric variables in the data set except for the CLASS variable, the FREQ variable, and the BY variables.

Since no analysis options are specified in the PROC NPAR1WAY statement, the ANOVA, WILCOXON, MEDIAN, VW, SAVAGE, and EDF options are invoked by default. The tables in the following figures show the results of these analyses.

The tables in Figure 64.1 are produced with the ANOVA option. For each level of the CLASS variable Dose, PROC NPAR1WAY displays the number of observations and the mean of the analysis variable Gain. PROC NPAR1WAY displays a standard analysis of variance on the raw data. This gives the same results as the GLM and ANOVA procedures. The p-value for the F test is <0.0001, which indicates that Dose accounts for a significant portion of the variability of the dependent variable Gain.

Figure 64.1 Analysis of Variance

The NPAR1WAY Procedure

Analysis of Variance for Variable Gain
Classified by Variable Dose

Dose	N	Mean
0	16	222.187500
0.04	11	217.363636
0.07	12	175.000000
0.1	17	120.176471
0.13	11	118.363636

Source	DF	Sum of Squares	Mean Square	F Value	Pr > F
Among	4	140082.986077	35020.74652	55.8143	<.0001
Within	62	38901.998997	627.45160		

Average scores were used for ties.

The WILCOXON option produces the output in Figure 64.2. PROC NPAR1WAY first provides a summary of the Wilcoxon scores for the analysis variable Gain by class level. For each level of the CLASS variable Dose, PROC NPAR1WAY displays the following information: number of observations, sum of the Wilcoxon scores, expected sum under the null hypothesis of no difference among class levels, standard deviation under the null hypothesis, and mean score.

Next PROC NPAR1WAY displays the one-way ANOVA statistic, which for Wilcoxon scores is known as the Kruskal-Wallis test. The statistic equals 52.6656, with four degrees of freedom, which is the number of class levels minus one. The p-value (probability of a larger statistic under the null hypothesis) is <0.0001. This leads to rejection of the null hypothesis that there is no difference in location for Gain among the levels of Dose. This p-value is asymptotic, computed from the asymptotic chi-square distribution of the test statistic. For certain data sets it might also be useful to compute the exact p-value—for example, for small data sets or for data sets that are sparse, skewed, or heavily tied. You can use the EXACT statement to request exact p-values for any of the location or scale tests available in PROC NPAR1WAY.

Figure 64.2 Wilcoxon Score Analysis

Wilcoxon Scores (Rank Sums) for Variable Gain
Classified by Variable Dose

Dose	N	Sum of Scores	Expected Under H0	Std Dev Under H0	Mean Score
0	16	890.50	544.0	67.978966	55.656250
0.04	11	555.00	374.0	59.063588	50.454545
0.07	12	395.50	408.0	61.136622	32.958333
0.1	17	275.50	578.0	69.380741	16.205882

Kruskal-Wallis Test

Chi-Square	52.6656
DF	4
Pr > Chi-Square	<.0001

Figure 64.3 through Figure 64.5 display the analyses produced by the MEDIAN, VW, and SAVAGE options. For each score type, PROC NPAR1WAY provides a summary of scores and the one-way ANOVA statistic, as previously described for Wilcoxon scores. Other score types available in PROC NPAR1WAY are Siegel-Tukey, Ansari-Bradley, Klotz, and Mood, which can be used to test for scale differences. Conover scores can be used to test for differences in both location and scale. Additionally, you can specify the SCORES=DATA option, which uses the input data as scores. This option gives you the flexibility to construct any scores for your data with the DATA step and then analyze these scores with PROC NPAR1WAY.

Figure 64.3 Median Score Analysis

Median Scores (Number of Points Above Median) for Variable Gain
Classified by Variable Dose

Dose	N	Sum of Scores	Expected Under H0	Std Dev Under H0	Mean Score

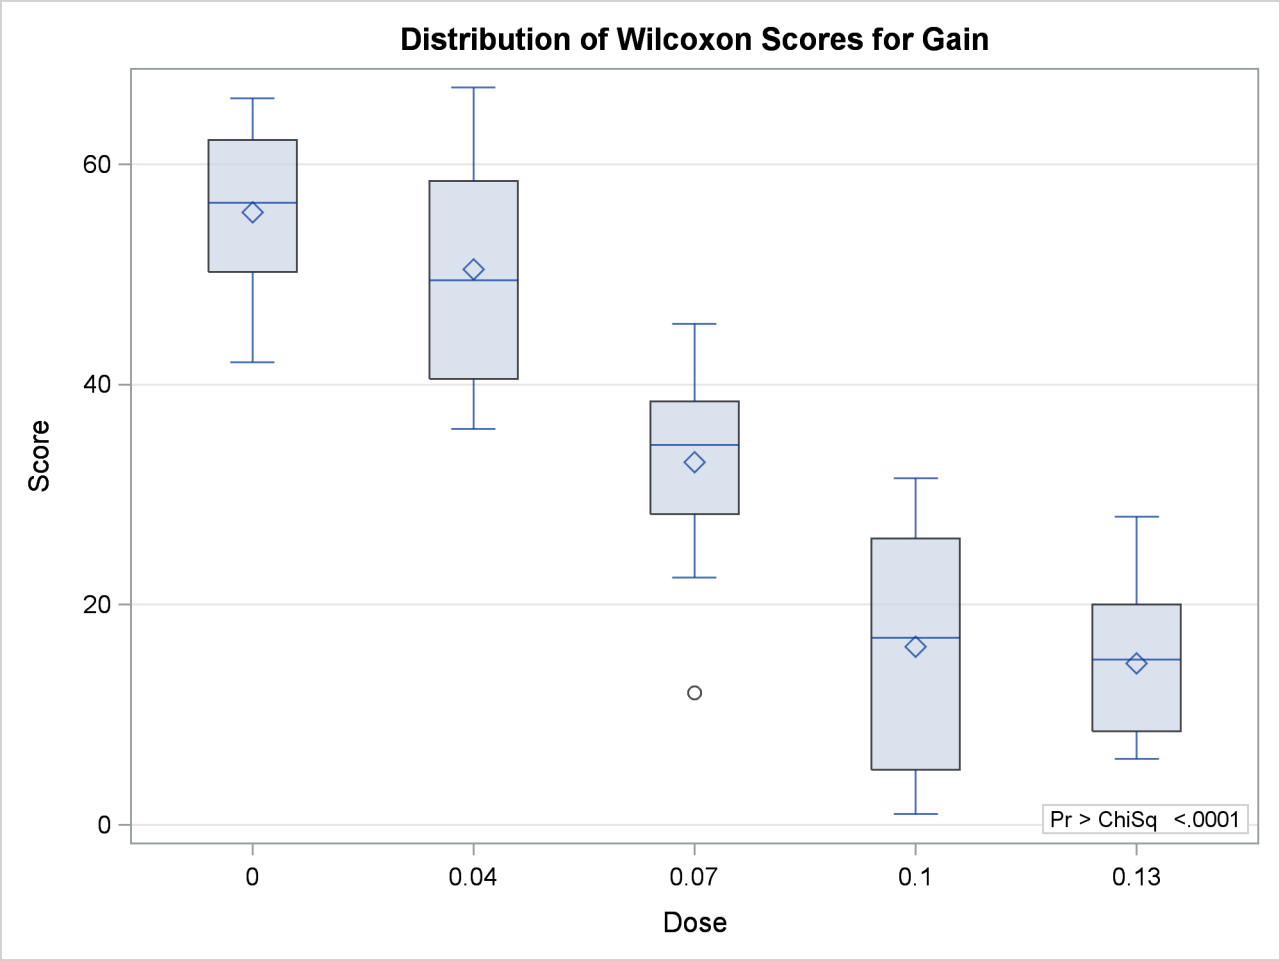
PROC NPAR1WAY uses ODS Graphics to create graphs as part of its output. The following statements produce a box plot of Wilcoxon scores for Gain classified by Dose. ODS Graphics must be enabled before producing graphs.

```
ods graphics on;
proc npar1way data=Gossypol plots(only)=wilcoxonboxplot;
   class Dose;
   var Gain;
run;
ods graphics off;
```

Figure 64.7 displays the box plot of Wilcoxon scores. This graph corresponds to the Wilcoxon scores analysis shown in Figure 64.2. To remove the *p*-value from the box plot display, you can specify the NOSTATS plot option in parentheses following the WILCOXONBOXPLOT option.

Box plots are available for all PROC NPAR1WAY score types except median scores, which are displayed with a stacked bar chart. If ODS Graphics is enabled but you do not specify the PLOTS= option, then PROC NPAR1WAY produces all plots that are associated with the analyses that you request.

Figure 64.7 Box Plot of Wilcoxon Scores



In the preceding example, the CLASS variable Dose has five levels, and the analyses examine possible differences among these five levels (samples). The following statements invoke the NPAR1WAY procedure to perform a nonparametric analysis of the two lowest levels of Dose:

```
proc npar1way data=Gossypol;
   where Dose <= .04;
   class Dose;
   var Gain;
run;
```

The tables in the following figures show the results of this two-sample analysis. The tables in Figure 64.8 are produced by the ANOVA option.

Figure 64.8 Analysis of Variance for Two-Sample Data

Average scores were used for ties.

Figure 64.9 displays the output produced by the WILCOXON option. PROC NPAR1WAY provides a summary of the Wilcoxon scores for the analysis variable Gain for each of the two class levels. Since there are only two levels, PROC NPAR1WAY displays the two-sample test, based on the simple linear rank statistic with Wilcoxon scores. The normal approximation includes a continuity correction. To remove the continuity correction, you can specify the CORRECT=NO option. PROC NPAR1WAY also gives a t approximation for the Wilcoxon two-sample test. Like the multisample analysis, PROC NPAR1WAY computes a one-way ANOVA statistic, which for Wilcoxon scores is known as the Kruskal-Wallis test. All these p-values show no difference in Gain for the two Dose levels at the 0.05 level of significance.

Figure 64.10 through Figure 64.12 display the two-sample analyses produced by the MEDIAN, VW, and SAVAGE options.

Figure 64.9 Wilcoxon Two-Sample Analysis

```

The tables in Figure 64.13 display the empirical distribution function statistics, comparing the distribution of Gain for the two levels of Dose. The *p*-value for the Kolmogorov-Smirnov two-sample test is 0.6199, which indicates no rejection of the null hypothesis that the Gain distributions are identical for the two levels of Dose.

Syntax: NPAR1WAY Procedure

The following statements are available in PROC NPAR1WAY:

PROC NPAR1WAY < *options* > **;**
BY *variables* **;**
CLASS *variable* **;**
EXACT *statistic-options* < / *computation-options* > **;**
FREQ *variable* **;**
OUTPUT < **OUT=***SAS-data-set* > < *options* > **;**
VAR *variables* **;**

Both the PROC NPAR1WAY statement and the CLASS statement are required for the NPAR1WAY procedure.

The rest of this section gives detailed syntax information for the BY, CLASS, EXACT, FREQ, OUTPUT, and VAR statements in alphabetical order after the description of the PROC NPAR1WAY statement. Table 64.1 summarizes the basic function of each PROC NPAR1WAY statement.

Table 64.1 Summary of PROC NPAR1WAY Statements

Statement	Description
BY	Provides separate analyses for each BY group
CLASS	Identifies the classification variable
EXACT	Requests exact tests
FREQ	Identifies a frequency variable
OUTPUT	Requests an output data set
VAR	Identifies analysis variables

PROC NPAR1WAY Statement

PROC NPAR1WAY < *options* > **;**

The PROC NPAR1WAY statement invokes the procedure and optionally identifies the input data set or requests particular analyses. By default, the procedure uses the most recently created SAS data set and omits missing values from the analysis. If you do not specify any analysis options, PROC NPAR1WAY performs an analysis of variance (ANOVA option), tests for location differences (WILCOXON, MEDIAN, SAVAGE, and VW options), and performs empirical distribution function tests (EDF option).

Table 64.2 lists the *options* available in the PROC NPAR1WAY statement. Descriptions of the *options* follow in alphabetical order.

Table 64.2 PROC NPAR1WAY Statement Options

Task	Options
Specify the input data set	DATA=
Include missing CLASS values	MISSING
Suppress all displayed output	NOPRINT
Request analyses	AB ANOVA CONOVER D EDF HL KLOTZ MEDIAN MOOD SAVAGE SCORES=DATA ST VW | NORMAL WILCOXON
Set confidence level	ALPHA=
Suppress continuity correction	CORRECT=NO
Request plots	PLOTS=

You can specify the following *options* in the PROC NPAR1WAY statement.

AB
requests an analysis of Ansari-Bradley scores. See the section "Ansari-Bradley Scores" on page 5301 for more information.

ALPHA=α
specifies the level of the confidence limits for location shift, which you request with the HL option. The value of α must be between 0 and 1, and the default is 0.05. A confidence level of α produces $100(1-\alpha)\%$ confidence limits. The default of ALPHA=0.05 produces 95% confidence limits for the Hodges-Lehmann estimate.

ANOVA
requests a standard analysis of variance on the raw data.

CONOVER
requests an analysis of Conover scores. See the section "Conover Scores" on page 5302 for more information.

CORRECT=NO
suppresses the continuity correction for the Wilcoxon two-sample test and the Siegel-Tukey two-sample test. See the section "Continuity Correction" on page 5299 for more information.

D

requests the one-sided Kolmogorov-Smirnov $D+$ and $D-$ statistics and their asymptotic p-values, in addition to the two-sided D statistic produced by the EDF option for two-sample data. The D option invokes the EDF option. The statistics $D+$ and $D-$ are provided by default if you request exact Kolmogorov-Smirnov statistics with the KS option in the EXACT statement for two-sample data. See the section "Tests Based on the Empirical Distribution Function" on page 5304 for details about Kolmogorov-Smirnov statistics.

DATA=*SAS-data-set*

names the SAS data set to be analyzed by PROC NPAR1WAY. If you omit the DATA= option, the procedure uses the most recently created SAS data set.

EDF

requests statistics based on the empirical distribution function. These include the Kolmogorov-Smirnov and Cramer-von Mises tests and, if there are only two classification levels, the Kuiper test. See the section "Tests Based on the Empirical Distribution Function" on page 5304 for more information.

The EDF option produces the Kolmogorov-Smirnov D statistic for two-sample data. You can request the one-sided $D+$ and $D-$ statistics for two-sample data with the D option.

HL

requests Hodges-Lehmann estimation of the location shift for two-sample data. The HL option provides asymptotic confidence limits for the location shift. These are sometimes known as Moses confidence limits. See the section "Hodges-Lehmann Estimation of Location Shift" on page 5302 for details. You can specify the level of the confidence limits by using the ALPHA= option. The default of ALPHA=0.5 produces 95% confidence limits for the location shift.

KLOTZ

requests an analysis of Klotz scores. See the section "Klotz Scores" on page 5302 for more information.

MEDIAN

requests an analysis of median scores. When there are two classification levels, this option produces the two-sample median test. When there are more than two samples, this option produces the multi-sample median test, which is also known as the Brown-Mood test. See the section "Median Scores" on page 5300 for more information.

MISSING

treats missing values of the CLASS variable as a valid class level.

MOOD

requests an analysis of Mood scores. See the section "Mood Scores" on page 5302 for more information.

NOPRINT

suppresses the display of all output. You can use the NOPRINT option when you only want to create an output data set. Note that this option temporarily disables the Output Delivery System (ODS). For more information, see Chapter 20, "Using the Output Delivery System."

PLOTS < (*global-plot-options*) > < = *plot-request* < (*plot-option*) > >
PLOTS < (*global-plot-options*) > < = (*plot-request* < (*plot-option*) > < . . . *plot-request* < (*plot-option*) > >) >

controls the plots that are produced through ODS Graphics. Available plots include box plots, median plots, and empirical distribution plots. See Figure 64.7, Output 64.1.2, Output 64.1.4, and Output 64.2.2 for examples of plots that PROC NPAR1WAY produces. For general information about ODS Graphics, see Chapter 21, "Statistical Graphics Using ODS."

Plot-requests specify the plots to produce, *plot-options* apply to individual plots, and *global-plot-options* apply to all plots. When you specify only one *plot-request*, you can omit the parentheses around the request. For example:

```
plots=all
plots=wilcoxonboxplot
plots=(wilcoxonboxplot edfplot)
plots(only)=(medianplot normalboxplot)
```

ODS Graphics must be enabled before requesting plots. For example:

```
ods graphics on;
proc npar1way plots=wilcoxonboxplot;
   variable response;
   class treatment;
run;
ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section "Enabling and Disabling ODS Graphics" on page 612 in Chapter 21, "Statistical Graphics Using ODS."

If ODS Graphics is enabled but you do not specify the PLOTS= option, PROC NPAR1WAY produces all plots that are associated with the analyses that you request. If you request a plot with the PLOTS= option but do not request the corresponding analysis, PROC NPAR1WAY automatically invokes that analysis. For example, if you specify PLOTS=CONOVERBOXPLOT but do not also specify the CONOVER option in the PROC NPAR1WAY statement, PROC NPAR1WAY produces the Conover scores analysis in addition to the box plot.

You can suppress default plots and request specific plots by using the PLOTS(ONLY)= option; PLOTS(ONLY)=(*plot-requests*) produces only the plots that are specified as *plot-requests*. You can suppress all plots with the PLOTS=NONE option. The PLOTS= option has no effect when you specify the NOPRINT option.

Global Plot Options

Global-plot-options apply to all plots produced by PROC NPAR1WAY unless they are altered by specific *plot-options*. You can specify the following *global-plot-options* in parentheses after the PLOTS option. You cannot specify both STATS and NOSTATS as *global-plot-options* in the same statement.

NOSTATS
suppresses the *p*-values that are displayed on the plots by default.

ONLY
suppresses the default plots and requests only the plots that are specified as *plot-requests*.

STATS
displays *p*-values on the plots. This is the default.

Plot Requests

The following *plot-requests* are available with the PLOTS= option.

ABBOXPLOT | AB
requests a box plot of Ansari-Bradley scores. This plot is associated with the Ansari-Bradley analysis, which you request with the AB option.

ALL
requests all plots that are associated with the specified analyses. This is the default if you do not specify the ONLY *global-plot-option*.

ANOVABOXPLOT | ANOVA
requests a box plot of the raw data. This plot is associated with the analysis of variance based on the raw data, which you request with the ANOVA option.

CONOVERBOXPLOT | CONOVER
requests a box plot of Conover scores. This plot is associated with the Conover analysis, which you request with the CONOVER option.

DATASCORESBOXPLOT | DATASCORES
requests a box plot of raw data scores. This plot is associated with the analysis that uses input data as scores, which you request with the SCORES=DATA option.

EDFPLOT | EDF
requests an empirical distribution plot. This plot is associated with the analyses based on the empirical distribution function, which you request with the EDF option.

KLOTZBOXPLOT | KLOTZ
requests a box plot of Klotz scores. This plot is associated with the Klotz analysis, which you request with the KLOTZ option.

MEDIANPLOT | MEDIAN
requests a stacked bar chart showing the frequencies above and below the overall median. This plot is associated with the median score analysis, which you request with the MEDIAN option.

MOODBOXPLOT | MOOD
requests a box plot of Mood scores. This plot is associated with the Mood analysis, which you request with the MOOD option.

NONE
suppresses all plots.

SAVAGEBOXPLOT | SAVAGE
requests a box plot of Savage scores. This plot is associated with the Savage analysis, which you request with the SAVAGE option.

STBOXPLOT | ST
requests a box plot of Siegel-Tukey scores. This plot is associated with the Siegel-Tukey analysis, which you request with the ST option.

VWBOXPLOT | VW

NORMALBOXPLOT | NORMAL

requests a box plot of Van der Waerden (normal) scores. This plot is associated with the Van der Waerden analysis, which you request with the VW or NORMAL option.

WILCOXONBOXPLOT | WILCOXON

requests a box plot of Wilcoxon scores. This plot is associated with the Wilcoxon analysis, which you request with the WILCOXON option.

Plot Options

The following *plot-options* are available for any *plot-request*. You cannot specify both STATS and NOSTATS as *plot-options* for the same plot. If you specify NOSTATS as a *global-plot-option*, specifying STATS as an individual *plot-option* overrides the *global-plot-option* for the individual plot and displays statistics on the plot.

NOSTATS

suppresses the p-values that are displayed on the plot by default.

STATS

displays p-values on the plot. This is the default.

SAVAGE

requests an analysis of Savage scores. See the section "Savage Scores" on page 5301 for more information.

SCORES=DATA

requests an analysis that uses input data as scores. This option gives you the flexibility to construct any scores for your data with the DATA step and then analyze these scores with PROC NPAR1WAY. See the section "Scores for Linear Rank and One-Way ANOVA Tests" on page 5300 for more information.

To produce the two-sample permutation test that is known as Pitman's test, provide raw (unscored) data in the input data set and specify the SCORES=DATA option in the EXACT statement. See the section "Exact Tests" on page 5307 for more information.

ST

requests an analysis of Siegel-Tukey scores. See the section "Siegel-Tukey Scores" on page 5301 for more information.

VW | NORMAL

requests an analysis of Van der Waerden (normal) scores. See the section "Van der Waerden (Normal) Scores" on page 5301 for more information.

WILCOXON

requests an analysis of Wilcoxon scores. When there are two classification levels (samples), this option produces the Wilcoxon rank-sum test. For any number of classification levels, this option produces the Kruskal-Wallis test. See the section "Wilcoxon Scores" on page 5300 for more information.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC NPAR1WAY to obtain separate analyses of observations in groups that are defined by the BY variables. If you specify more than one BY statement, the procedure uses only the last BY statement and ignores any previous BY statements.

When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the NPAR1WAY procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variable* **;**

The CLASS statement, which is required, names one and only one classification variable. The variable can be character or numeric. The CLASS variable identifies groups (samples) in the data, and PROC NPAR1WAY provides analyses to examine differences among these groups. There can be two or more groups in the data.

EXACT Statement

EXACT *statistic-options* < / *computation-options* > **;**

The EXACT statement requests exact tests for the specified statistics. Optionally, PROC NPAR1WAY computes Monte Carlo estimates of the exact *p*-values. The *statistic-options* specify the exact tests to compute. The *computation-options* specify options for the computation of exact statistics. See the section "Exact Tests" on page 5307 for details.

NOTE: PROC NPAR1WAY computes exact tests with fast and efficient algorithms that are superior to direct enumeration. Exact tests are appropriate when a data set is small, sparse, skewed, or heavily tied.

For some large problems, computation of exact tests might require a large amount of time and memory. Consider using asymptotic tests for such problems. Alternatively, when asymptotic methods might not be sufficient for such large problems, consider using Monte Carlo estimation of exact *p*-values. See the section "Computational Resources" on page 5308 for more information.

Statistic Options

Statistic-options specify the exact tests to compute.

Exact *p*-values are available for all nonparametric tests of location and scale differences that are produced by PROC NPAR1WAY. These include tests based on the following scores: Wilcoxon, median, Van der Waerden (normal), Savage, Siegel-Tukey, Ansari-Bradley, Klotz, Mood, and Conover. Additionally, exact *p*-values are available for tests that use the raw input data as scores. The procedure computes exact *p*-values when the data are classified into two levels (two-sample tests) and when the data are classified into more than two levels (multisample tests). Two-sample tests are based on simple linear rank statistics. Multisample tests are based on one-way ANOVA statistics. See the section "Exact Tests" on page 5307 for details.

Exact *p*-values are also available for the two-sample Kolmogorov-Smirnov test. Additionally, exact confidence limits are available for the Hodges-Lehmann estimate of location shift. See the section "Hodges-Lehmann Estimation of Location Shift" on page 5302 for details.

Table 64.3 lists the available *statistic-options* and the exact tests computed. The option names are identical to the corresponding options in the PROC NPAR1WAY statement and the OUTPUT statement.

If you list no *statistic-options* in the EXACT statement, then PROC NPAR1WAY computes all available exact *p*-values for those tests that you request in the PROC NPAR1WAY statement.

Table 64.3 EXACT Statement Statistic Options

Statistic Option	Exact Test
AB	Ansari-Bradley test
CONOVER	Conover test
HL	Hodges-Lehmann confidence limits
KLOTZ	Klotz test
KS | EDF	Two-sample Kolmogorov-Smirnov test
MEDIAN	Median test
MOOD	Mood test
SAVAGE	Savage test
SCORES=DATA	Test with input data as scores
ST	Siegel-Tukey test
VW | NORMAL	Van der Waerden (normal scores) test
WILCOXON	Wilcoxon test for two-sample data or Kruskal-Wallis test for multisample data

Computation Options

Computation-options specify options for computation of exact statistics. You can specify the following *computation-options* in the EXACT statement after a slash (/).

ALPHA=α

specifies the level of the confidence limits for Monte Carlo p-value estimates. The value of α must be between 0 and 1, and the default is 0.01. A confidence level of α produces $100(1-\alpha)\%$ confidence limits. The default of ALPHA=0.01 produces 99% confidence limits for the Monte Carlo estimates.

The ALPHA= option invokes the MC option.

MAXTIME=*value*

specifies the maximum clock time (in seconds) that PROC NPAR1WAY can use to compute an exact p-value. If the procedure does not complete the computation within the specified time, the computation terminates. The value of MAXTIME= must be a positive number. The MAXTIME= option is valid for both Monte Carlo estimation of exact p-values and direct exact p-value computation. See the section "Computational Resources" on page 5308 for more information.

MC

requests Monte Carlo estimation of exact p-values, instead of direct exact p-value computation. Monte Carlo estimation can be useful for large problems that require a great amount of time and memory for exact computations but for which asymptotic approximations might not be sufficient. See the section "Monte Carlo Estimation" on page 5309 for more information.

The MC option is available for all EXACT statement *statistic-options* except the HL option, which produces exact Hodges-Lehmann confidence limits. The ALPHA=, N=, and SEED= options also invoke the MC option.

N=*n*

specifies the number of samples for Monte Carlo estimation. The value of *n* must be a positive integer, and the default is 10,000 samples. Larger values of *n* produce more precise estimates of exact p-values. Because larger values of *n* generate more samples, the computation time increases.

The N= option invokes the MC option.

POINT

requests exact point probabilities for the test statistics.

The POINT option is available for all EXACT statement *statistic-options* except the HL option, which produces exact Hodges-Lehmann confidence limits. The POINT option is not available with the MC option.

SEED=*number*

specifies the initial seed for random number generation for Monte Carlo estimation. The value of the SEED= option must be an integer. If you do not specify the SEED= option or if the SEED= value is negative or zero, PROC NPAR1WAY uses the time of day from the computer's clock to obtain the initial seed.

The SEED= option invokes the MC option.

FREQ Statement

FREQ *variable* **;**

The FREQ statement names a numeric variable that provides a frequency for each observation in the input data set. If you use a FREQ statement, PROC NPAR1WAY assumes that an observation occurs n times, where n is the value of the FREQ variable for the observation. The sum of the FREQ variable values represents the total number of observations, and the analysis is based on this expanded number of observations.

If the value of the FREQ variable is missing or is less than one, PROC NPAR1WAY does not use that observation in the analysis. If the value of the FREQ variable is not an integer, PROC NPAR1WAY uses only the integer portion as the frequency of the observation.

OUTPUT Statement

OUTPUT < **OUT=***SAS-data-set* > < *options* > **;**

The OUTPUT statement creates a SAS data set that contains statistics computed by PROC NPAR1WAY. You specify which statistics to store in the output data set by using options that are identical to those that are available in the PROC NPAR1WAY statement. The output data set contains one observation for each analysis variable named in the VAR statement. For more information about the contents of the output data set, see the section "Output Data Set" on page 5311.

Note that you can use the Output Delivery System (ODS) to create a SAS data set from any piece of PROC NPAR1WAY output. For more information, see the section "ODS Table Names" on page 5321 and Chapter 20, "Using the Output Delivery System."

You can specify the following *options* in the OUTPUT statement:

OUT=*SAS-data-set*

names the output data set. If you omit the OUT= option, the data set is named DATAn, where n is the smallest integer that makes the name unique.

options

specifies the statistics you want in the output data set. The *options* are identical to those that you can use in the PROC NPAR1WAY statement to request analyses. Table 64.4 shows the available *options*. When you specify one of these options in the OUTPUT statement, the output data set contains all statistics from that analysis. See the section "Output Data Set" on page 5311 for a list of the output data set variables corresponding to each option.

If you do not specify any statistics options in the OUTPUT statement, then the output data set includes statistics from all analyses that you request in the PROC NPAR1WAY statement.

Table 64.4 OUTPUT Statement Options

Option	Output Data Set Statistics
AB	Ansari-Bradley test
ANOVA	Analysis of variance
CONOVER	Conover test
EDF	Kolmogorov-Smirnov test, Cramer-von Mises test, and Kuiper test for two-sample data
HL	Hodges-Lehmann estimates
KLOTZ	Klotz test
MEDIAN	Median test
MOOD	Mood test
SAVAGE	Savage test
SCORES=DATA	Test with input data as scores
ST	Siegel-Tukey test
VW | NORMAL	Van der Waerden (normal scores) test
WILCOXON	Wilcoxon test for two-sample data and Kruskal-Wallis test

VAR Statement

VAR *variables* **;**

The VAR statement names the response (dependent) variables to be included in the analysis. These variables must be numeric. If you omit the VAR statement, the procedure includes all numeric variables in the data set except for the CLASS variable, the FREQ variable, and the BY variables.

Details: NPAR1WAY Procedure

Missing Values

If an observation has a missing value for a response (VAR) variable, PROC NPAR1WAY excludes that observation from the analysis. Any observation with a missing or nonpositive value for the FREQ variable is also excluded from the analysis.

By default, PROC NPAR1WAY also excludes observations with missing values of the CLASS variable. If you specify the MISSING option, PROC NPAR1WAY treats missing values of the CLASS variable as a valid class level and includes these observations in the analysis.

PROC NPAR1WAY treats missing BY variable values like any other BY variable value. The missing values form a separate, valid BY group.

Tied Values

Tied values occur when two or more observations are equal, whether the observations occur in the same sample or in different samples. In theory, nonparametric tests were developed for continuous distributions where the probability of a tie is zero. In practice, however, ties often occur. PROC NPAR1WAY uses the same method to handle ties for all score types. The procedure computes the scores as if there were no ties, averages the scores for tied observations, and assigns this average score to each observation with the same value.

When there are tied values, PROC NPAR1WAY first sorts the observations in ascending order and assigns ranks as if there were no ties. Then the procedure computes the scores based on these ranks by using the formula for the specified score type. The procedure averages the scores for tied observations and assigns this average score to each of the tied observations. Thus, all equal data values have the same score value. PROC NPAR1WAY then computes the test statistic from these scores.

Note that the asymptotic tests might be less accurate when the distribution of the data is heavily tied. For such data, it might be appropriate to use the exact tests provided by PROC NPAR1WAY as described in the section "Exact Tests" on page 5307.

When computing empirical distribution function statistics for data with ties, PROC NPAR1WAY uses the formulas given in the section "Tests Based on the Empirical Distribution Function" on page 5304. No special handling of ties is necessary.

Note that PROC NPAR1WAY bases its computations on the internal numeric values of the analysis variables; the procedure does not format or round these values before analysis. When values differ in their internal representation, even slightly, PROC NPAR1WAY does not treat them as tied values. If this is a concern for your data, then round the analysis variables by an appropriate amount before invoking PROC NPAR1WAY. For information about the ROUND function, see the discussion in *SAS Language Reference: Dictionary*.

Statistical Computations

Simple Linear Rank Tests for Two-Sample Data

Statistics of the form

$$S = \sum_{j=1}^{n} c_j \, a(R_j)$$

are called *simple linear rank statistics*, where

R_j is the rank of observation j

$a(R_j)$ is the score based on the rank of observation j

c_j is an indicator variable denoting the class to which the jth observation belongs

n is the total number of observations

For two-sample data (where the observations are classified into two levels), PROC NPAR1WAY calculates simple linear rank statistics for the scores that you specify. The section "Scores for Linear Rank and One-Way ANOVA Tests" on page 5300 describes the available scores, which you can use to test for differences in location and differences in scale.

To compute the linear rank statistic S, PROC NPAR1WAY sums the scores of the observations in the smaller of the two samples. If both samples have the same number of observations, PROC NPAR1WAY sums those scores for the sample that appears first in the input data set.

For each score that you specify, PROC NPAR1WAY computes an asymptotic test of the null hypothesis of no difference between the two classification levels. Exact tests are also available for these two-sample linear rank statistics. PROC NPAR1WAY computes exact tests for each score type that you specify in the EXACT statement. See the section "Exact Tests" on page 5307 for details.

To compute an asymptotic test for a linear rank sum statistic, PROC NPAR1WAY uses a standardized test statistic z, which has an asymptotic standard normal distribution under the null hypothesis. The standardized test statistic is computed as

$$z = (S - \mathrm{E}_0(S)) \,/\, \sqrt{\mathrm{Var}_0(S)}$$

where $\mathrm{E}_0(S)$ is the expected value of S under the null hypothesis, and $\mathrm{Var}_0(S)$ is the variance under the null hypothesis. As shown in Randles and Wolfe (1979),

$$\mathrm{E}_0(S) = \frac{n_1}{n} \sum_{j=1}^{n} a(R_j)$$

where n_1 is the number of observations in the first (smaller) class level (sample), n_2 is the number of observations in the other class level, and

$$\mathrm{Var}_0(S) = \frac{n_1 n_2}{n(n-1)} \sum_{j=1}^{n} \left(a(R_j) - \bar{a}\right)^2$$

where $\bar{a}$ is the average score,

$$\bar{a} = \frac{1}{n} \sum_{j=1}^{n} a(R_j)$$

Definition of p-Values

PROC NPAR1WAY computes one-sided and two-sided asymptotic p-values for each two-sample linear rank test. When the test statistic z is greater than its null hypothesis expected value of zero, PROC NPAR1WAY computes the right-sided p-value, which is the probability of a larger value of the statistic occurring under the null hypothesis. When the test statistic is less than or equal to zero, PROC NPAR1WAY computes the left-sided p-value, which is the probability of a smaller value of the statistic occurring under the null hypothesis. The one-sided p-value $P_1(z)$ can be expressed as

$$P_1(z) = \begin{cases} \mathrm{Prob}(Z > z) & \text{if } z > 0 \\ \mathrm{Prob}(Z < z) & \text{if } z \leq 0 \end{cases}$$

where Z has a standard normal distribution. The two-sided p-value $P_2(z)$ is computed as

$$P_2(z) = \mathrm{Prob}(|Z| > |z|)$$

Continuity Correction

PROC NPAR1WAY uses a continuity correction for the asymptotic two-sample Wilcoxon and Siegel-Tukey tests by default. You can remove the continuity correction by specifying the CORRECT=NO option. PROC NPAR1WAY incorporates the continuity correction when computing the standardized test statistic z by subtracting 0.5 from the numerator $(S - \mathrm{E}_0(S))$ if it is greater than zero. If the numerator is less than zero, PROC NPAR1WAY adds 0.5. Some sources recommend a continuity correction for nonparametric tests that use a continuous distribution to approximate a discrete distribution. (See Sheskin 1997.)

If you specify CORRECT=NO, PROC NPAR1WAY does not use a continuity correction for any test.

One-Way ANOVA Tests

PROC NPAR1WAY computes a one-way ANOVA test for each score type that you specify. Under the null hypothesis of no difference among class levels (samples), this test statistic has an asymptotic chi-square distribution with $r - 1$ degrees of freedom, where r is the number of class levels. For Wilcoxon scores, this test is known as the Kruskal-Wallis test.

Exact one-way ANOVA tests are also available for multisample data (where the data are classified into more than two levels). For two-sample data, exact simple linear rank tests are available. PROC NPAR1WAY computes exact tests for each score type that you specify in the EXACT statement. See the section "Exact Tests" on page 5307 for details.

PROC NPAR1WAY computes the one-way ANOVA test statistic as

$$C = \left(\sum_{i=1}^{r} (T_i - \mathrm{E}_0(T_i))^2 \; / \; n_i \right) / \; S^2$$

where T_i is the total of scores for class level i, $\mathrm{E}_0(T_i)$ is the expected total for level i under the null hypothesis of no difference among levels, n_i is the number of observations in level i, and S^2 is the sample variance of the scores. The total of scores for class level i is given by

$$T_i = \sum_{j=1}^{n} c_{ij} \; a(R_j)$$

where $a(R_j)$ is the score for observation j, and c_{ij} indicates whether observation j is in level i. The expected total of scores for class level i under the null hypothesis is equal to

$$\mathrm{E}_0(T_i) = \frac{n_i}{n} \sum_{j=1}^{n} a(R_j)$$

The sample variance of the scores is computed as

$$S^2 = \frac{1}{(n-1)} \sum_{j=1}^{n} \left(a(R_j) - \bar{a} \right)^2$$

where $\bar{a}$ is the average score,

$$\bar{a} = \frac{1}{n} \sum_{j=1}^{n} a(R_j)$$

Scores for Linear Rank and One-Way ANOVA Tests

For each score type that you specify, PROC NPAR1WAY computes a one-way ANOVA statistic and also a linear rank statistic for two-sample data. The following score types are used primarily to test for differences in location: Wilcoxon, median, Van der Waerden (normal), and Savage. The following scores types are used to test for scale differences: Siegel-Tukey, Ansari-Bradley, Klotz, and Mood. Conover scores can be used to test for differences in both location and scale. This section gives formulas for the score types available in PROC NPAR1WAY. For further information about the formulas and the applicability of each score, see Randles and Wolfe (1979), Gibbons and Chakraborti (1992), Conover (1999), and Hollander and Wolfe (1999).

In addition to the score types described in this section, you can specify the SCORES=DATA option to use the input data observations as scores. This enables you to produce a wide variety of tests. You can construct any scores by using the DATA step, and then you can use PROC NPAR1WAY to compute the corresponding linear rank and one-way ANOVA tests for these scores. You can also analyze raw (unscored) data with the SCORES=DATA option; for two-sample data, the corresponding exact test is a permutation test that is known as Pitman's test.

Wilcoxon Scores

Wilcoxon scores are the ranks of the observations, which can be written as

$$a(R_j) = R_j$$

where R_j is the rank of observation j, and $a(R_j)$ is the score of observation j.

Using Wilcoxon scores in the linear rank statistic for two-sample data produces the rank sum statistic of the Mann-Whitney-Wilcoxon test. Using Wilcoxon scores in the one-way ANOVA statistic produces the Kruskal-Wallis test. Wilcoxon scores are locally most powerful for location shifts of a logistic distribution.

When computing the asymptotic Wilcoxon two-sample test, PROC NPAR1WAY uses a continuity correction by default, as described in the section "Continuity Correction" on page 5299. If you specify the CORRECT=NO option in the PROC NPAR1WAY statement, the procedure does not use a continuity correction.

Median Scores

Median scores equal 1 for observations greater than the median, and 0 otherwise. In terms of the observation ranks, median scores are defined as

$$a(R_j) = \begin{cases} 1 & \text{if } R_j > (n+1)/2 \\ 0 & \text{if } R_j \leq (n+1)/2 \end{cases}$$

Using median scores in the linear rank statistic for two-sample data produces the two-sample median test. The one-way ANOVA statistic with median scores is equivalent to the Brown-Mood test. Median scores are particularly powerful for distributions that are symmetric and heavy-tailed.

Van der Waerden (Normal) Scores

Van der Waerden scores are the quantiles of a standard normal distribution and are also known as *quantile normal scores*. Van der Waerden scores are computed as

$$a(R_j) = \Phi^{-1}\left(\frac{R_j}{n+1}\right)$$

where Φ is the cumulative distribution function of a standard normal distribution. These scores are powerful for normal distributions.

Savage Scores

Savage scores are expected values of order statistics from the exponential distribution, with 1 subtracted to center the scores around 0. Savage scores are computed as

$$a(R_j) = \sum_{i=1}^{R_j}\left(\frac{1}{n-i+1}\right) - 1$$

Savage scores are powerful for comparing scale differences in exponential distributions or location shifts in extreme value distributions (Hajek 1969, p. 83).

Siegel-Tukey Scores

Siegel-Tukey scores are defined as

$$\begin{array}{llll} a(1)=1, & a(n)=2, & a(n-1)=3, & a(2)=4, \\ a(3)=5, & a(n-2)=6, & a(n-3)=7, & a(4)=8, \ \ldots \end{array}$$

where the score values continue to increase in this pattern toward the middle ranks until all observations have been assigned a score.

When computing the asymptotic Siegel-Tukey two-sample test, PROC NPAR1WAY uses a continuity correction by default, as described in the section "Continuity Correction" on page 5299. If you specify the CORRECT=NO option in the PROC NPAR1WAY statement, the procedure does not use a continuity correction.

Ansari-Bradley Scores

Ansari-Bradley scores are similar to Siegel-Tukey scores, but Ansari-Bradley scoring assigns the same score value to corresponding extreme ranks. (Siegel-Tukey scores are a permutation of the ranks $1, 2, \ldots, n$.) Ansari-Bradley scores are defined as

$$\begin{array}{ll} a(1)=1, & a(n)=1, \\ a(2)=2, & a(n-1)=2, \ \ldots \end{array}$$

Equivalently, Ansari-Bradley scores are equal to

$$a(R_j) = \frac{n+1}{2} - \left|R_j - \frac{n+1}{2}\right|$$

Klotz Scores

Klotz scores are the squares of the Van der Waerden (normal) scores. Klotz scores are computed as

$$a(R_j) = \left(\Phi^{-1}\left(\frac{R_j}{n+1}\right)\right)^2$$

where Φ is the cumulative distribution function of a standard normal distribution.

Mood Scores

Mood scores are computed as the square of the difference between the observation rank and the average rank. Mood scores can be written as

$$a(R_j) = \left(R_j - \frac{n+1}{2}\right)^2$$

Conover Scores

Conover scores are based on the squared ranks of the absolute deviations from the sample means. For observation j the absolute deviation from the mean is computed as

$$U_j = |X_{j(i)} - \bar{X}_i|$$

where $X_{j(i)}$ is the value of observation j, observation j belongs to sample i, and $\bar{X}_i$ is the mean of sample i. The values of U_j are ranked, and the Conover score for observation j is computed as

$$\text{Score}_j = \left(\text{Rank}(U_j)\right)^2$$

Following Conover (1999), when there are ties among the values of U_j, PROC NPAR1WAY assigns the average rank to each of the tied observations. To compute the average rank, PROC NPAR1WAY ranks the U_j as if there were no ties, and then averages the ranks of the tied observations.

The Conover score test is also known as the squared ranks test for variances. See Conover (1999) for more information.

Hodges-Lehmann Estimation of Location Shift

If you specify the HL option, PROC NPAR1WAY computes the Hodges-Lehmann estimate of location shift for two-sample data. PROC NPAR1WAY also provides confidence limits for the location shift. These confidence limits are sometimes called Moses confidence limits. You can set the level of the confidence limits with the ALPHA= option. The default is ALPHA=0.05, which produces 95% confidence limits. Additionally, you can request exact confidence limits for the location shift by specifying the HL option in the EXACT statement.

The Hodges-Lehmann estimator of location shift is associated with the Wilcoxon linear rank statistic. See Hollander and Wolfe (1999) and Hodges and Lehmann (1983) for details.

PROC NPAR1WAY computes the Hodges-Lehmann estimate $\hat{\Delta}$ as the median of all paired differences between observations in the two samples, which can be written as

$$\hat{\Delta} = \text{median}\left((Y_j - X_i) \quad \text{where} \quad j = 1, 2, \ldots, n_1;\ i = 1, 2, \ldots, n_2 \right)$$

The Y_j are observations in sample 1, the X_i are observations in sample 2, and n_1 and n_2 denote the number of observations in sample 1 and sample 2, respectively. PROC NPAR1WAY uses the smaller of the two samples as sample 1. If both samples have the same number of observations, PROC NPAR1WAY uses the sample that appears first in the input data set as sample 1. Sample 1 is the same sample that PROC NPAR1WAY uses to compute the two-sample linear rank statistic.

Let m denote the total number of differences ($n_1 \times n_2$), and let $U^{(k)}$ denote the kth value of $(Y_j - X_i)$ among the ordered differences. When m is an odd number, then the median difference is the value with rank $(m + 1)/2$,

$$\hat{\Delta} = U^{(k)} \quad \text{where} \quad k = (m + 1)/2$$

When m is an even number, the median difference is the average of the values with ranks $(m/2)$ and $((m/2) + 1)$,

$$\hat{\Delta} = \left(U^{(k)} + U^{(k+1)} \right) / 2 \quad \text{where} \quad k = m/2$$

Following Hollander and Wolfe (1999), the asymptotic lower and upper confidence limits for the location shift are

$$\left(\Delta_L = U^{(C_\alpha)}, \quad \Delta_U = U^{(m+1-C_\alpha)} \right)$$

where C_α is the largest integer less than or equal to C_α^*, which is computed as

$$C_\alpha^* = \mathrm{E}_0(S) - z_{\alpha/2} \sqrt{\mathrm{Var}_0(S)}$$

where $\mathrm{E}_0(S)$ and $\mathrm{Var}_0(S)$ are the expected value and variance, respectively, of the Wilcoxon statistic S under the null hypothesis (as described in the section "Simple Linear Rank Tests for Two-Sample Data" on page 5297), and $z_{\alpha/2}$ is the $100(1 - \alpha/2)$th percentile of the standard normal distribution. For Wilcoxon rank scores,

$$\mathrm{E}_0(S) = n_1 n_2 / 2$$

When there are no tied values, $\mathrm{Var}_0(S)$ for Wilcoxon scores equals

$$\mathrm{Var}_0(S) = n_1 n_2 (n_1 + n_2 + 1)/12$$

PROC NPAR1WAY displays the midpoint of the confidence interval (Δ_L, Δ_U), which can also be used as an estimate of location shift. See Lehmann (1963) for details. Additionally, PROC NPAR1WAY provides an estimate of the asymptotic standard error of $\hat{\Delta}$ based on the length of the confidence interval, which is computed as

$$\mathrm{se}(\hat{\Delta}) = (\Delta_U - \Delta_L) \ / \ (2\, z_{\alpha/2})$$

Exact Confidence Limits

If you specify the HL option in the EXACT statement, PROC NPAR1WAY computes exact confidence limits for the location shift between the two samples. As for the asymptotic confidence limits, you can set the confidence level with the ALPHA= option. The default is ALPHA=0.05, which produces 95% confidence limits.

PROC NPAR1WAY computes exact confidence limits for the location shift as described in Randles and Wolfe (1979, p. 180). PROC NPAR1WAY first generates the exact conditional distribution of the Mann-Whitney U statistic, which equals the number of pairwise differences $(Y_i - X_j)$ that are positive, plus half the number of pairwise differences that are zero. The Mann-Whitney statistic is defined as

$$MW = \sum_{i=1}^{n_1} \sum_{j=i}^{n_2} \phi\left(X_i - Y_j\right)$$

where

$$\phi(Y_i, X_j) = \begin{cases} 1 & \text{if } Y_i > X_j \\ 1/2 & \text{if } Y_i = X_j \\ 0 & \text{otherwise} \end{cases}$$

From the exact conditional distribution of the Mann-Whitney statistic MW, PROC NPAR1WAY chooses $C^*_{L,\alpha}$ as the largest value such that $\text{Prob}(MW \geq C^*_{L,\alpha}) \geq \alpha/2$. Rounding $C^*_{L,\alpha}$ up to the nearest integer $C_{L,\alpha}$, the lower confidence limit equals the difference $(Y_i - X_j)$ that has a rank of $(n_1 n_2 - C_{L,\alpha} + 1)$.

To find the upper confidence limit, PROC NPAR1WAY chooses $C^*_{U,\alpha}$ as the smallest value such that $\text{Prob}(MW \leq C^*_{U,\alpha}) \geq \alpha/2$. Rounding $C^*_{U,\alpha}$ down to the nearest integer $C_{L,\alpha}$, the upper confidence limit equals the difference $(Y_i - X_j)$ that has a rank of $(n_1 n_2 - C_{U,\alpha})$.

Because this is a discrete problem, the confidence coefficient for these exact confidence limits is not exactly $(1 - \alpha)$ but is at least $(1 - \alpha)$. Thus, these confidence limits are conservative.

Tests Based on the Empirical Distribution Function

If you specify the EDF option, PROC NPAR1WAY computes tests based on the empirical distribution function. These include the Kolmogorov-Smirnov and Cramer-von Mises tests, and also the Kuiper test for two-sample data. This section gives formulas for these test statistics. For further information about the formulas and the interpretation of EDF statistics, see Hollander and Wolfe (1999) and Gibbons and Chakraborti (1992). For details about the k-sample analogs of the Kolmogorov-Smirnov and Cramer-von Mises statistics, see Kiefer (1959).

The *empirical distribution function* (EDF) of a sample $\{x_j\}$, $j = 1, 2, \ldots, n$, is defined as

$$F(x) = \frac{1}{n}(\text{number of } x_j \leq x) = \frac{1}{n} \sum_{j=1}^{n} I(x_j \leq x)$$

where $I(\cdot)$ is an indicator function. PROC NPAR1WAY uses the subsample of values within the ith class level to generate an EDF for the class, F_i. The EDF for the overall sample, pooled over classes, can also be

expressed as

$$F(x) = \frac{1}{n} \sum_i (n_i F_i(x))$$

where n_i is the number of observations in the ith class level, and n is the total number of observations.

Kolmogorov-Smirnov Test

The Kolmogorov-Smirnov statistic measures the maximum deviation of the EDF within the classes from the pooled EDF. PROC NPAR1WAY computes the Kolmogorov-Smirnov statistic as

$$KS = \max_j \sqrt{\frac{1}{n} \sum_i n_i \left(F_i(x_j) - F(x_j)\right)^2} \quad \text{where} \quad j = 1, 2, \ldots, n$$

The asymptotic Kolmogorov-Smirnov statistic is computed as

$$KS_a = KS \times \sqrt{n}$$

For each class level i and overall, PROC NPAR1WAY displays the value of F_i at the maximum deviation from F and the value $\sqrt{n_i}\ (F_i - F)$ at the maximum deviation from F. PROC NPAR1WAY also gives the observation where the maximum deviation occurs.

If there are only two class levels, PROC NPAR1WAY computes the two-sample Kolmogorov-Smirnov test statistic D as

$$D = \max_j \left|F_1(x_j) - F_2(x_j)\right| \quad \text{where} \quad j = 1, 2, \ldots, n$$

The p-value for this test is the probability that D is greater than the observed value d under the null hypothesis of no difference between class levels (samples). PROC NPAR1WAY computes the asymptotic p-value for D with the approximation

$$\text{Prob}(D > d) = 2 \sum_{i=1}^{\infty} (-1)^{(i-1)}\ e^{(-2i^2\ z^2)}$$

where

$$z = d \sqrt{n_1\ n_2\ /\ n}$$

The quality of this approximation has been studied by Hodges (1957).

If you specify the D option, or if you request exact Kolmogorov-Smirnov p-values with the KS option in the EXACT statement, PROC NPAR1WAY also computes the one-sided Kolmogorov-Smirnov statistics $D+$ and $D-$ for two-sample data as

$$D+ = \max_j \left(F_1(x_j) - F_2(x_j)\right) \quad \text{where} \quad j = 1, 2, \ldots, n$$

$$D- = \max_j \left(F_2(x_j) - F_1(x_j)\right) \quad \text{where} \quad j = 1, 2, \ldots, n$$

The asymptotic probability that $D+$ is greater than the observed value d^+, under the null hypothesis of no difference between the two class levels, is computed as

$$\text{Prob}(D+ > d^+) = e^{-2z^2} \quad \text{where} \quad z = d^+\sqrt{n_1\, n_2\, /\, n}$$

Similarly, the asymptotic probability that $D-$ is greater than the observed value d^- is computed as

$$\text{Prob}(D- > d^-) = e^{-2z^2} \quad \text{where} \quad z = d^-\sqrt{n_1\, n_2\, /\, n}$$

To request exact p-values for the Kolmogorov-Smirnov statistics, you can specify the KS option in the EXACT statement. See the section "Exact Tests" on page 5307 for more information.

Cramer-von Mises Test

The Cramer-von Mises statistic is defined as

$$CM = \frac{1}{n^2}\sum_i \left(n_i \sum_{j=1}^{p} t_j \left(F_i(x_j) - F(x_j)\right)^2 \right)$$

where t_j is the number of ties at the jth distinct value and p is the number of distinct values. The asymptotic value is computed as

$$CM_a = CM \times n$$

PROC NPAR1WAY displays the contribution of each class level to the sum CM_a.

Kuiper Test

For data with two class levels, PROC NPAR1WAY computes the Kuiper statistic, its scaled value for the asymptotic distribution, and the asymptotic p-value. The Kuiper statistic is computed as

$$K = \max_j \left(F_1(x_j) - F_2(x_j)\right) - \min_j \left(F_1(x_j) - F_2(x_j)\right) \quad \text{where} \quad j = 1, 2, \ldots, n$$

The asymptotic value is

$$K_a = K\sqrt{n_1\, n_2\, /\, n}$$

PROC NPAR1WAY displays the value of $(\max_j \left|F_1(x_j) - F_2(x_j)\right|)$ for each class level.

The p-value for the Kuiper test is the probability of observing a larger value of K_a under the null hypothesis of no difference between the two classes. PROC NPAR1WAY computes this p-value according to Owen (1962, p. 441).

Exact Tests

PROC NPAR1WAY provides exact *p*-values for tests for location and scale differences based on the following scores: Wilcoxon, median, van der Waerden (normal), Savage, Siegel-Tukey, Ansari-Bradley, Klotz, Mood, and Conover. Additionally, PROC NPAR1WAY provides exact *p*-values for tests that use the raw data as scores. Exact tests are available for two-sample and multisample data. When the data are classified into two samples, tests are based on simple linear rank statistics. When the data are classified into more than two samples, tests are based on one-way ANOVA statistics.

Exact tests can be useful in situations where the asymptotic assumptions are not met and the asymptotic *p*-values are not close approximations for the true *p*-values. Standard asymptotic methods involve the assumption that the test statistic follows a particular distribution when the sample size is sufficiently large. When the sample size is not large, asymptotic results might not be valid, with the asymptotic *p*-values differing perhaps substantially from the exact *p*-values. Asymptotic results might also be unreliable when the distribution of the data is sparse, skewed, or heavily tied. See Agresti (2007) and Bishop, Fienberg, and Holland (1975). Exact computations are based on the statistical theory of exact conditional inference for contingency tables, reviewed by Agresti (1992).

In addition to computation of exact *p*-values, PROC NPAR1WAY provides the option of estimating exact *p*-values by Monte Carlo simulation. This can be useful for problems that are so large that exact computations require a great amount of time and memory, but for which asymptotic approximations might not be sufficient.

The following sections summarize the exact computational algorithms, define the exact *p*-values that PROC NPAR1WAY computes, discuss the computational resource requirements, and describe the Monte Carlo estimation option.

Computational Algorithms

PROC NPAR1WAY computes exact *p*-values by using the network algorithm developed by Mehta and Patel (1983). This algorithm provides a substantial advantage over direct enumeration, which can be very time-consuming and feasible only for small problems. See Agresti (1992) for a review of algorithms for computation of exact *p*-values, and see Mehta, Patel, and Tsiatis (1984) and Mehta, Patel, and Senchaudhuri (1991) for information about the performance of the network algorithm.

PROC NPAR1WAY constructs a contingency table from the input data, with rows formed by the levels of the classification variable and columns formed by the response variable values. The reference set for a given contingency table is the set of all contingency tables with the observed marginal row and column sums. Corresponding to this reference set, the network algorithm forms a directed acyclic network consisting of nodes in a number of stages. A path through the network corresponds to a distinct table in the reference set. The distances between nodes are defined so that the total distance of a path through the network is the corresponding value of the test statistic. At each node, the algorithm computes the shortest and longest path distances for all the paths that pass through that node. For the two-sample linear rank statistics, which can be expressed as linear combinations of cell frequencies multiplied by increasing row and column scores, PROC NPAR1WAY computes shortest and longest path distances by using the algorithm given by Agresti, Mehta, and Patel (1990). For the multisample one-way test statistics, PROC NPAR1WAY computes an upper bound for the longest path and a lower bound for the shortest path by following the approach of Valz and Thompson (1994).

The longest and shortest path distances (bounds) for a node are compared to the value of the test statistic to determine whether all paths through the node contribute to the p-value, none of the paths through the node contribute to the p-value, or neither of these situations occurs. If all paths through the node contribute, the p-value is incremented accordingly, and these paths are eliminated from further analysis. If no paths contribute, these paths are eliminated from the analysis. Otherwise, the algorithm continues, still processing this node and the associated paths. The algorithm finishes when all nodes have been accounted for.

In applying the network algorithm, PROC NPAR1WAY uses full numerical precision to represent all statistics, row and column scores, and other quantities involved in the computations. Although it is possible to use rounding to improve the speed and memory requirements of the algorithm, PROC NPAR1WAY does not do this because it can result in reduced accuracy of the p-values.

Definition of p-Values

For two-sample linear rank tests, PROC NPAR1WAY computes exact one-sided and two-sided p-values for each test that is specified in the EXACT statement. For the one-sided test, PROC NPAR1WAY displays the right-sided p-value when the observed value of the test statistic is greater than its expected value. The right-sided p-value is the sum of probabilities for those tables having a test statistic greater than or equal to the observed test statistic. Otherwise, when the test statistic is less than or equal to its expected value, PROC NPAR1WAY displays the left-sided p-value. The left-sided p-value is the sum of probabilities for those tables having a test statistic less than or equal to the one observed. The one-sided p-value P_1 can be expressed as

$$P_1(t) = \begin{cases} \text{Prob}(\text{ Test Statistic} \geq t\ ) & \text{if } t > \mathrm{E}_0(T) \\ \text{Prob}(\text{ Test Statistic} \leq t\ ) & \text{if } t \leq \mathrm{E}_0(T) \end{cases}$$

where t is the observed value of the test statistic and $\mathrm{E}_0(T)$ is the expected value of the test statistic under the null hypothesis. PROC NPAR1WAY computes the two-sided p-value as the sum of the one-sided p-value and the corresponding area in the opposite tail of the distribution of the statistic, equidistant from the expected value. The two-sided p-value P_2 can be expressed as

$$P_2(t) = \text{Prob}\left(|\text{Test Statistic} - \mathrm{E}_0(T)| \geq |t - \mathrm{E}_0(T)|\right)$$

For multisample data, the tests are based on one-way ANOVA statistics. For a test of this form, large values of the test statistic indicate a departure from the null hypothesis; the test is inherently two-sided. The exact p-value is the sum of probabilities for those tables having a test statistic greater than or equal to the value of the observed test statistic.

If you specify the POINT option in the EXACT statement, PROC NPAR1WAY also displays exact point probabilities for the test statistics. The exact point probability is the exact probability that the test statistic equals the observed value.

Computational Resources

PROC NPAR1WAY uses relatively fast and efficient algorithms for exact computations. These algorithms, together with improvements in computer power, now make it feasible to perform exact computations for data sets where previously only asymptotic methods could be applied. Nevertheless, there are still large problems that might require a prohibitive amount of time and memory for exact computations, depending

on the speed and memory available on your computer. For large problems, consider whether exact methods are really needed or whether asymptotic methods might give results quite close to the exact results while requiring much less computer time and memory. When asymptotic methods might not be sufficient for such large problems, consider using Monte Carlo estimation of exact *p*-values, as described in the section "Monte Carlo Estimation" on page 5309.

A formula does not exist that can predict in advance how much time and memory are needed to compute an exact *p*-value for a certain problem. The time and memory required depend on several factors, including which test is being performed, the total sample size, the number of rows and columns, and the specific arrangement of the observations into table cells. Generally, larger problems (in terms of total sample size, number of rows, and number of columns) tend to require more time and memory. Additionally, for a fixed total sample size, time and memory requirements tend to increase as the number of rows and columns increase, since this corresponds to an increase in the number of tables in the reference set. Also for a fixed sample size, time and memory requirements increase as the marginal row and column totals become more homogeneous. See Agresti, Mehta, and Patel (1990) and Gail and Mantel (1977) for details.

At any time while PROC NPAR1WAY is computing exact *p*-values, you can terminate the computations by pressing the system interrupt key sequence (see the *SAS Companion* for your system) and choosing to stop computations. After you terminate exact computations, PROC NPAR1WAY completes all other remaining tasks. The procedure produces the requested output and reports missing values for any exact *p*-values not computed by the time of termination.

You can also use the MAXTIME= option in the EXACT statement to limit the amount of time PROC NPAR1WAY uses for exact computations. You specify a MAXTIME= value that is the maximum amount of time (in seconds) that PROC NPAR1WAY can use to compute an exact *p*-value. If PROC NPAR1WAY does not finish computing the exact *p*-value within that time, it terminates the computation and completes all other remaining tasks.

Monte Carlo Estimation

If you specify the MC option in the EXACT statement, PROC NPAR1WAY computes Monte Carlo estimates of the exact *p*-values instead of directly computing the exact *p*-values. Monte Carlo estimation can be useful for large problems that require a great amount of time and memory for exact computations but for which asymptotic approximations might not be sufficient. To describe the precision of each Monte Carlo estimate, PROC NPAR1WAY provides the asymptotic standard error and $100(1-\alpha)\%$ confidence limits. The confidence level α is determined by the ALPHA= option in the EXACT statement, which, by default, equals 0.01 and produces 99% confidence limits. The N= option in the EXACT statement specifies the number of samples PROC NPAR1WAY uses for Monte Carlo estimation; the default is 10,000 samples. You can specify a larger value for n to improve the precision of the Monte Carlo estimates. Because larger values of n generate more samples, the computation time increases. Or you can specify a smaller value of n to reduce the computation time.

To compute a Monte Carlo estimate of an exact *p*-value, PROC NPAR1WAY generates a random sample of tables with the same total sample size, row totals, and column totals as the observed table. PROC NPAR1WAY uses the algorithm of Agresti, Wackerly, and Boyett (1979), which generates tables in proportion to their hypergeometric probabilities conditional on the marginal frequencies. For each sample table, PROC NPAR1WAY computes the value of the test statistic and compares it to the value for the observed

table. When estimating a right-sided p-value, PROC NPAR1WAY counts all sample tables for which the test statistic is greater than or equal to the observed test statistic. Then the p-value estimate equals the number of these tables divided by the total number of tables sampled, which can be written as

$$\begin{aligned} \hat{P}_{MC} &= M \ / \ N \\ M &= \text{number of samples with (Test Statistic} \geq t) \\ N &= \text{total number of samples} \\ t &= \text{observed Test Statistic} \end{aligned}$$

PROC NPAR1WAY computes left-sided and two-sided p-value estimates in a similar manner. For left-sided p-values, PROC NPAR1WAY evaluates whether the test statistic for each sampled table is less than or equal to the observed test statistic. For two-sided p-values, PROC NPAR1WAY examines the sample test statistics according to the expression for $P_2(t)$ given in the section "Definition of p-Values" on page 5308.

The variable M is a binomial variable with N trials and success probability p. It follows that the asymptotic standard error of the Monte Carlo estimate is

$$\text{se}(\hat{P}_{MC}) = \sqrt{\hat{P}_{MC} \ (1 - \hat{P}_{MC}) \ / \ (N - 1)}$$

PROC NPAR1WAY constructs asymptotic confidence limits for the p-values according to

$$\hat{P}_{MC} \ \pm \ \left(z_{\alpha/2} \ \times \ \text{se}(\hat{P}_{MC}) \right)$$

where $z_{\alpha/2}$ is the $100(1 - \alpha/2)$th percentile of the standard normal distribution, and the confidence level α is determined by the ALPHA= option in the EXACT statement.

When the Monte Carlo estimate $\hat{P}_{MC}$ equals 0, PROC NPAR1WAY computes confidence limits for the p-value as

$$(\ 0, \ \ 1 - \alpha^{(1/N)} \ )$$

When the Monte Carlo estimate $\hat{P}_{MC}$ equals 1, PROC NPAR1WAY computes the confidence limits as

$$(\ \alpha^{(1/N)}, \ \ 1 \ )$$

Output Data Set

The OUTPUT statement creates a SAS data set that contains statistics computed by PROC NPAR1WAY. You specify which statistics to store in the output data set by using options identical to those in the PROC NPAR1WAY statement. When you specify one of these options in the OUTPUT statement, PROC NPAR1WAY includes all available statistics from that analysis in the output data set.

The output data set contains one observation for each analysis variable within a BY group. (You can name the analysis variables in the VAR statement.) The OUTPUT data set includes the following variables:

- BY variables, if you use a BY statement
- _VAR_, which identifies the analysis variable
- Variables containing the specified statistics

Table 64.5 lists the variable names and descriptions for all available statistics. Note that some statistics are available only for the two-sample case (where the CLASS variable groups the data into two classes); other statistics are available only for the multisample case.

If you request exact tests by using the EXACT statement, the output data set also includes exact *p*-values for those tests when you specify the corresponding options in the OUTPUT statement. If you do not request exact tests with the EXACT statement, the output data set does not include exact *p*-values.

Monte Carlo estimates of exact *p*-values are not available in this output data set, but you can use the Output Delivery System (ODS) to store Monte Carlo estimates in a SAS data set. You can use the Output Delivery System to create a SAS data set from any piece of PROC NPAR1WAY output. For more information, see the section "ODS Table Names" on page 5321 and Chapter 20, "Using the Output Delivery System."

Table 64.5 Output Data Set Variable Names and Descriptions

Option	Output Variables		Variable Descriptions
AB	_AB_	*	Two-sample Ansari-Bradley statistic
	Z_AB	*	Ansari-Bradley statistic, standardized
	PL_AB	*	*p*-value (left-sided), Ansari-Bradley test
	PR_AB	*	*p*-value (right-sided), Ansari-Bradley test
	P2_AB	*	*p*-value (two-sided), Ansari-Bradley test
	XPL_AB	*	Exact *p*-value (left-sided), Ansari-Bradley test
	XPR_AB	*	Exact *p*-value (right-sided), Ansari-Bradley test
	XPT_AB	*	Exact point probability, Ansari-Bradley test
	XP2_AB	*	Exact *p*-value (two-sided), Ansari-Bradley test
	CHAB		Ansari-Bradley chi-square
	DF_CHAB		Degrees of freedom, Ansari-Bradley chi-square
	P_CHAB		*p*-value, Ansari-Bradley chi-square test
	XP_CHAB	**	Exact *p*-value, Ansari-Bradley chi-square test
	XPT_CHAB	**	Exact point probability, Ansari-Bradley chi-square

Table 64.5 *continued*

Option	Output Variables		Variable Descriptions
ANOVA	_MSA_		ANOVA effect mean square, among MS
	MSE		ANOVA error mean square, within MS
	_F_		*F* statistic for ANOVA
	P_F		*p*-value, *F* statistic for ANOVA
CONOVER	_CON_	*	Two-sample Conover statistic
	Z_CON	*	Conover statistic, standardized
	PL_CON	*	*p*-value (left-sided), Conover test
	PR_CON	*	*p*-value (right-sided), Conover test
	P2_CON	*	*p*-value (two-sided), Conover test
	XPL_CON	*	Exact *p*-value (left-sided), Conover test
	XPR_CON	*	Exact *p*-value (right-sided), Conover test
	XPT_CON	*	Exact point probability, Conover test
	XP2_CON	*	Exact *p*-value (two-sided), Conover test
	CHCON		Conover chi-square
	DF_CHCON		Degrees of freedom, Conover chi-square
	P_CHCON		*p*-value, Conover chi-square test
	XP_CHCON	**	Exact *p*-value, Conover chi-square test
	XPT_CHCO	**	Exact point probability, Conover chi-square
EDF	_KS_		Kolmogorov-Smirnov statistic
	KSA		Kolmogorov-Smirnov statistic (asymptotic)
	_Dp_	*	Two-sample Kolmogorov-Smirnov D+
	P_Dp	*	*p*-value, D+
	_Dm_	*	Two-sample Kolmogorov-Smirnov D-
	P_Dm	*	*p*-value, D-
	_D_	*	Two-sample Kolmogorov-Smirnov statistic D
	P_KSA	*	*p*-value, D
	XP_Dp	*	Exact *p*-value, D+
	XPT_Dp	*	Exact point probability, D+
	XP_Dm	*	Exact *p*-value, D-
	XPT_Dm	*	Exact point probability, D-
	XP_D	*	Exact *p*-value, D
	XPT_D	*	Exact point probability, D
	_CM_		Cramer-von Mises statistic
	CMA		Cramer-von Mises statistic (asymptotic)
	_K_	*	Kuiper two-sample statistic
	_KA_	*	Kuiper two-sample statistic (asymptotic)
	P_KA	*	*p*-value, two-sample Kuiper test

Table 64.5 *continued*

Option	Output Variables		Variable Descriptions
HL	_HL_	*	Hodges-Lehmann estimate, location shift
	L_HL	*	Lower confidence limit, Hodges-Lehmann
	U_HL	*	Upper confidence limit, Hodges-Lehmann
	M_HL	*	Confidence limit midpoint, Hodges-Lehmann
	E_HL	*	ASE of Hodges-Lehmann estimate
	XL_HL	*	Exact lower confidence limit, Hodges-Lehmann
	XU_HL	*	Exact upper confidence limit, Hodges-Lehmann
	XM_HL	*	Exact confidence limit midpoint
KLOTZ	_KLOTZ_	*	Two-sample Klotz statistic
	Z_K	*	Klotz statistic, standardized
	PL_K	*	*p*-value (left-sided), Klotz test
	PR_K	*	*p*-value (right-sided), Klotz test
	P2_K	*	*p*-value (two-sided), Klotz test
	XPL_K	*	Exact *p*-value (left-sided), Klotz test

** Statistic included only for multisample cases.

Displayed Output

If you specify the ANOVA option, PROC NPAR1WAY displays a "Class Means" table and an "Analysis of Variance" table for each response variable. The "Class Means" table includes the following information for each CLASS variable value (level):

- N, which is the number of observations
- Mean of the response variable

The "Analysis of Variance" table includes the following information for each Source of variation (Among classes and Within classes):

- DF, which is the degrees of freedom associated with the source
- Sum of Squares
- Mean Square, which is the sum of squares divided by the degrees of freedom

The "Analysis of Variance" table also includes the following:

- F Value for testing the hypothesis that the class means are equal, which is computed by dividing the Mean Square (Among) by the Mean Square (Within)
- Pr > F, which is the significance probability corresponding to the F Value

For each score type that you specify, PROC NPAR1WAY displays a "Class Scores" table. The available score types include Wilcoxon, median, Van der Waerden (normal), Savage, Siegel-Tukey, Ansari-Bradley, Klotz, Mood, Conover, and raw data scores. PROC NPAR1WAY computes the scores for the response variable values and classifies the scored observations according to the CLASS variable values. The "Class Scores" table includes the following information for each CLASS variable level:

- N, which is the number of observations
- Sum of Scores
- Expected Under H0, which is the expected sum of scores under the null hypothesis of no difference among classes
- Std Dev Under H0, which is the standard deviation under the null hypothesis
- Mean Score

When there are two levels of the CLASS variable, PROC NPAR1WAY displays a "Two-Sample Test" table for each analysis of scores. The "Two-Sample Test" table includes the following information:

- Statistic, which is the sum of scores for the class with the smaller sample size
- Z, which is the standardized test statistic and has an asymptotic standard normal distribution under the null hypothesis
- One-Sided Pr < Z or One-Sided Pr > Z, which is the asymptotic one-sided p-value. This is displayed as Pr < Z or Pr > Z depending on whether Z is ≤ 0 or > 0.
- Two-Sided Pr > |Z|, which is the asymptotic two-sided p-value

For Wilcoxon scores, the "Two-Sample Test" table also includes a t Approximation for the Wilcoxon two-sample test.

If you request an exact test by specifying the score type in the EXACT statement, the "Two-Sample Test" table also includes the following exact p-values:

- One-Sided Pr $\leq$ S or One-Sided Pr $\geq$ S, which is the exact one-sided p-value. This is displayed as Pr $\leq$ S or Pr $\geq$ S depending on whether S $\leq$ Mean or S > Mean, where S is the test statistic and Mean is its expected value under the null hypothesis.
- Point Pr = S, which is the point probability. This is displayed if you specify the POINT option in the EXACT statement.
- Two-Sided Pr $\geq$ |S - Mean|, which is the exact two-sided p-value

If you request Monte Carlo estimates for a two-sample exact test by specifying the MC option in the EXACT statement, PROC NPAR1WAY displays the "Monte Carlo Estimates for the Exact Test" table, which includes the following information:

- Estimate of One-Sided Pr $\leq$ S or One-Sided Pr $\geq$ S, which is the exact one-sided p-value, together with its Lower and Upper Confidence Limits
- Estimate of Two-Sided Pr $\geq$ |S - Mean|, which is the exact two-sided p-value, together with its Lower and Upper Confidence Limits
- Number of Samples used to compute the Monte Carlo estimates
- Initial Seed used to compute the Monte Carlo estimates

For both two-sample and multisample data, PROC NPAR1WAY displays a "One-Way Analysis" table, which includes the following information:

- Chi-Square, which is the one-way ANOVA statistic for testing the null hypothesis of no difference among classes
- DF, which is the degrees of freedom
- Pr > Chi-Square, which is the asymptotic p-value

For multisample data, if you request an exact test by specifying the score type in the EXACT statement, the "One-Way Analysis" table also displays the exact p-value as follows:

- Exact Pr $\geq$ Chi-Square
- Exact Pr = Chi-Square, which is the point probability. This is displayed if you specify the POINT option in the EXACT statement.

For multisample data, if you specify the MC option in the EXACT statement, PROC NPAR1WAY displays the following information in the "Monte Carlo Estimate for the Exact Test" table:

- Estimate of Exact Pr $\geq$ Chi-Square, together with its Lower and Upper Confidence Limits
- Number of Samples used to compute the Monte Carlo estimate
- Initial Seed used to compute the Monte Carlo estimate

If you specify the HL option for two-sample data, PROC NPAR1WAY produces a "Hodges-Lehmann Estimation" table, which includes the following information:

- Location Shift estimate
- Confidence Limits for the Location Shift
- Confidence Interval Midpoint
- Asymptotic Standard Error estimate, which is based on the confidence interval

If you request exact Hodges-Lehmann confidence limits by specifying the HL option in the EXACT statement, the "Hodges-Lehmann Estimation" table also includes Exact Confidence Limits and the exact Interval Midpoint.

If you specify the EDF option, PROC NPAR1WAY produces tables for the Kolmogorov-Smirnov test, the Cramer-von Mises test, and for two-sample data only, the Kuiper test.

The "Kolmogorov-Smirnov Test" table includes the following information for each CLASS variable level:

- N, which is the number of observations
- EDF at Maximum, which is the value of the class EDF (empirical distribution function) at its maximum deviation from the pooled EDF
- Deviation from Mean at Maximum, which is the value of $\sqrt{n_i}\sqrt{F_i - F}$ at its maximum, where n_i is the class sample size, F_i is the class EDF, and F is the pooled EDF

The "Kolmogorov-Smirnov Test" table displays the following statistics:

- KS, which is the Kolmogorov-Smirnov statistic
- KSa, which is the asymptotic Kolmogorov-Smirnov statistic, KSa = $\sqrt{n}$ KS

For two-sample data, the "Kolmogorov-Smirnov Test" table also displays the following statistics:

- Pr > KSa, which is the asymptotic p-value for KSa and equals Pr > D
- D, which is the two-sample Kolmogorov-Smirnov statistic, $\max_j |F_1(x_j) - F_2(x_j)|$

If you specify the D option for two-sample data, PROC NPAR1WAY displays the following one-sided Kolmogorov-Smirnov statistics and their asymptotic p-values in the "Kolmogorov-Smirnov Two-Sample Test" table:

- D+, which is $\max_j (F_1(x_j) - F_2(x_j))$
- Pr > D+
- D-, which is $\max_j (F_2(x_j) - F_1(x_j))$
- Pr > D-

For two-sample data, if you request an exact Kolmogorov-Smirnov test by specifying the KS option in the EXACT statement, PROC NPAR1WAY displays the following exact p-values in the "Kolmogorov-Smirnov Two-Sample Test" table:

- Exact Pr $\geq$ D
- Exact Pr $\geq$ D+

- Exact Pr $\geq$ D-
- Exact Point Pr = D, Exact Point Pr = D+, and Exact Point Pr = D-, if you specify the POINT option in the EXACT statement

If you request Monte Carlo estimates for the two-sample exact Kolmogorov-Smirnov test, PROC NPAR1WAY displays the following information in the "Kolmogorov-Smirnov Two-Sample Test" table:

- Estimate of Exact Pr $\geq$ D, together with its Lower and Upper Confidence Limits
- Estimate of Exact Pr $\geq$ D+, together with its Lower and Upper Confidence Limits
- Estimate of Exact Pr $\geq$ D-, together with its Lower and Upper Confidence Limits
- Number of Samples used to compute the Monte Carlo estimates
- Initial Seed used to compute the Monte Carlo estimates

The "Cramer-von Mises Test" table includes the following information for each CLASS variable level:

- N, which is the number of observations
- Summed Deviation from Mean, which is $(n_i/n)\sum_{j=1}^{p} t_j \left(F_i(x_j) - F(x_j)\right)^2$

The "Cramer-von Mises Statistics" table displays the following statistics:

- CM, which is the Cramer-von Mises statistic
- CMa, which is the asymptotic Cramer-von Mises statistic, CMa = n CM

For two-sample data, PROC NPAR1WAY displays the "Kuiper Test" table, which includes the following information for each CLASS variable level:

- N, which is the number of observations
- Deviation from Mean, which is $\max_j |F_1(x_j) - F_2(x_j)|$

The "Kuiper Two-Sample Statistics" table displays the following statistics:

- K, which is the Kuiper two-sample test statistic
- Ka, which is the asymptotic Kuiper two-sample test statistic, Ka = K $\sqrt{n_1 n_2/n}$
- Pr > Ka

ODS Table Names

PROC NPAR1WAY assigns a name to each table that it creates. You can use these names to refer to tables when you use the Output Delivery System (ODS) to select tables and create output data sets. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 64.6 lists the ODS table names together with their descriptions and the options required to produce the tables. If you do not specify any analysis options in the PROC NPAR1WAY statement, the procedure provides the ANOVA, WILCOXON, MEDIAN, VW (NORMAL), SAVAGE, and EDF analyses by default.

Table 64.6 ODS Tables Produced by PROC NPAR1WAY

ODS Table Name	Description	Statement	Option
ANOVA	Analysis of variance	PROC	ANOVA
ABAnalysis	Ansari-Bradley one-way analysis	PROC	AB
ABMC	Monte Carlo estimates for the Ansari-Bradley exact test	EXACT	AB / MC

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, "Statistical Graphics Using ODS."

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section "Enabling and Disabling ODS Graphics" on page 612 in Chapter 21, "Statistical Graphics Using ODS."

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section "A Primer on ODS Statistical Graphics" on page 611 in Chapter 21, "Statistical Graphics Using ODS."

When ODS Graphics is enabled, you can request specific plots with the PLOTS= option in the PROC NPAR1WAY statement. If you do not specify the PLOTS= option but have enabled ODS Graphics, PROC NPAR1WAY produces all plots that are associated with the analyses that you request.

PROC NPAR1WAY assigns a name to each graph that it creates with ODS Graphics. You can use these names to refer to the graphs. Table 64.7 lists the names of the graphs that PROC NPAR1WAY generates together with their descriptions and the options that are required to produce the graphs.

Table 64.7 Graphs Produced by PROC NPAR1WAY

Examples: NPAR1WAY Procedure

Example 64.1: Two-Sample Location Tests and Plots

Fifty-nine female patients with rheumatoid arthritis who participated in a clinical trial were assigned to two groups, active and placebo. The response status (excellent=5, good=4, moderate=3, fair=2, poor=1) of each patient was recorded.

The following SAS statements create the data set Arthritis, which contains the observed status values for all the patients. The variable Treatment denotes the treatment received by a patient, and the variable Response contains the response status of the patient. The variable Freq contains the frequency of the observation, which is the number of patients with the Treatment and Response combination.

```
data Arthritis;
   input Treatment $ Response Freq @@;
   datalines;
Active 5 5 Active 4 11 Active 3 5 Active 2 1 Active 1 5
Placebo 5 2 Placebo 4 4 Placebo 3 7 Placebo 2 7 Placebo 1 12
;
```

The following PROC NPAR1WAY statements test the null hypothesis that there is no difference in the patient response status against the alternative hypothesis that the patient response status differs in the two treatment groups. The WILCOXON option requests the Wilcoxon test for difference in location, and the MEDIAN option requests the median test for difference in location. The variable Treatment is the CLASS variable, and the VAR statement specifies that the variable Response is the analysis variable.

The PLOTS= option requests a box plot of the Wilcoxon scores and a median plot for Response classified by Treatment. ODS Graphics must be enabled before producing plots.

```
ods graphics on;
proc npar1way data=Arthritis wilcoxon median
              plots=(wilcoxonboxplot medianplot);
   class Treatment;
   var Response;
   freq Freq;
run;
ods graphics off;
```

Output 64.1.1 shows the results of the Wilcoxon analysis. The Wilcoxon two-sample test statistic equals 999.0, which is the sum of the Wilcoxon scores for the smaller sample (Active). This sum is greater than 810.0, which is the expected value under the null hypothesis of no difference between the two samples, Active and Placebo. The one-sided p-value is 0.0016, which indicates that the patient response for the Active treatment is significantly more than for the Placebo group.

Output 64.1.1 Wilcoxon Two-Sample Test

The NPAR1WAY Procedure

Wilcoxon Scores (Rank Sums) for Variable Response
Classified by Variable Treatment

Treatment	N	Sum of Scores	Expected Under H0	Std Dev Under H0	Mean Score
Active	27	999.0	810.0	63.972744	37.000000
Placebo	32	771.0	960.0	63.972744	24.093750

Average scores were used for ties.

Wilcoxon Two-Sample Test

Statistic	999.0000
Normal Approximation	
Z	2.9466
One-Sided Pr > Z	0.0016
Two-Sided Pr > |Z|	0.0032
t Approximation	
One-Sided Pr > Z	0.0023
Two-Sided Pr > |Z|	0.0046

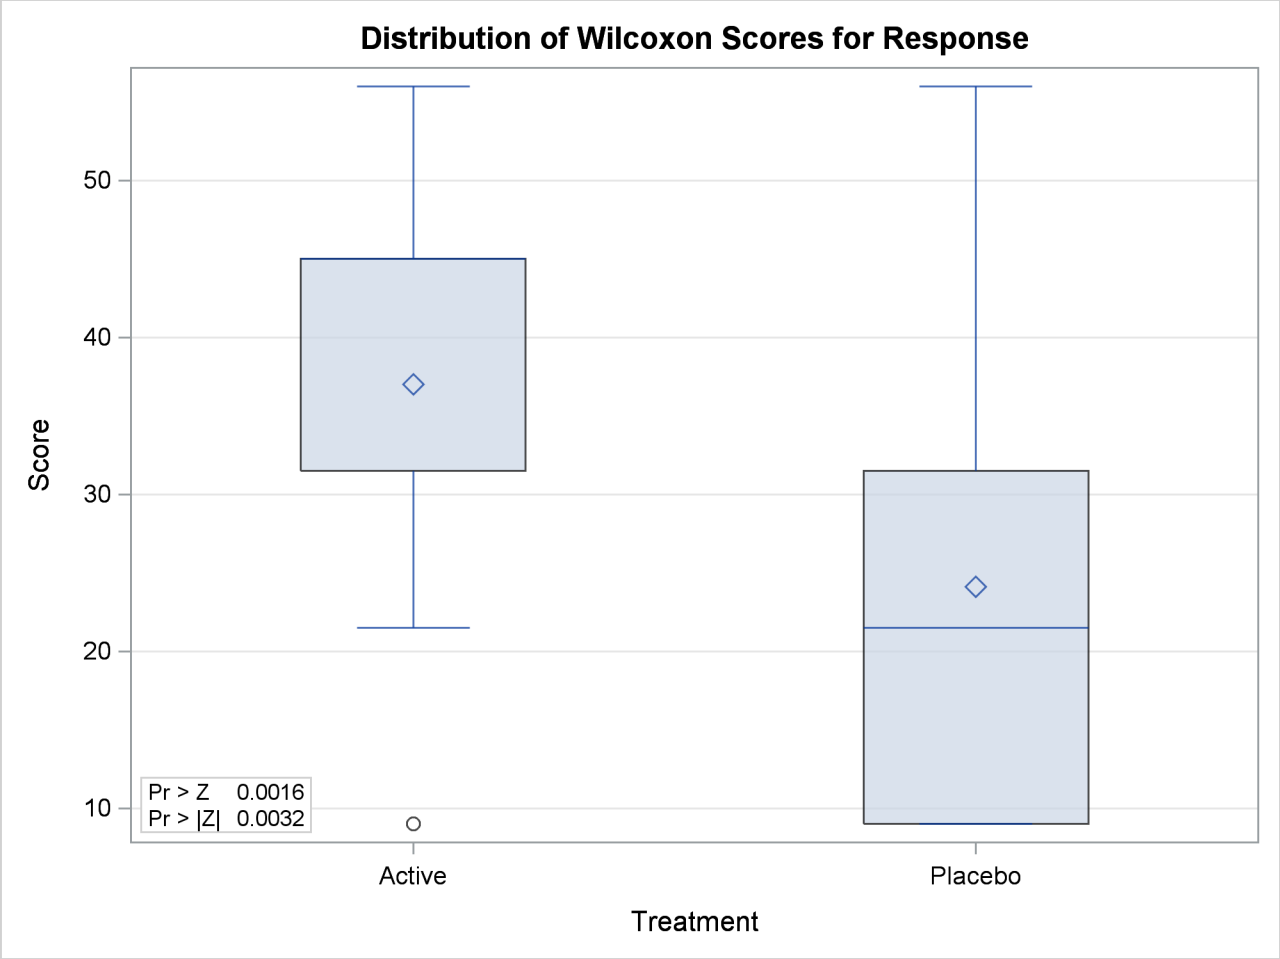
Z includes a continuity correction of 0.5.

Kruskal-Wallis Test

Chi-Square	8.7284
DF	1
Pr > Chi-Square	0.0031

Output 64.1.2 displays the box plot of Wilcoxon scores classified by Treatment, which corresponds to the Wilcoxon analysis in Output 64.1.1. To remove the *p*-values from the box plot display, you can specify the NOSTATS plot option in parentheses following the WILCOXONBOXPLOT option.

Output 64.1.2 Box Plot of Wilcoxon Scores



Output 64.1.3 shows the results of the median two-sample test. The test statistic equals 18.9167, and its standardized Z value is 3.1667. The one-sided p-value Pr > Z equals 0.0005. This supports the alternative hypothesis that the effect of the Active treatment is greater than that of the Placebo.

Output 64.1.4 displays the median plot for the analysis of Response classified by Treatment. The median plot is a stacked bar chart showing the frequencies above and below the overall median. This plot corresponds to the median scores analysis in Output 64.1.3.

Output 64.1.3 Median Two-Sample Test

Median Scores (Number of Points Above Median) for Variable Response
Classified by Variable Treatment

Treatment	N	Sum of Scores	Expected Under H0	Std Dev Under H0	Mean Score
Active	27	18.916667	13.271186	1.728195	0.700617
Placebo	32	10.083333	15.728814	1.728195	0.315104

Average scores were used for ties.

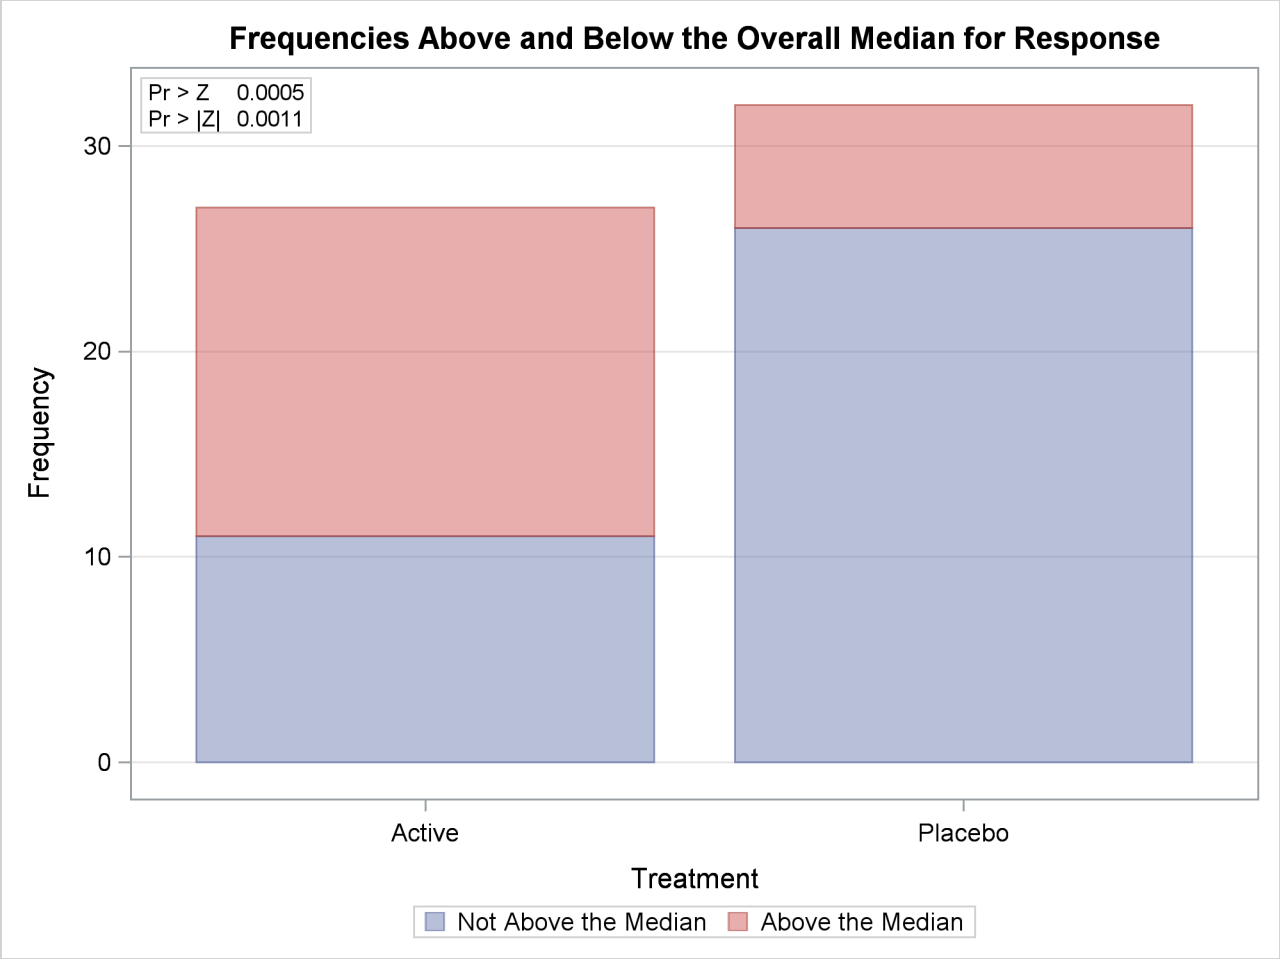
Median Two-Sample Test

Statistic	18.9167
Z	3.2667
One-Sided Pr > Z	0.0005
Two-Sided Pr > |Z|	0.0011

Median One-Way Analysis

Chi-Square	10.6713
DF	1
Pr > Chi-Square	0.0011

Output 64.1.4 Median Plot



Example 64.2: EDF Statistics and EDF Plot

This example uses the SAS data set Arthritis created in Example 64.1. The data set contains the variable Treatment, which denotes the treatment received by a patient, and the variable Response, which contains the response status of the patient. The variable Freq contains the frequency of the observation, which is the number of patients with the Treatment and Response combination.

The following statements request empirical distribution function (EDF) statistics, which test whether the distribution of a variable is the same across different groups. The EDF option requests the EDF analysis. The variable Treatment is the CLASS variable, and the variable Response specified in the VAR statement is the analysis variable. The FREQ statement names Freq as the frequency variable.

The PLOTS= option requests an EDF plot for Response classified by Treatment. ODS Graphics must be enabled before producing plots.

```
ods graphics on;
proc npar1way edf plots=edfplot data=Arthritis;
   class Treatment;
   var Response;
   freq Freq;
run;
ods graphics off;
```

Output 64.2.1 shows EDF statistics that compare the two levels of Treatment, Active and Placebo. The asymptotic p-value for the Kolmogorov-Smirnov test is 0.0164. This supports rejection of the null hypothesis that the distributions are the same for the two samples.

Output 64.2.2 shows the EDF plot for Response classified by Treatment.

Output 64.2.1 Empirical Distribution Function Statistics

The NPAR1WAY Procedure

Kolmogorov-Smirnov Test for Variable Response
Classified by Variable Treatment

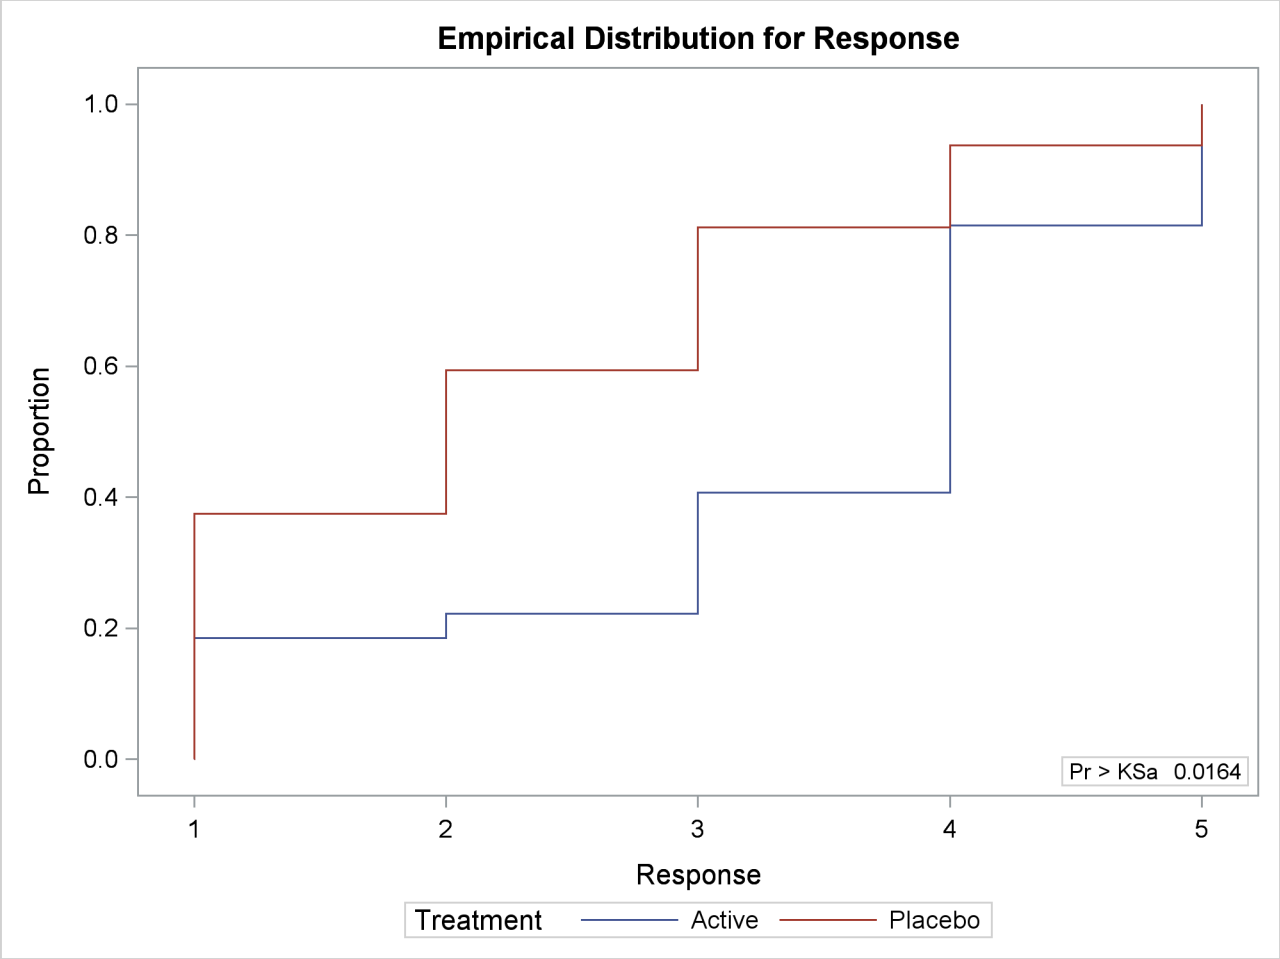
Treatment	N	EDF at Maximum	Deviation from Mean at Maximum
Active	27	0.407407	-1.141653
Placebo	32	0.812500	1.048675
Total	59	0.627119	

Maximum Deviation Occurred at Observation 3
Value of Response at Maximum = 3.0

Kolmogorov-Smirnov Two-Sample Test (Asymptotic)

KS	0.201818	D	0.405093
KSa	1.550191	Pr > KSa	0.0164

Output 64.2.2 Empirical Distribution Function Plot



Example 64.3: Exact Wilcoxon Two-Sample Test

Researchers conducted an experiment to compare the effects of two stimulants. Thirteen randomly selected subjects received the first stimulant, and six randomly selected subjects received the second stimulant. The reaction times (in minutes) were measured while the subjects were under the influence of the stimulants.

The following SAS statements create the data set React, which contains the observed reaction times for each stimulant. The variable Stim represents Stimulant 1 or 2. The variable Time contains the reaction times observed for subjects under the stimulant.

```
data React;
   input Stim Time @@;
   datalines;
1 1.94   1 1.94   1 2.92   1 2.92   1 2.92   1 2.92   1 3.27
1 3.27   1 3.27   1 3.27   1 3.70   1 3.70   1 3.74
2 3.27   2 3.27   2 3.27   2 3.70   2 3.70   2 3.74
;
```

The following statements request a Wilcoxon test of the null hypothesis that there is no difference between the effects of the two stimulants. Stim is the CLASS variable, and Time is the analysis variable. The

WILCOXON option requests an analysis of Wilcoxon scores. The CORRECT=NO option removes the continuity correction from the computation of the standardized z test statistic. The WILCOXON option in the EXACT statement requests exact p-values for the Wilcoxon test. Because the sample size is small, the large-sample normal approximation might not be adequate, and it is appropriate to compute the exact test. These statements produce the results shown in Output 64.3.1.

```
proc npar1way wilcoxon correct=no data=React;
   class Stim;
   var Time;
   exact wilcoxon;
run;
```

Output 64.3.1 displays the results of the Wilcoxon two-sample test. The Wilcoxon statistic equals 79.50. Since this value is greater than 60.0, the expected value under the null hypothesis, PROC NPAR1WAY displays the right-sided p-values. The normal approximation for the Wilcoxon two-sample test yields a one-sided p-value of 0.0421 and a two-sided p-value of 0.0843. For the exact Wilcoxon test, the one-sided p-value is 0.0527, and the two-sided p-value is 0.1054.

Output 64.3.1 Wilcoxon Two-Sample Test

The NPAR1WAY Procedure

Wilcoxon Scores (Rank Sums) for Variable Time
Classified by Variable Stim

Stim	N	Sum of Scores	Expected Under H0	Std Dev Under H0	Mean Score
1	13	110.50	130.0	11.004784	8.500
2	6	79.50	60.0	11.004784	13.250

Average scores were used for ties.

Two-Sided Pr >= |S - Mean|	0.1054

Kruskal-Wallis Test

Chi-Square	3.1398
DF	1
Pr > Chi-Square	0.0764

Example 64.4: Hodges-Lehmann Estimation

This example uses the SAS data set React created in Example 64.3. The data set contains the variable Stim, which represents Stimulant 1 or 2, and the variable Time, which contains the reaction times observed for subjects under the stimulant.

The following statements request Hodges-Lehmann estimation of the location shift between the two groups. Stim is the CLASS variable, and Time is the analysis variable. The HL option requests Hodges-Lehmann estimation. The ALPHA= option sets the confidence level for the Hodges-Lehmann confidence limits. The HL option in the EXACT statement requests exact confidence limits for the estimate of location shift. The ODS SELECT statement selects which tables to display. Output 64.4.1 shows the Hodges-Lehmann results.

```
proc npar1way hl alpha=.02 data=React;
   class Stim;
   var Time;
   exact hl;
   ods select WilcoxonScores HodgesLehmann;
run;
```

The HL option automatically invokes the WILCOXON option, producing a table of Wilcoxon scores (Output 64.4.1). The Hodges-Lehmann estimate of location shift is 0.35, and the asymptotic confidence limits are 0.00 and 0.82. The confidence interval midpoint equals 0.41, which can also be used as an estimate of the location shift. The ASE estimate of 0.1762 is based on the length of the confidence interval. The exact confidence limits are 0.00 and 1.33.

Output 64.4.1 Hodges-Lehmann Estimate of Location Shift

The NPAR1WAY Procedure

Wilcoxon Scores (Rank Sums) for Variable Time
Classified by Variable Stim

Stim	N	Sum of Scores	Expected Under H0	Std Dev Under H0	Mean Score
1	13	110.50	130.0	11.004784	8.500
2	6	79.50	60.0	11.004784	13.250

Average scores were used for ties.

Hodges-Lehmann Estimation

Location Shift 0.3500

Type	98% Confidence Limits		Interval Midpoint	Asymptotic Standard Error
Asymptotic (Moses)	0.0000	0.8200	0.4100	0.1762
Exact	0.0000	1.3300	0.6650	

Example 64.5: Exact Savage Multisample Test

A researcher conducting a laboratory experiment randomly assigned 15 mice to receive one of three drugs. The survival time (in days) was then recorded.

The following SAS statements create the data set Mice, which contains the observed survival times for the mice. The variable Treatment denotes the treatment received. The variable Days contains the number of days the mouse survived.

```
data Mice;
   input Treatment $ Days @@;
   datalines;
1 1 1 1 1 3 1 3 1 4
2 3 2 4 2 4 2 4 2 15
3 4 3 4 3 10 3 10 3 26
;
```

The following statements request a Savage test of the null hypothesis that there is no difference in survival time among the three drugs. Treatment is the CLASS variable, and Days is the analysis variable. The SAVAGE option requests an analysis of Savage scores. The SAVAGE option in the EXACT statement requests exact *p*-values for the Savage test. Because the sample size is small, the large-sample normal approximation might not be adequate, and it is appropriate to compute the exact test.

PROC NPAR1WAY tests the null hypothesis that there is no difference in the survival times among the three drugs against the alternative hypothesis of difference among the drugs. The SAVAGE option specifies an analysis based on Savage scores. The variable Treatment is the CLASS variable, and the variable Days is the response variable. The EXACT statement requests the exact Savage test.

```
proc npar1way savage data=Mice;
   class Treatment;
   var Days;
   exact savage;
run;
```

Output 64.5.1 shows the results of the Savage test. The exact *p*-value is 0.0445, which supports a difference in survival times among the drugs at the 0.05 level. The asymptotic *p*-value based on the chi-square approximation is 0.0638.

Output 64.5.1 Savage Multisample Exact Test

The NPAR1WAY Procedure

Savage Scores (Exponential) for Variable Days
Classified by Variable Treatment

Chapter 65

The ORTHOREG Procedure

Contents

Overview: ORTHOREG Procedure

The ORTHOREG procedure fits general linear models by the method of least squares. Other SAS/STAT software procedures, such as the GLM and REG procedures, fit the same types of models, but PROC ORTHOREG can produce more accurate estimates than other regression procedures when your data are ill-conditioned. Instead of collecting crossproducts, PROC ORTHOREG uses Gentleman-Givens transformations to update and compute the upper triangular matrix **R** of the QR decomposition of the data matrix, with special care for scaling (Gentleman 1972, 1973). This method has the advantage over other orthogonalization methods (for example, Householder transformations) of not requiring the data matrix to be stored in memory.

The standard SAS regression procedures (PROC REG and PROC GLM) are very accurate for most problems. However, if you have very ill-conditioned data, these procedures can produce estimates that yield an error sum of squares very close to the minimum but still different from the exact least squares estimates. Normally, this coincides with estimates that have very high standard errors. In other words, the numerical error is much smaller than the statistical standard error.

PROC ORTHOREG fits models by the method of linear least squares, minimizing the sum of the squared residuals for predicting the responses—that is, the distance between the regression line and the observed Ys. The "ORTHO" in the name of the procedure refers to the orthogonalization approach to solving the least squares equations. In particular, PROC ORTHOREG does *not* perform the modeling method known as "orthogonal regression," which minimizes a different criterion (namely, the distance between the regression line and the X/Y points taken together.)

Getting Started: ORTHOREG Procedure

Longley Data

The labor statistics data set of Longley (1967) is noted for being ill-conditioned. Both the ORTHOREG and GLM procedures are applied for comparison (only portions of the PROC GLM results are shown).

NOTE: The results from this example vary from machine to machine, depending on floating-point configuration.

The following statements read the data into the SAS data set Longley:

```

;
```

The data set contains one dependent variable, Employment (total derived employment), and six independent variables: Prices (GNP implicit price deflator normalized to the value 100 in 1954), GNP (gross national product), Jobless (unemployment), Military (size of armed forces), PopSize (noninstitutional population aged 14 and over), and Year (year).

The following statements use the ORTHOREG procedure to model the Longley data by using a quadratic model in each independent variable, without interaction:

```
proc orthoreg data=Longley;
   model Employment = Prices   Prices*Prices
                      GNP      GNP*GNP
                      Jobless  Jobless*Jobless
                      Military Military*Military
                      PopSize  PopSize*PopSize
                      Year     Year*Year;
run;
```

Figure 65.1 shows the resulting analysis.

Figure 65.1 PROC ORTHOREG Results

```

PopSize	1	-0.0303997234299	5.9272538242	-0.01	0.9962
PopSize**2	1	-1.212511414607E-6	0.0000237262	-0.05	0.9625
Year	1	-194907.139041839	157739.28757	-1.24	0.3045
Year**2	1	50.8067603538501	40.279878943	1.26	0.2963

The estimates in Figure 65.1 compare very well with the best estimates available; for additional information, see Longley (1967) and Beaton, Rubin, and Barone (1976).

The following statements request the same analysis from the GLM procedure:

```
proc glm data=Longley;
   model Employment = Prices   Prices*Prices
                      GNP      GNP*GNP
                      Jobless  Jobless*Jobless
                      Military Military*Military
                      PopSize  PopSize*PopSize
                      Year     Year*Year;
   ods select OverallANOVA
              FitStatistics
              ParameterEstimates
              Notes;
run;
```

Figure 65.2 contains the overall ANOVA table and the parameter estimates produced by PROC GLM. Notice that the PROC ORTHOREG fit achieves a somewhat smaller root mean square error (RMSE) and also that the GLM procedure detects spurious singularities.

Figure 65.2 Partial PROC GLM Results

PROC ORTHOREG used with Longley data

The GLM Procedure

Dependent Variable: Employment

Source	DF	Sum of Squares	Mean Square	F Value	Pr > F

Year	0.000 B	.	.	.
Year*Year	1.038	0.419	2.48	0.0683

NOTE: The X'X matrix has been found to be singular, and a generalized inverse was used to solve the normal equations. Terms whose estimates are followed by the letter 'B' are not uniquely estimable.

Syntax: ORTHOREG Procedure

The following statements are available in PROC ORTHOREG:

PROC ORTHOREG < *options* > **;**
CLASS *variables* < */ option* > **;**
MODEL *dependent-variable=independent-effects* < */ option* > **;**
BY *variables* **;**
EFFECT *name = effect-type (variables* < */ options* > *)* **;**
EFFECTPLOT < *plot-type* < *(plot-definition-options)* > >< */ options* > **;**
ESTIMATE < *'label'* > *estimate-specification* < */ options* > **;**
LSMEANS < *model-effects* > < */ options* > **;**
LSMESTIMATE *model-effect lsmestimate-specification* < */ options* > **;**
SLICE *model-effect* < */ options* > **;**
STORE < **OUT=** >*item-store-name* < / **LABEL=***'label'* > **;**
TEST < *model-effects* > < */ options* > **;**
WEIGHT *variable* **;**

The BY, CLASS, MODEL, and WEIGHT statements are described in full after the PROC ORTHOREG statement in alphabetical order. The EFFECT, EFFECTPLOT, ESTIMATE, LSMEANS, LSMESTIMATE, SLICE, STORE, and TEST statements are common to many procedures. Summary descriptions of functionality and syntax for these statements are also given after the PROC ORTHOREG statement in alphabetical order, and full documentation about them is available in Chapter 19, "Shared Concepts and Topics."

PROC ORTHOREG Statement

PROC ORTHOREG < *options* > **;**

The PROC ORTHOREG statement has the following options:

DATA=*SAS-data-set*
specifies the input SAS data set to use. By default, the procedure uses the most recently created SAS data set. The data set specified cannot be a TYPE=CORR, TYPE=COV, or TYPE=SSCP data set.

NOPRINT
suppresses the normal display of results. This option temporarily disables the Output Delivery System (ODS); see Chapter 20, "Using the Output Delivery System" for more information.

ORDER=DATA | FORMATTED | FREQ | INTERNAL
specifies the order in which to sort the levels of the classification variables (which are specified in the CLASS statement). This ordering determines which parameters in the model correspond to each level in the data, so the ORDER= option may be useful when you use ESTIMATE statement. This option applies to the levels for all classification variables, except when you use the (default) ORDER=FORMATTED option with numeric classification variables that have no explicit format. With this option, the levels of such variables are ordered by their internal value.

The ORDER= option can take the following values:

Value of ORDER=	Levels Sorted By
DATA	Order of appearance in the input data set
FORMATTED	External formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ	Descending frequency count; levels with the most observations come first in the order
INTERNAL	Unformatted value

By default, ORDER=FORMATTED. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine-dependent.

For more information about sorting order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

OUTEST=*SAS-data-set*
produces an output data set that contains the parameter estimates, the BY variables, and the special variables _TYPE_ (value "`PARMS`"), _NAME_ (blank), and _RMSE_ (root mean squared error).

SINGULAR=*s*
specifies a singularity criterion ($s \geq 0$) for the inversion of the triangular matrix $\mathbf{R}$. By default, SINGULAR=10E−12.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC ORTHOREG to obtain separate analyses on observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the ORTHOREG procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variables* < / **TRUNCATE** > **;**

The CLASS statement names the classification variables to be used in the model. Typical classification variables are Treatment, Sex, Race, Group, and Replication. If you use the CLASS statement, it must appear before the MODEL statement.

Classification variables can be either character or numeric. By default, class levels are determined from the entire set of formatted values of the CLASS variables.

NOTE: Prior to SAS 9, class levels were determined by using no more than the first 16 characters of the formatted values. To revert to this previous behavior, you can use the TRUNCATE option in the CLASS statement.

In any case, you can use formats to group values into levels. See the discussion of the FORMAT procedure in the *Base SAS Procedures Guide* and the discussions of the FORMAT statement and SAS formats in *SAS Formats and Informats: Reference*. You can adjust the order of CLASS variable levels with the ORDER= option in the PROC ORTHOREG statement. You can specify the following option in the CLASS statement after a slash (/):

TRUNCATE
specifies that class levels should be determined by using only up to the first 16 characters of the formatted values of CLASS variables. When formatted values are longer than 16 characters, you can use this option to revert to the levels as determined in releases prior to SAS 9.

EFFECT Statement

EFFECT *name = effect-type (variables* < */ options* > *)* **;**

The EFFECT statement enables you to construct special collections of columns for design matrices. These collections are referred to as *constructed effects* to distinguish them from the usual model effects formed from continuous or classification variables, as discussed in the section "GLM Parameterization of Classification Variables and Effects" on page 397 of Chapter 19, "Shared Concepts and Topics."

The following *effect-types* are available:

COLLECTION
is a collection effect that defines one or more variables as a single effect with multiple degrees of freedom. The variables in a collection are considered as a unit for estimation and inference.

LAG — is a classification effect in which the level that is used for a given period corresponds to the level in the preceding period.

Note: The LAG *effect-type* is experimental in this release.

MULTIMEMBER | MM — is a multimember classification effect whose levels are determined by one or more variables that appear in a CLASS statement.

POLYNOMIAL | POLY — is a multivariate polynomial effect in the specified numeric variables.

SPLINE — is a regression spline effect whose columns are univariate spline expansions of one or more variables. A spline expansion replaces the original variable with an expanded or larger set of new variables.

Table 65.1 summarizes important options for each type of EFFECT statement.

Table 65.1 Important EFFECT Statement Options

Option	Description
Options for Collection Effects	
DETAILS	Displays the constituents of the collection effect
Options for Lag Effects	
DESIGNROLE=	Names a variable that controls to which lag design an observation is assigned
DETAILS	Displays the lag design of the lag effect
NLAG=	Specifies the number of periods in the lag
PERIOD=	Names the variable that defines the period
WITHIN=	Names the variable or variables that define the group within which each period is defined
Options for Multimember Effects	
NOEFFECT	Specifies that observations with all missing levels for the multimember variables should have zero values in the corresponding design matrix columns
WEIGHT=	Specifies the weight variable for the contributions of each of the classification effects
Options for Polynomial Effects	
DEGREE=	Specifies the degree of the polynomial
MDEGREE=	Specifies the maximum degree of any variable in a term of the polynomial
STANDARDIZE=	Specifies centering and scaling suboptions for the variables that define the polynomial

Table 65.1 *continued*

Option	Description
Options for Spline Effects	
BASIS=	Specifies the type of basis (B-spline basis or truncated power function basis) for the spline expansion
DEGREE=	Specifies the degree of the spline transformation
KNOTMETHOD=	Specifies how to construct the knots for spline effects

For further details about the syntax of these *effect-types* and how columns of constructed effects are computed, see the section "EFFECT Statement" on page 406 of Chapter 19, "Shared Concepts and Topics."

EFFECTPLOT Statement

EFFECTPLOT < *plot-type* < *(plot-definition-options)* > > < / *options* > **;**

The EFFECTPLOT statement produces a display of the fitted model and provides options for changing and enhancing the displays. Table 65.2 describes the available *plot-types* and their *plot-definition-options*.

Table 65.2 *Plot-Types* and *Plot-Definition-Options*

Plot-Type and Description	Plot-Definition-Options
BOX Displays a box plot of continuous response data at each level of a CLASS effect, with predicted values superimposed and connected by a line. This is an alternative to the INTERACTION *plot-type*.	PLOTBY= variable or CLASS effect X= CLASS variable or effect
CONTOUR Displays a contour plot of predicted values against two continuous covariates.	PLOTBY= variable or CLASS effect X= continuous variable Y= continuous variable
FIT Displays a curve of predicted values versus a continuous variable.	PLOTBY= variable or CLASS effect X= continuous variable
INTERACTION Displays a plot of predicted values (possibly with error bars) versus the levels of a CLASS effect. The predicted values are connected with lines and can be grouped by the levels of another CLASS effect.	PLOTBY= variable or CLASS effect SLICEBY= variable or CLASS effect X= CLASS variable or effect
SLICEFIT Displays a curve of predicted values versus a continuous variable grouped by the levels of a CLASS effect.	PLOTBY= variable or CLASS effect SLICEBY= variable or CLASS effect X= continuous variable

For full details about the syntax and options of the EFFECTPLOT statement, see the section "EFFECTPLOT Statement" on page 425 of Chapter 19, "Shared Concepts and Topics."

ESTIMATE Statement

ESTIMATE < *'label'* > *estimate-specification* < **(***divisor***=***n***)** >
< **,** . . . < *'label'* > *estimate-specification* < **(***divisor***=***n***)** > >
< **/** *options* > **;**

The ESTIMATE statement provides a mechanism for obtaining custom hypothesis tests. Estimates are formed as linear estimable functions of the form $\mathbf{L}\boldsymbol{\beta}$. You can perform hypothesis tests for the estimable functions, construct confidence limits, and obtain specific nonlinear transformations.

Table 65.3 summarizes important *options* in the ESTIMATE statement.

Table 65.3 Important ESTIMATE Statement Options

Option	Description
Construction and Computation of Estimable Functions	
DIVISOR=	Specifies a list of values to divide the coefficients
NOFILL	Suppresses the automatic fill-in of coefficients for higher-order effects
SINGULAR=	Tunes the estimability checking difference
Degrees of Freedom and *p*-values	
ADJUST=	Determines the method for multiple comparison adjustment of estimates
ALPHA=α	Determines the confidence level $(1-\alpha)$
LOWER	Performs one-sided, lower-tailed inference
STEPDOWN	Adjusts multiplicity-corrected p-values further in a step-down fashion
TESTVALUE=	Specifies values under the null hypothesis for tests
UPPER	Performs one-sided, upper-tailed inference
Statistical Output	
CL	Constructs confidence limits
CORR	Displays the correlation matrix of estimates
COV	Displays the covariance matrix of estimates
E	Prints the $\mathbf{L}$ matrix
JOINT	Produces a joint F or chi-square test for the estimable functions
SEED=	Specifies the seed for computations that depend on random numbers

For details about the syntax of the ESTIMATE statement, see the section "ESTIMATE Statement" on page 451 of Chapter 19, "Shared Concepts and Topics."

LSMEANS Statement

LSMEANS < *model-effects* > < / *options* > **;**

The LSMEANS statement computes and compares least squares means (LS-means) of fixed effects. LS-means are *predicted population margins*—that is, they estimate the marginal means over a balanced population. In a sense, LS-means are to unbalanced designs as class and subclass arithmetic means are to balanced designs.

Table 65.4 summarizes important options in the LSMEANS statement.

Table 65.4 Important LSMEANS Statement Options

Option	Description
Construction and Computation of LS-Means	
AT	Modifies the covariate value in computing LS-means
BYLEVEL	Computes separate margins
DIFF	Requests differences of LS-means
OM=	Specifies the weighting scheme for LS-means computation as determined by the input data set
SINGULAR=	Tunes estimability checking
Degrees of Freedom and *p*-values	
ADJUST=	Determines the method for multiple comparison adjustment of LS-means differences
ALPHA=α	Determines the confidence level ($1 - \alpha$)
STEPDOWN	Adjusts multiple comparison *p*-values further in a step-down fashion
Statistical Output	
CL	Constructs confidence limits for means and mean differences
CORR	Displays the correlation matrix of LS-means
COV	Displays the covariance matrix of LS-means
E	Prints the **L** matrix
LINES	Produces a "Lines" display for pairwise LS-means differences
MEANS	Prints the LS-means
PLOTS=	Requests ODS statistical graphics of means and mean comparisons
SEED=	Specifies the seed for computations that depend on random numbers

For details about the syntax of the LSMEANS statement, see the section "LSMEANS Statement" on page 467 of Chapter 19, "Shared Concepts and Topics."

LSMESTIMATE Statement

LSMESTIMATE *model-effect* < *'label'* > *values* < *divisor*=*n* >
< , . . . < *'label'* > *values* < *divisor*=*n* > >
< / *options* > ;

The LSMESTIMATE statement provides a mechanism for obtaining custom hypothesis tests among least squares means.

Table 65.5 summarizes important options in the LSMESTIMATE statement.

Table 65.5 Important LSMESTIMATE Statement Options

Option	Description
Construction and Computation of LS-Means	
AT	Modifies covariate values in computing LS-means
BYLEVEL	Computes separate margins
DIVISOR=	Specifies a list of values to divide the coefficients
OM=	Specifies the weighting scheme for LS-means computation as determined by a data set
SINGULAR=	Tunes estimability checking
Degrees of Freedom and *p*-values	
ADJUST=	Determines the method for multiple comparison adjustment of LS-means differences
ALPHA=α	Determines the confidence level $(1-\alpha)$
LOWER	Performs one-sided, lower-tailed inference
STEPDOWN	Adjusts multiple comparison p-values further in a step-down fashion
TESTVALUE=	Specifies values under the null hypothesis for tests
UPPER	Performs one-sided, upper-tailed inference
Statistical Output	
CL	Constructs confidence limits for means and mean differences
CORR	Displays the correlation matrix of LS-means
COV	Displays the covariance matrix of LS-means
E	Prints the **L** matrix
ELSM	Prints the **K** matrix
JOINT	Produces a joint F or chi-square test for the LS-means and LS-means differences
SEED=	Specifies the seed for computations that depend on random numbers

For details about the syntax of the LSMESTIMATE statement, see the section "LSMESTIMATE Statement" on page 483 of Chapter 19, "Shared Concepts and Topics."

MODEL Statement

MODEL *dependent-variable=independent-effects* < / *option* > **;**

The MODEL statement names the dependent variable and the independent effects. Only one MODEL statement is allowed. The specification of effects and the parameterization of the linear model are the same as in the GLM procedure; see Chapter 41, "The GLM Procedure" for further details.

The following option can be used in the MODEL statement:

NOINT

omits the intercept term from the model. Often, this omission also changes the total sum of squares in the ANOVA and the value of R square to forms of these statistics that are not corrected for the mean. However, if the model is determined to contain an implicit intercept, in the sense that the all-ones intercept vector is in the column space of the design, then the usual mean-corrected forms of these statistics are used.

SLICE Statement

SLICE *model-effect* < / *options* > **;**

The SLICE statement provides a general mechanism for performing a partitioned analysis of the LS-means for an interaction. This analysis is also known as an analysis of simple effects.

The SLICE statement uses the same options as the LSMEANS statement, which are summarized in Table 19.19. For details about the syntax of the SLICE statement, see the section "SLICE Statement" on page 513 of Chapter 19, "Shared Concepts and Topics."

STORE Statement

STORE < **OUT=** >*item-store-name* < / **LABEL=***'label'* > **;**

The STORE statement requests that the procedure save the context and results of the statistical analysis. The resulting item store is a binary file format that cannot be modified. The contents of the item store can be processed with the PLM procedure.

For details about the syntax of the STORE statement, see the section "STORE Statement" on page 516 of Chapter 19, "Shared Concepts and Topics."

TEST Statement

TEST < *model-effects* > < / *options* > **;**

The TEST statement enables you to perform *F* tests for model effects that test Type I, II, or Type III hypotheses. See Chapter 15, "The Four Types of Estimable Functions," for details about the construction of Type I, II, and III estimable functions.

Table 65.6 summarizes options in the TEST statement.

Table 65.6 TEST Statement Options

Option	Description
CHISQ	Requests chi-square tests
DDF=	Specifies denominator degrees of freedom for fixed effects
E	Requests Type I, Type II, and Type III coefficients
E1	Requests Type I coefficients
E2	Requests Type II coefficients
E3	Requests Type III coefficients
HTYPE=	Indicates the type of hypothesis test to perform
INTERCEPT	Adds a row that corresponds to the overall intercept

For details about the syntax of the TEST statement, see the section "TEST Statement" on page 517 of Chapter 19, "Shared Concepts and Topics."

WEIGHT Statement

WEIGHT *variable* **;**

A WEIGHT statement names a variable in the input data set whose values are relative weights for a weighted least squares regression. If the weight value is proportional to the reciprocal of the variance for each observation, the weighted estimates are the best linear unbiased estimates (BLUE). For a more complete description of the WEIGHT statement, see the section "WEIGHT Statement" on page 3208 in the GLM procedure.

Details: ORTHOREG Procedure

Missing Values

If there is a missing value for any model variable in an observation, the entire observation is dropped from the analysis.

Output Data Set

The OUTEST= option produces a TYPE=EST output SAS data set that contains the BY variables, parameter estimates, and four special variables. For each new value of the BY variables, PROC ORTHOREG outputs an observation to the OUTEST= data set. The variables in the data set are as follows:

- parameter estimates for all variables listed in the MODEL statement
- BY variables
- _TYPE_, which is a character variable with the value PARMS for every observation
- _NAME_, which is a character variable left blank for every observation
- _RMSE_, which is the root mean square error (the estimate of the standard deviation of the true errors)
- Intercept, which is the estimated intercept. This variable does not exist in the OUTEST= data set if the NOINT option is specified.

Displayed Output

PROC ORTHOREG displays the parameter estimates and associated statistics. These include the following:

- overall model analysis of variance, including the error mean square, which is an estimate of σ^2 (the variance of the true errors), and the overall F test for a model effect.
- root mean square error, which is an estimate of the standard deviation of the true errors. It is calculated as the square root of the mean squared error.
- R square (R^2) measures how much variation in the dependent variable can be accounted for by the model. R square, which can range from 0 to 1, is the ratio of the sum of squares for the model to the corrected total sum of squares. In general, the larger the value of R square, the better the model's fit.
- estimates for the parameters in the linear model

The table of parameter estimates consists of the following:

- the terms used as regressors, including the intercept.
- degrees of freedom (DF) for the variable. There is one degree of freedom for each parameter being estimated unless the model is not full rank.
- estimated linear coefficients.
- estimates of the standard errors of the parameter estimates.
- the critical t values for testing whether the parameters are zero. This is computed as the parameter estimate divided by its standard error.
- the two-sided p-value for the t test, which is the probability that a t statistic would obtain a greater absolute value than that observed given that the true parameter is zero.

ODS Table Names

PROC ORTHOREG assigns a name to each table it creates. You can use these names to reference the table when you use the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 65.7. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Each of the EFFECT, ESTIMATE, LSMEANS, LSMESTIMATE, and SLICE statements also creates tables, which are not listed in Table 65.7. For information about these tables, see the corresponding sections of Chapter 19, "Shared Concepts and Topics."

Table 65.7 ODS Tables Produced by PROC ORTHOREG

ODS Table Name	Description	Statement
ANOVA	Analysis of variance	Default
FitStatistics	Overall statistics for fit	Default
Levels	Table of class levels	CLASS statement
ParameterEstimates	Parameter estimates	Default

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, "Statistical Graphics Using ODS."

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section "Enabling and Disabling ODS Graphics" on page 612 in Chapter 21, "Statistical Graphics Using ODS."

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section "A Primer on ODS Statistical Graphics" on page 611 in Chapter 21, "Statistical Graphics Using ODS."

When ODS Graphics is enabled, then each of the EFFECT, ESTIMATE, LSMEANS, LSMESTIMATE, and SLICE statements can produce plots associated with their analyses. For information about these plots, see the corresponding sections of Chapter 19, "Shared Concepts and Topics."

Examples: ORTHOREG Procedure

Example 65.1: Precise Analysis of Variance

The data for the following example are from Powell, Murphy, and Gramlich (1982). In order to calibrate an instrument for measuring atomic weight, 24 replicate measurements of the atomic weight of silver (chemical symbol Ag) are made with the new instrument and with a reference instrument.

NOTE: The results from this example vary from machine to machine, depending on floating-point configuration.

The following statements read the measurements for the two instruments into the SAS data set AgWeight:

```
title 'Atomic Weight of Silver by Two Different Instruments';

;
```

Notice that the variation in the atomic weight measurements is several orders of magnitude less than their mean. This is a situation that can be difficult for standard, regression-based analysis-of-variance procedures to handle correctly.

The following statements invoke the ORTHOREG procedure to perform a simple one-way analysis of variance, testing for differences between the two instruments:

```
proc orthoreg data=AgWeight;
   class Instrument;
   model AgWeight = Instrument;
run;
```

Output 65.1.1 shows the resulting analysis.

Output 65.1.1 PROC ORTHOREG Results for Atomic Weight Example

Atomic Weight of Silver by Two Different Instruments

The ORTHOREG Procedure

Class Level Information

Factor	Levels	-Values-
Instrument	2	1 2

Atomic Weight of Silver by Two Different Instruments

The ORTHOREG Procedure

Dependent Variable: AgWeight

Source	DF	Sum of Squares	Mean Square	F Value	Pr > F
Model	1	3.6383419E-9	3.6383419E-9	15.95	0.0002
Error	46	1.0495173E-8	2.281559E-10		
Corrected Total	47	1.4133515E-8			

Root MSE	0.0000151048
R-Square	0.2574265445

Parameter	DF	Parameter Estimate	Standard Error	t Value	Pr > |t|
Intercept	1	107.868136354166	3.0832608E-6	3.499E7	<.0001
(Instrument='1')	1	0.00001741249999	4.3603893E-6	3.99	0.0002
(Instrument='2')	0	0	.	.	.

The mean difference between instruments is about 1.74×10^{-5} (the value of the **(Instrument='1')** parameter in the parameter estimates table), whereas the level of background variation in the measurements is about 1.51×10^{-5} (the value of the root mean square error). At this level of error, the difference is significant, with a p-value of 0.0002.

The National Institute of Standards and Technology (1998) has provided certified ANOVA values for this data set. The following statements use ODS to examine the ANOVA values produced by both the ORTHOREG and GLM procedures more precisely for comparison with the NIST-certified values:

```
ods listing close;
ods output ANOVA         = OrthoregANOVA
           FitStatistics = OrthoregFitStat;

proc orthoreg data=AgWeight;
   class Instrument;
   model AgWeight = Instrument;
run;

ods output OverallANOVA  = GLMANOVA
           FitStatistics = GLMFitStat;
proc glm data=AgWeight;
   class Instrument;
   model AgWeight = Instrument;
run;
ods listing;

data _null_; set OrthoregANOVA  (in=inANOVA)
                 OrthoregFitStat(in=inFitStat);
   if (inANOVA) then do;
      if (Source = 'Model') then put "Model SS: " ss e20.;
      if (Source = 'Error') then put "Error SS: " ss e20.;
   end;
   if (inFitStat) then do;
      if (Statistic = 'Root MSE') then
                           put "Root MSE: " nValue1 e20.;
      if (Statistic = 'R-Square') then
                         put "R-Square: " nValue1 best20.;
   end;
data _null_; set GLMANOVA  (in=inANOVA)
                 GLMFitStat(in=inFitStat);
   if (inANOVA) then do;
      if (Source = 'Model') then put "Model SS: " ss e20.;
      if (Source = 'Error') then put "Error SS: " ss e20.;
   end;
   if (inFitStat) then      put "Root MSE: " RootMSE e20.;
   if (inFitStat) then   put "R-Square: " RSquare best20.;
run;
```

In SAS/STAT software prior to SAS 8, PROC GLM gave much less accurate results than PROC ORTHOREG. Table 65.8 and Table 65.9 compare the ANOVA values certified by NIST with those produced by the two procedures.

Table 65.8 Accuracy Comparison for Sums of Squares

Values	Model SS	Error SS
NIST-certified	3.6383418750000E−09	1.0495172916667E−08
ORTHOREG	3.6383418747907E−09	1.0495172916797E−08
GLM, since SAS 8	3.6383418747907E−09	1.0495172916797E−08
GLM, before SAS 8	0	1.0331496763990E−08

Table 65.9 Accuracy Comparison for Fit Statistics

Values	Root MSE	R Square
NIST-certified	1.5104831444641E−05	0.25742654453832
ORTHOREG	1.5104831444735E−05	0.25742654452494
GLM, since SAS 8	1.5104831444735E−05	0.25742654452494
GLM, before SAS 8	1.4986585859992E−05	0

Although the PROC ORTHOREG values and the PROC GLM values for the current version are quite close to the certified ones, the PROC GLM values for releases prior to SAS 8 are not. In fact, since the model sum of squares is so small, in prior releases the GLM procedure set it (and consequently R square) to zero.

Example 65.2: Wampler Data

This example applies the ORTHOREG procedure to a collection of data sets noted for being ill-conditioned. The OUTEST= data set is used to collect the results for comparison with values certified to be correct by the National Institute of Standards and Technology (1998).

NOTE: The results from this example vary from machine to machine, depending on floating-point configuration.

The data are from Wampler (1970). The independent variates for all five data sets are x^i, $i = 1, \ldots 5$, for $x = 0, 1, \ldots, 20$. Two of the five dependent variables are exact linear functions of the independent terms:

$$\begin{aligned} y_1 &= 1 + x + x^2 + x^3 + x^4 + x^5 \\ y_2 &= 1 + 0.1x + 0.01x^2 + 0.001x^3 + 0.0001x^4 + 0.00001x^5 \end{aligned}$$

The other three dependent variables have the same mean value as y_1, but with nonzero errors:

$$\begin{aligned} y_3 &= y_1 + \mathbf{e} \\ y_4 &= y_1 + 100\mathbf{e} \\ y_5 &= y_1 + 10000\mathbf{e} \end{aligned}$$

where $\mathbf{e}$ is a vector of values with standard deviation $\sim$2044, chosen to be orthogonal to the mean model for y_1.

The following statements create a SAS data set Wampler that contains the Wampler data, run a SAS macro program that uses PROC ORTHOREG to fit a fifth-order polynomial in x to each of the Wampler dependent variables, and collect the results in a data set named ParmEst:

```
data Wampler;
   do x=0 to 20;
      input e @@;
      y1 = 1 +       x    +        x**2 +      x**3
             +       x**4 +        x**5;
      y2 = 1 + .1   *x    + .01   *x**2 + .001*x**3
             + .0001*x**4 + .00001*x**5;
      y3 = y1 +       e;
      y4 = y1 +   100*e;
      y5 = y1 + 10000*e;
      output;
   end;
   datalines;
759 -2048 2048 -2048 2523 -2048 2048 -2048 1838 -2048 2048
-2048 1838 -2048 2048 -2048 2523 -2048 2048 -2048 759
;

%macro WTest;
   data ParmEst; if (0); run;
   %do i = 1 %to 5;
      proc orthoreg data=Wampler outest=ParmEst&i noprint;
         model y&i = x x*x x*x*x x*x*x*x x*x*x*x*x;
      data ParmEst&i; set ParmEst&i; Dep = "y&i";
      data ParmEst; set ParmEst ParmEst&i;
         label Col1='x'     Col2='x**2'  Col3='x**3'
               Col4='x**4'  Col5='x**5';
      run;
   %end;
%mend;
%WTest;
```

Instead of displaying the raw values of the RMSE and parameter estimates, use an additional DATA step as follows to compute the deviations from the values certified to be correct by the National Institute of Standards and Technology (1998):

```
data ParmEst; set ParmEst;
   if      (Dep = 'y1') then
      _RMSE_ = _RMSE_ - 0.00000000000000;
   else if (Dep = 'y2') then
      _RMSE_ = _RMSE_ - 0.00000000000000;
   else if (Dep = 'y3') then
      _RMSE_ = _RMSE_ - 2360.14502379268;
   else if (Dep = 'y4') then
      _RMSE_ = _RMSE_ - 236014.502379268;
   else if (Dep = 'y5') then
      _RMSE_ = _RMSE_ - 23601450.2379268;
   if (Dep ^= 'y2') then do;
      Intercept = Intercept - 1.00000000000000;
      Col1      = Col1      - 1.00000000000000;
      Col2      = Col2      - 1.00000000000000;
      Col3      = Col3      - 1.00000000000000;
      Col4      = Col4      - 1.00000000000000;
      Col5      = Col5      - 1.00000000000000;
```

```
   end;
   else do;
      Intercept = Intercept - 1.00000000000000;
      Col1      = Col1      - 0.100000000000000;
      Col2      = Col2      - 0.100000000000000e-1;
      Col3      = Col3      - 0.100000000000000e-2;
      Col4      = Col4      - 0.100000000000000e-3;
      Col5      = Col5      - 0.100000000000000e-4;
   end;
run;

proc print data=ParmEst label noobs;
   title 'Wampler data: Deviations from Certified Values';
   format _RMSE_ Intercept Col1-Col5 e9.;
   var Dep _RMSE_ Intercept Col1-Col5;
run;
```

The results, shown in Output 65.2.1, indicate that the values computed by PROC ORTHOREG are quite close to the NIST-certified values.

Output 65.2.1 Wampler Data: Deviations from Certified Values

Wampler data: Deviations from Certified Values

Dep	_RMSE_	Intercept	x	x**2	x**3	x**4	x**5
y1	0.00E+00	5.46E-12	-9.82E-11	1.55E-11	-5.68E-13	3.55E-14	-6.66E-16
y2	0.00E+00	8.88E-16	-3.19E-15	1.24E-15	-1.88E-16	1.20E-17	-2.57E-19
y3	-2.09E-11	-7.73E-11	1.46E-11	-2.09E-11	2.50E-12	-1.28E-13	2.66E-15
y4	-4.07E-10	-5.38E-10	8.99E-10	-3.29E-10	4.23E-11	-2.27E-12	4.35E-14
y5	-3.35E-08	-4.10E-08	8.07E-08	-2.77E-08	3.54E-09	-1.90E-10	3.64E-12

Example 65.3: Fitting Polynomials

The extra accuracy of the regression algorithm used by PROC ORTHOREG is most useful when the model contains near-singularities that you want to be able to distinguish from true singularities. This example demonstrates this usefulness in the context of fitting polynomials of high degree.

NOTE: The results from this example vary from machine to machine, depending on floating-point configuration.

The following DATA step computes a response y as an exact ninth-degree polynomial function of a predictor x evaluated at 0, 0.01, 0.02, . . . , 1.

```
title 'Polynomial Data';
data Polynomial;
   do i = 1 to 101;
      x = (i-1)/(101-1);
      y = 10**(9/2);
      do j = 0 to 8;
         y = y * (x - j/8);
```

```
      end;
      output;
   end;
run;
```

The polynomial is constructed in such a way that its zeros lie at $x = i/8$ for $i = 0, \ldots, 8$. The following statements use the EFFECT statement to fit a ninth-degree polynomial to this data with PROC ORTHOREG. The EFFECT statement makes it easy to specify complicated polynomial models.

```
ods graphics on;

proc orthoreg data=Polynomial;
   effect xMod = polynomial(x / degree=9);
   model y = xMod;
   effectplot fit / obs;
   store OStore;
run;

ods graphics off;
```

The effect xMod defined by the EFFECT statement refers to all nine degrees of freedom in the ninth-degree polynomial (excluding the intercept term). The resulting output is shown in Output 65.3.1. Note that the R square for the fit is 1, indicating that the ninth-degree polynomial has been correctly fit.

Output 65.3.1 PROC ORTHOREG Results for Ninth-Degree Polynomial

Polynomial Data

The ORTHOREG Procedure

Dependent Variable: y

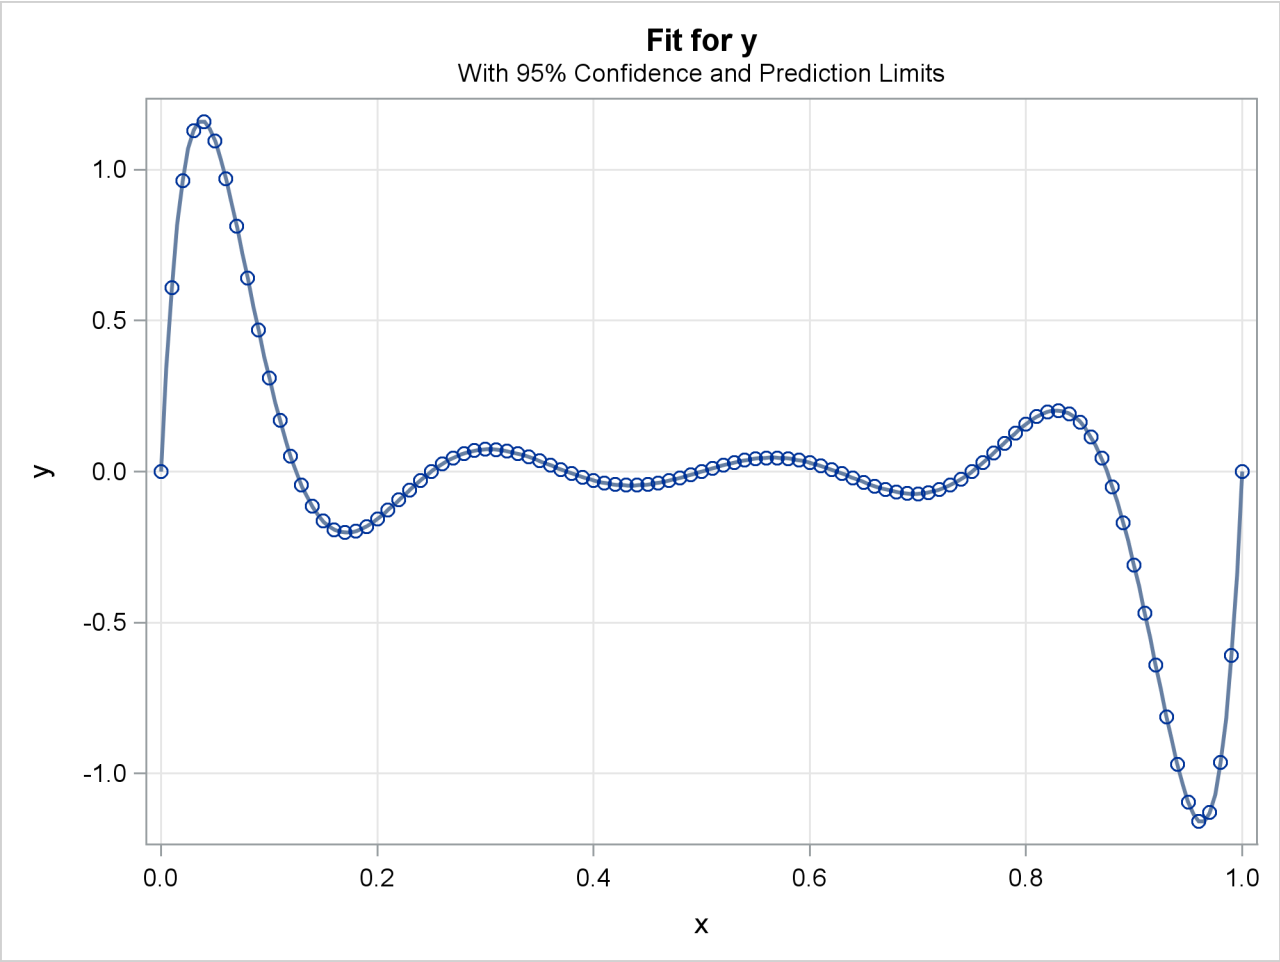
Source	DF	Sum of Squares	Mean Square	F Value	Pr > F
Model	9	15.527180055	1.7252422284	1.65E22	<.0001
Error	91	9.496616E-21	1.043584E-22		
Corrected Total	100	15.527180055			

Root MSE	1.02156E-11
R-Square	1

Parameter	DF	Parameter Estimate	Standard Error	t Value	Pr > |t|
Intercept	1	-3.24572035915E-11	8.114115E-12	-4.00	0.0001
x	1	75.9977312440678	4.898326E-10	1.55E11	<.0001
x^2	1	-1652.40781362191	9.5027919E-9	-174E9	<.0001
x^3	1	14249.4539769783	8.3110512E-8	1.71E11	<.0001
x^4	1	-64932.461575205	3.8997072E-7	-167E9	<.0001
x^5	1	173315.359360779	1.066611E-6	1.62E11	<.0001
x^6	1	-280158.03646002	1.7523078E-6	-16E10	<.0001
x^7	1	269781.812887653	1.7021134E-6	1.58E11	<.0001
x^8	1	-142302.494710055	9.0027891E-7	-158E9	<.0001
x^9	1	31622.7766022468	1.997493E-7	1.58E11	<.0001

The fit plot produced by the EFFECTPLOT statement, Output 65.3.2, also demonstrates the perfect fit.

Output 65.3.2 PROC ORTHOREG Fit Plot for Ninth-Degree Polynomial



Finally, you can use the PLM procedure with the fit model saved by the STORE statement in the item store OStore to check the predicted values for the known zeros of the polynomial, as shown in the following statements:

```
data Zeros(keep=x);
   do j = 0 to 8;
      x = j/8;
      output;
   end;
run;

proc plm restore=OStore noprint;
   score data=Zeros out=OZeros pred=OPred;
run;

proc print noobs;
run;
```

The predicted values of the zeros, shown in Output 65.3.3, are again all miniscule.

Output 65.3.3 Predicted Zeros for Ninth-Degree Polynomial

Polynomial Data

x	OPred
0.000	-3.2457E-11
0.125	-2.1262E-11
0.250	-9.5867E-12
0.375	-2.2895E-11
0.500	-5.2154E-11
0.625	-1.2329E-10
0.750	-2.5329E-10
0.875	-3.9836E-10
1.000	-5.9663E-10

To compare these results with those from a least squares fit produced by an alternative algorithm, consider fitting a polynomial to this data using the GLM procedure. PROC GLM does not have an EFFECT statement, but the familiar bar notation can still be used to specify a ninth-degree polynomial fairly succinctly, as shown in the following statements:

```
proc glm data=Polynomial;
   model y = x|x|x|x|x|x|x|x|x;
   store GStore;
run;
```

Partial results are shown in Output 65.3.4. In this case, the R square for the fit is only about 0.83, indicating that the full ninth-degree polynomial was not correctly fit.

Output 65.3.4 PROC GLM for Ninth-Degree Polynomial

Polynomial Data

The GLM Procedure

Dependent Variable: y

Source	DF	Sum of Squares	Mean Square	F Value	Pr > F
Model	8	12.91166643	1.61395830	56.77	<.0001

Chapter 66

The PHREG Procedure

Contents

Overview: PHREG Procedure

The analysis of survival data requires special techniques because the data are almost always incomplete and familiar parametric assumptions might be unjustifiable. Investigators follow subjects until they reach a prespecified endpoint (for example, death). However, subjects sometimes withdraw from a study, or the study is completed before the endpoint is reached. In these cases, the survival times (also known as failure times) are *censored*; subjects survived to a certain time beyond which their status is unknown. The uncensored survival times are sometimes referred to as *event* times. Methods of survival analysis must account for both censored and uncensored data.

Many types of models have been used for survival data. Two of the more popular types of models are the accelerated failure time model (Kalbfleisch and Prentice 1980) and the Cox proportional hazards model (Cox 1972). Each has its own assumptions about the underlying distribution of the survival times. Two closely related functions often used to describe the distribution of survival times are the survivor function and the hazard function. See the section "Failure Time Distribution" on page 5430 for definitions. The accelerated

failure time model assumes a parametric form for the effects of the explanatory variables and usually assumes a parametric form for the underlying survivor function. The Cox proportional hazards model also assumes a parametric form for the effects of the explanatory variables, but it allows an unspecified form for the underlying survivor function.

The PHREG procedure performs regression analysis of survival data based on the Cox proportional hazards model. Cox's semiparametric model is widely used in the analysis of survival data to explain the effect of explanatory variables on hazard rates.

The survival time of each member of a population is assumed to follow its own hazard function, $\lambda_i(t)$, expressed as

$$\lambda_i(t) = \lambda(t; \mathbf{Z}_i) = \lambda_0(t) \exp(\mathbf{Z}_i' \boldsymbol{\beta})$$

where $\lambda_0(t)$ is an arbitrary and unspecified baseline hazard function, $\mathbf{Z}_i$ is the vector of explanatory variables for the ith individual, and $\boldsymbol{\beta}$ is the vector of unknown regression parameters that is associated with the explanatory variables. The vector $\boldsymbol{\beta}$ is assumed to be the same for all individuals. The survivor function can be expressed as

$$S(t; \mathbf{Z}_i) = [S_0(t)]^{\exp(\mathbf{Z}_i' \boldsymbol{\beta})}$$

where $S_0(t) = \exp(-\int_0^t \lambda_0(u)du)$ is the baseline survivor function. To estimate $\boldsymbol{\beta}$, Cox (1972, 1975) introduced the partial likelihood function, which eliminates the unknown baseline hazard $\lambda_0(t)$ and accounts for censored survival times.

The partial likelihood of Cox also allows time-dependent explanatory variables. An explanatory variable is time-dependent if its value for any given individual can change over time. Time-dependent variables have many useful applications in survival analysis. You can use a time-dependent variable to model the effect of subjects changing treatment groups. Or you can include time-dependent variables such as blood pressure or blood chemistry measures that vary with time during the course of a study. You can also use time-dependent variables to test the validity of the proportional hazards model.

An alternative way to fit models with time-dependent explanatory variables is to use the counting process style of input. The counting process formulation enables PROC PHREG to fit a superset of the Cox model, known as the multiplicative hazards model. This extension also includes recurrent events data and left-truncation of failure times. The theory of these models is based on the counting process pioneered by Andersen and Gill (1982), and the model is often referred to as the Andersen-Gill model.

Multivariate failure-time data arise when each study subject can potentially experience several events (for example, multiple infections after surgery) or when there exists some natural or artificial clustering of subjects (for example, a litter of mice) that induces dependence among the failure times of the same cluster. Data in the former situation are referred to as multiple events data, which include recurrent events data as a special case; data in the latter situation are referred to as clustered data. You can use PROC PHREG to carry out various methods of analyzing these data.

The population under study can consist of a number of subpopulations, each of which has its own baseline hazard function. PROC PHREG performs a stratified analysis to adjust for such subpopulation differences. Under the stratified model, the hazard function for the *j*th individual in the *i*th stratum is expressed as

$$\lambda_{ij}(t) = \lambda_{i0}(t) \exp(\mathbf{Z}_{ij}' \boldsymbol{\beta})$$

where $\lambda_{i0}(t)$ is the baseline hazard function for the ith stratum and $\mathbf{Z}_{ij}$ is the vector of explanatory variables for the individual. The regression coefficients are assumed to be the same for all individuals across all strata.

Ties in the failure times can arise when the time scale is genuinely discrete or when survival times that are generated from the continuous-time model are grouped into coarser units. The PHREG procedure includes four methods of handling ties. The *discrete* logistic model is available for discrete time-scale data. The other three methods apply to continuous time-scale data. The *exact* method computes the exact conditional probability under the model that the set of observed tied event times occurs before all the censored times with the same value or before larger values. *Breslow* and *Efron* methods provide approximations to the exact method.

Variable selection is a typical exploratory exercise in multiple regression when the investigator is interested in identifying important prognostic factors from a large number of candidate variables. The PHREG procedure provides four selection methods: forward selection, backward elimination, stepwise selection, and best subset selection. The best subset selection method is based on the likelihood score statistic. This method identifies a specified number of best models that contain one, two, or three variables and so on, up to the single model that contains all of the explanatory variables.

The PHREG procedure also enables you to do the following: include an offset variable in the model; weight the observations in the input data; test linear hypotheses about the regression parameters; perform conditional logistic regression analysis for matched case-control studies; output survivor function estimates, residuals, and regression diagnostics; and estimate and plot the survivor function for a new set of covariates.

PROC PHREG can also be used to fit the multinomial logit choice model to discrete choice data. See `http://support.sas.com/resources/papers/tnote/tnote_marketresearch.html` for more information about discrete choice modeling and the multinomial logit model. Look for the "Discrete Choice" report.

The PHREG procedure uses ODS Graphics to create graphs as part of its output. For example, the ASSESS statement uses a graphical method that uses ODS Graphics to check the adequacy of the model. See Chapter 21, "Statistical Graphics Using ODS," for general information about ODS Graphics.

For both the BASELINE and OUTPUT statements, the default method of estimating a survivor function has changed to the Breslow (1972) estimator—that is, METHOD=CH. The option NOMEAN that was available in the BASELINE statement prior to SAS/STAT 9.2 has become obsolete—that is, requested statistics at the sample average values of the covariates are no longer computed and added to the OUT= data set. However, if the COVARIATES= data set is not specified, the requested statistics are computed and output for the covariate set that consists of the reference levels for the CLASS variables and sample averages for the continuous variable. In addition to the requested statistics, the OUT= data set also contains all variables in the COVARIATES= data set.

The remaining sections of this chapter contain information about how to use PROC PHREG, information about the underlying statistical methodology, and some sample applications of the procedure. The section "Getting Started: PHREG Procedure" on page 5369 introduces PROC PHREG with two examples. The section "Syntax: PHREG Procedure" on page 5378 describes the syntax of the procedure. The section "Details: PHREG Procedure" on page 5430 summarizes the statistical techniques used in PROC PHREG. The section "Examples: PHREG Procedure" on page 5497 includes eight additional examples of useful applications. Experienced SAS/STAT software users might decide to proceed to the "Syntax" section, while other users might choose to read both the "Getting Started" and "Examples" sections before proceeding to "Syntax" and "Details."

Getting Started: PHREG Procedure

This section uses the two-sample vaginal cancer mortality data from Kalbfleisch and Prentice (1980, p. 2) in two examples to illustrate some of the basic features of PROC PHREG. The first example carries out a classical Cox regression analysis and the second example performs a Bayesian analysis of the Cox model.

Two groups of rats received different pretreatment regimes and then were exposed to a carcinogen. Investigators recorded the survival times of the rats from exposure to mortality from vaginal cancer. Four rats died of other causes, so their survival times are censored. Interest lies in whether the survival curves differ between the two groups.

The following DATA step creates the data set Rats, which contains the variable Days (the survival time in days), the variable Status (the censoring indicator variable: 0 if censored and 1 if not censored), and the variable Group (the pretreatment group indicator).

```
data Rats;
   label Days  ='Days from Exposure to Death';
   input Days Status Group @@;
   datalines;
143 1 0   164 1 0   188 1 0   188 1 0
190 1 0   192 1 0   206 1 0   209 1 0
213 1 0   216 1 0   220 1 0   227 1 0
230 1 0   234 1 0   246 1 0   265 1 0
304 1 0   216 0 0   244 0 0   142 1 1
156 1 1   163 1 1   198 1 1   205 1 1
232 1 1   232 1 1   233 1 1   233 1 1
233 1 1   233 1 1   239 1 1   240 1 1
261 1 1   280 1 1   280 1 1   296 1 1
296 1 1   323 1 1   204 0 1   344 0 1
;
```

By using ODS Graphics, PROC PHREG allows you to plot the survival curve for Group=0 and the survival curve for Group=1, but first you must save these two covariate values in a SAS data set as in the following DATA step:

```
data Regimes;
  Group=0;
  output;
  Group=1;
  output;
run;
```

Classical Method of Maximum Likelihood

PROC PHREG fits the Cox model by maximizing the partial likelihood and computes the baseline survivor function by using the Breslow (1972) estimate. The following statements produce Figure 66.1 and Figure 66.2:

```
ods graphics on;
proc phreg data=Rats plot(overlay)=survival;
   model Days*Status(0)=Group;
   baseline covariates=regimes out=_null_;
run;
ods graphics off;
```

In the MODEL statement, the response variable, Days, is crossed with the censoring variable, Status, with the value that indicates censoring is enclosed in parentheses. The values of Days are considered censored if the value of Status is 0; otherwise, they are considered event times.

Graphs are produced when ODS Graphics is enabled. The survival curves for the two observations in the data set Regime, specified in the COVARIATES= option in the BASELINE statement, are requested through the PLOTS= option with the OVERLAY option for overlaying both survival curves in the same plot.

Figure 66.2 shows a typical printed output of a classical analysis. Since Group takes only two values, the null hypothesis for no difference between the two groups is identical to the null hypothesis that the regression coefficient for Group is 0. All three tests in the "Testing Global Null Hypothesis: BETA=0" table (see the section "Testing the Global Null Hypothesis" on page 5448) suggest that the survival curves for the two pretreatment groups might not be the same. In this model, the hazard ratio (or risk ratio) for Group, defined as the exponentiation of the regression coefficient for Group, is the ratio of the hazard functions between the two groups. The estimate is 0.551, implying that the hazard function for Group=1 is smaller than that for Group=0. In other words, rats in Group=1 lived longer than those in Group=0. This conclusion is also revealed in the plot of the survivor functions in Figure 66.2.

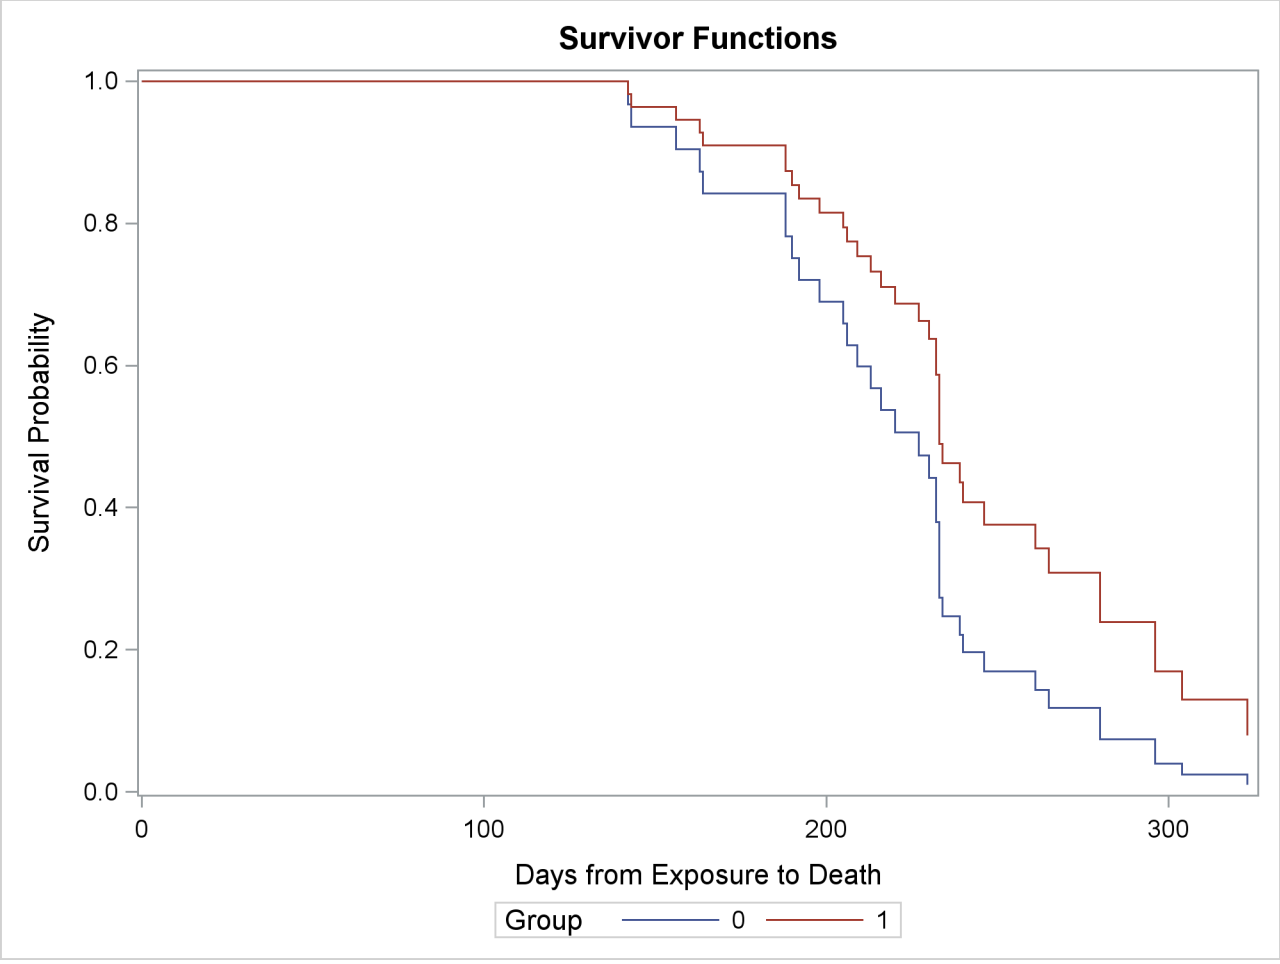
Figure 66.2 Survivorship for the Two Pretreatment Regimes



In this example, the comparison of two survival curves is put in the form of a proportional hazards model. This approach is essentially the same as the log-rank (Mantel-Haenszel) test. In fact, if there are no ties in the survival times, the likelihood score test in the Cox regression analysis is identical to the log-rank test. The advantage of the Cox regression approach is the ability to adjust for the other variables by including them in the model. For example, the present model could be expanded by including a variable that contains the initial body weights of the rats.

Next, consider a simple test of the validity of the proportional hazards assumption. The proportional hazards model for comparing the two pretreatment groups is given by the following:

$$\lambda(t) = \begin{cases} \lambda_0(t) & \text{if GROUP} = 0 \\ \lambda_0(t)e^{\beta_1} & \text{if GROUP} = 1 \end{cases}$$

The ratio of hazards is e^{β_1}, which does not depend on time. If the hazard ratio changes with time, the proportional hazards model assumption is invalid. Simple forms of departure from the proportional hazards model can be investigated with the following time-dependent explanatory variable $x = x(t)$:

$$x(t) = \begin{cases} 0 & \text{if GROUP} = 0 \\ \log(t) - 5.4 & \text{if GROUP} = 1 \end{cases}$$

Here, $\log(t)$ is used instead of t to avoid numerical instability in the computation. The constant, 5.4, is the average of the logs of the survival times and is included to improve interpretability. The hazard ratio in the two groups then becomes $e^{\beta_1 - 5.4\beta_2} t^{\beta_2}$, where β_2 is the regression parameter for the time-dependent variable x. The term e^{β_1} represents the hazard ratio at the geometric mean of the survival times. A nonzero value of β_2 would imply an increasing ($\beta_2 > 0$) or decreasing ($\beta_2 < 0$) trend in the hazard ratio with time.

The following statements implement this simple test of the proportional hazards assumption. The MODEL statement includes the time-dependent explanatory variable X, which is defined subsequently by the programming statement. At each event time, subjects in the risk set (those alive just before the event time) have their X values changed accordingly.

```
proc phreg data=Rats;
   model Days*Status(0)=Group X;
   X=Group*(log(Days) - 5.4);
run;
```

The analysis of the parameter estimates is displayed in Figure 66.3. The Wald chi-square statistic for testing the null hypothesis that $\beta_2 = 0$ is 0.0158. The statistic is not statistically significant when compared to a chi-square distribution with one degree of freedom ($p = 0.8999$). Thus, you can conclude that there is no evidence of an increasing or decreasing trend over time in the hazard ratio.

Figure 66.3 A Simple Test of Trend in the Hazard Ratio

The PHREG Procedure

Analysis of Maximum Likelihood Estimates

Parameter	DF	Parameter Estimate	Standard Error	Chi-Square	Pr > ChiSq	Hazard Ratio
Group	1	-0.59976	0.34837	2.9639	0.0851	0.549
X	1	-0.22952	1.82489	0.0158	0.8999	0.795

Bayesian Analysis

PROC PHREG uses the partial likelihood of the Cox model as the likelihood and generates a chain of posterior distribution samples by the Gibbs Sampler. Summary statistics, convergence diagnostics, and diagnostic plots are provided for each parameter. The following statements generate Figure 66.4–Figure 66.10:

```
ods graphics on;
proc phreg data=Rats;
   model Days*Status(0)=Group;
   bayes seed=1 outpost=Post;
run;
ods graphics off;
```

The BAYES statement invokes the Bayesian analysis. The SEED= option is specified to maintain reproducibility; the OUTPOST= option saves the posterior distribution samples in a SAS data set for postprocessiong; no other options are specified in the BAYES statement. By default, a uniform prior distribution is assumed on the regression coefficient Group. The uniform prior is a flat prior on the real line with a distribution that reflects ignorance of the location of the parameter, placing equal probability on all possible values the regression coefficient can take. Using the uniform prior in the following example, you would expect the Bayesian estimates to resemble the classical results of maximizing the likelihood. If you can elicit an informative prior on the regression coefficients, you should use the COEFFPRIOR= option to specify it.

You should make sure that the posterior distribution samples have achieved convergence before using them for Bayesian inference. PROC PHREG produces three convergence diagnostics by default. If ODS Graphics is enabled before calling PROC PHREG as in the preceding program, diagnostics plots are also displayed.

The results of this analysis are shown in the following figures.

The "Model Information" table in Figure 66.4 summarizes information about the model you fit and the size of the simulation.

Figure 66.4 Model Information

The PHREG Procedure

Bayesian Analysis

Model Information

Data Set	WORK.RATS	
Dependent Variable	Days	Days from Exposure to Death
Censoring Variable	Status	
Censoring Value(s)	0	
Model	Cox	
Ties Handling	BRESLOW	
Sampling Algorithm	ARMS	
Burn-In Size	2000	
MC Sample Size	10000	
Thinning	1	

PROC PHREG first fits the Cox model by maximizing the partial likelihood. The only parameter in the model is the regression coefficient of Group. The maximum likelihood estimate (MLE) of the parameter and its 95% confidence interval are shown in Figure 66.5.

Figure 66.5 Classical Parameter Estimates

Maximum Likelihood Estimates

Parameter	DF	Estimate	Standard Error	95% Confidence Limits	
Group	1	−0.5959	0.3484	−1.2788	0.0870

Since no prior is specified for the regression coefficient, the default uniform prior is used. This information is displayed in the "Uniform Prior for Regression Coefficients" table in Figure 66.6.

Figure 66.6 Coefficient Prior

Uniform Prior for Regression Coefficients

Parameter	Prior
Group	Constant

The "Fit Statistics" table in Figure 66.7 lists information about the fitted model. The table displays the DIC (deviance information criterion) and pD (effective number of parameters). See the section "Fit Statistics" on page 5480 for details.

Figure 66.7 Fit Statistics

Fit Statistics

DIC (smaller is better)	203.444
pD (Effective Number of Parameters)	1.003

Summary statistics of the posterior samples are displayed in the "Posterior Summaries" table and "Posterior Intervals" table as shown in Figure 66.8. Note that the mean and standard deviation of the posterior samples are comparable to the MLE and its standard error, respectively, due to the use of the uniform prior.

Figure 66.8 Summary Statistics

The PHREG Procedure

Bayesian Analysis

Posterior Summaries

Parameter	N	Mean	Standard Deviation	Percentiles 25%	50%	75%
Group	10000	-0.5998	0.3511	-0.8326	-0.5957	-0.3670

Posterior Intervals

Parameter	Alpha	Equal-Tail Interval		HPD Interval	
Group	0.050	-1.3042	0.0721	-1.2984	0.0756

PROC PHREG provides diagnostics to assess the convergence of the generated Markov chain. Figure 66.9 shows three of these diagnostics: the lag1, lag5, lag10, and lag50 autocorrelations; the Geweke diagnostic; and the effective sample size. There is no indication that the Markov chain has not reached convergence. Refer to the section "Statistical Diagnostic Tests" on page 149 for information about interpreting these diagnostics.

Figure 66.9 Convergence Diagnostics

The PHREG Procedure

Bayesian Analysis

Posterior Autocorrelations

Parameter	Lag 1	Lag 5	Lag 10	Lag 50
Group	-0.0079	0.0091	-0.0161	0.0101

Figure 66.9 *continued*

Geweke Diagnostics

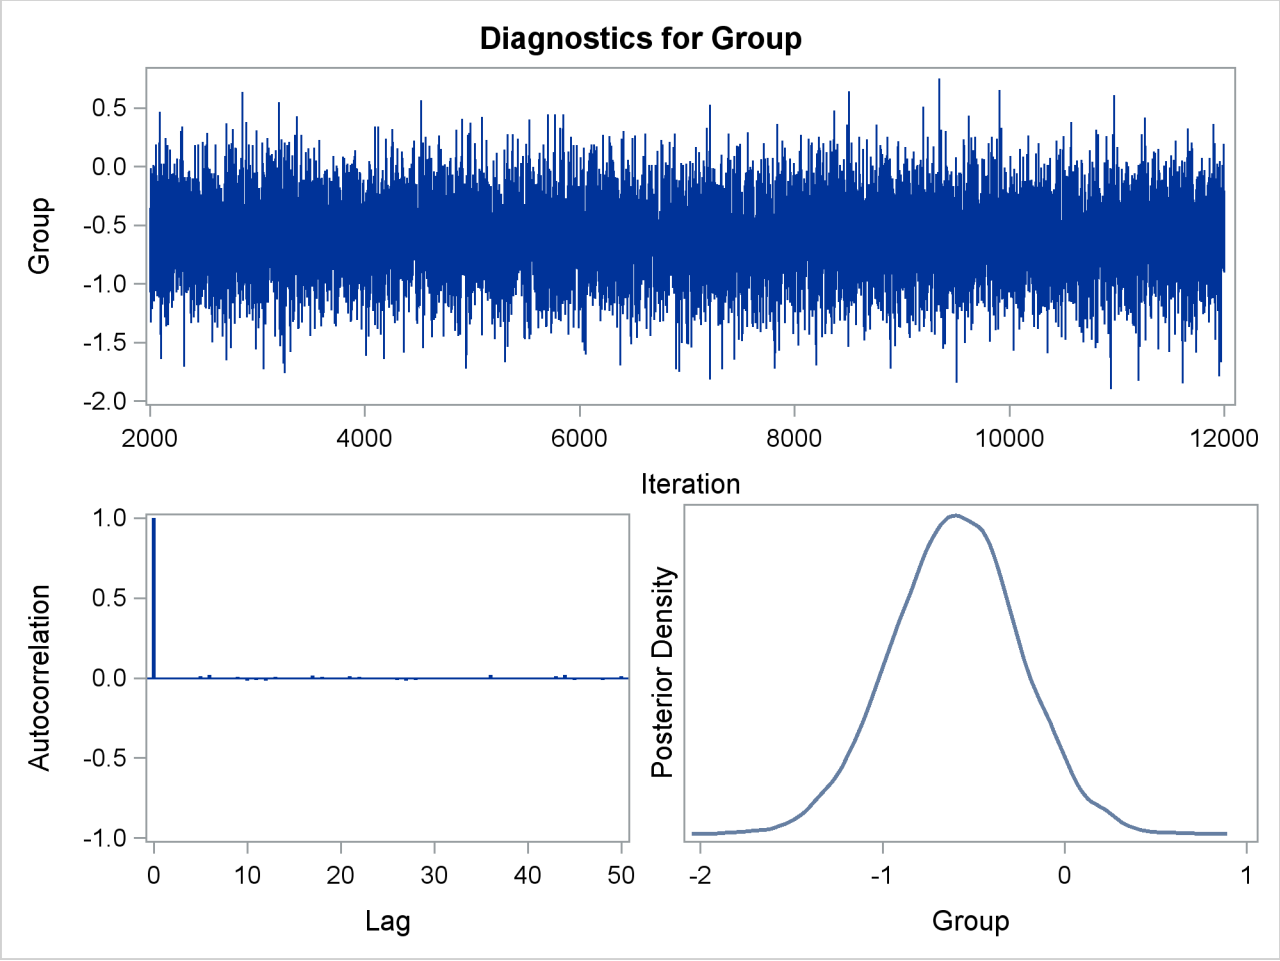
Parameter	z	Pr > |z|
Group	0.0149	0.9881

Effective Sample Sizes

Parameter	ESS	Autocorrelation Time	Efficiency
Group	10000.0	1.0000	1.0000

You can also assess the convergence of the generated Markov chain by examining the trace plot, the autocorrelation function plot, and the posterior density plot. Figure 66.10 displays a panel of these three plots for the parameter Group. This graphical display is automatically produced when ODS Graphics is enabled. Note that the trace of the samples centers on –0.6 with only small fluctuations, the autocorrelations are quite small, and the posterior density appears bell-shaped—all exemplifying the behavior of a converged Markov chain.

Figure 66.10 Diagnostic Plots



The proportional hazards model for comparing the two pretreatment groups is

$$\lambda(t) = \begin{cases} \lambda_0(t) & \text{if Group=0} \\ \lambda_0(t)e^{\beta} & \text{if Group=1} \end{cases}$$

The probability that the hazard of Group=0 is greater than that of Group=1 is

$$\Pr(\lambda_0(t) > \lambda_0(t)e^{\beta}) = \Pr(\beta < 0)$$

This probability can be enumerated from the posterior distribution samples by computing the fraction of samples with a coefficient less than 0. The following DATA step and PROC MEANS perform this calculation:

```
data New;
   set Post;
   Indicator=(Group < 0);
   label Indicator='Group < 0';
   run;
proc means data=New(keep=Indicator) n mean;
   run;
```

Figure 66.11 Prob(Hazard(Group=0) > Hazard(Group=1))

```
                          The MEANS Procedure

                Analysis Variable : Indicator Group < 0

                     N            Mean
                ----------------------
                10000       0.9581000
                ----------------------
```

The PROC MEANS results are displayed in Figure 66.11. There is a 95.8% chance that the hazard rate of Group=0 is greater than that of Group=1. The result is consistent with the fact that the average survival time of Group=0 is less than that of Group=1.

Syntax: PHREG Procedure

The following statements are available in PROC PHREG. Items within < > are optional.

PROC PHREG < *options* > ;

The PROC PHREG and MODEL statements are required. The CLASS statement, if present, must precede the MODEL statement, and the ASSESS or CONTRAST statement, if present, must come after the MODEL statement. The BAYES statement, that invokes a Bayesian analysis, is not compatible with the ASSESS, CONTRAST, ID, OUTPUT, and TEST statements, as well as a number of options in the PROC PHREG and MODEL statements. See the section "Specifics for Bayesian Analysis" on page 5471 for details.

The rest of this section provides detailed syntax information for each statement, beginning with the PROC PHREG statement. The remaining statements are covered in alphabetical order.

PROC PHREG Statement

PROC PHREG < *options* > **;**

You can specify the following *options* in the PROC PHREG statement.

ALPHA=*number*

specifies the level of significance α for $100(1-\alpha)\%$ confidence intervals. The value *number* must be between 0 and 1; the default value is 0.05, which results in 95% intervals. This value is used as the default confidence level for limits computed by the BASELINE, BAYES, CONTRAST, HAZARDRATIO, and MODEL statements. You can override this default by specifying the ALPHA= option in the separate statements.

ATRISK

displays a table that contains the number of units at risk at each event time and the corresponding number of events in the risk sets. For example, the following risk set information is displayed if the ATRISK option is specified in the example in the section "Getting Started: PHREG Procedure" on page 5369.

Risk Set Information		
	Number of Units	
Days	At Risk	Event
142	40	1
143	39	1
156	38	1
⋮	⋮	⋮
296	5	2
304	3	1
323	2	1

COVOUT

adds the estimated covariance matrix of the parameter estimates to the OUTEST= data set. The COVOUT option has no effect unless the OUTEST= option is specified.

COVM

requests that the model-based covariance matrix (which is the inverse of the observed information matrix) be used in the analysis if the COVS option is also specified. The COVM option has no effect if the COVS option is not specified.

COVSANDWICH < (AGGREGATE) >

COVS < (AGGREGATE) >

requests the robust sandwich estimate of Lin and Wei (1989) for the covariance matrix. When this option is specified, this robust sandwich estimate is used in the Wald tests for testing the global null hypothesis, null hypotheses of individual parameters, and the hypotheses in the CONTRAST and TEST statements. In addition, a modified score test is computed in the testing of the global null hypothesis, and the parameter estimates table has an additional StdErrRatio column, which contains the ratios of

the robust estimate of the standard error relative to the corresponding model-based estimate. Optionally, you can specify the keyword AGGREGATE enclosed in parentheses after the COVSANDWICH (or COVS) option, which requests a summing up of the score residuals for each distinct ID pattern in the computation of the robust sandwich covariance estimate. This AGGREGATE option has no effect if the ID statement is not specified.

DATA=*SAS-data-set*

names the SAS data set containing the data to be analyzed. If you omit the DATA= option, the procedure uses the most recently created SAS data set.

INEST=*SAS-data-set*

names the SAS data set that contains initial estimates for all the parameters in the model. BY-group processing is allowed in setting up the INEST= data set. See the section "INEST= Input Data Set" on page 5483 for more information.

MULTIPASS

requests that, for each Newton-Raphson iteration, PROC PHREG recompile the risk sets corresponding to the event times for the (start,stop) style of response and recomputes the values of the time-dependent variables defined by the programming statements for each observation in the risk sets. If the MULTIPASS option is not specified, PROC PHREG computes all risk sets and all the variable values and saves them in a utility file. The MULTIPASS option decreases required disk space at the expense of increased execution time; however, for very large data, it might actually save time since it is time-consuming to write and read large utility files. This option has an effect only when the (start,stop) style of response is used or when there are time-dependent explanatory variables.

NAMELEN=*n*

specifies the length of effect names in tables and output data sets to be *n* characters, where *n* is a value between 20 and 200. The default length is 20 characters.

NOPRINT

suppresses all displayed output. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 20, "Using the Output Delivery System," for more information.

NOSUMMARY

suppresses the summary display of the event and censored observation frequencies.

OUTEST=*SAS-data-set*

creates an output SAS data set that contains estimates of the regression coefficients. The data set also contains the convergence status and the log likelihood. If you use the COVOUT option, the data set also contains the estimated covariance matrix of the parameter estimators. See the section "OUTEST= Output Data Set" on page 5482 for more information.

PLOTS<(*global-plot-options***)> = ***plot-request*

PLOTS<(*global-plot-options***)> = (***plot-request* < . . . < *plot-request* > >**)**

controls the baseline functions plots produced through ODS Graphics. Each observation in the COVARIATES= data set in the BASELINE statement represents a set of covariates for which a curve is produced for each *plot-request* and for each stratum. You can use the ROWID= option in the BASELINE statement to specify a variable in the COVARIATES= data set for identifying the curves produced for the covariate sets. If the ROWID= option is not specified, the curves produced are identified by the covariate values if there is only a single covariate or by the observation numbers of the

COVARIATES= data set if the model has two or more covariates. If the COVARIATES= data set is not specified, a reference set of covariates consisting of the reference levels for the CLASS variables and the average values for the continuous variables is used. For plotting more than one curve, you can use the OVERLAY= option to group the curves in separate plots. When you specify one *plot-request*, you can omit the parentheses around the plot request. Here are some examples:

```
plots=survival
plots=(survival cumhaz)
```

ODS Graphics must be enabled before requesting plots. For example:

```
ods graphics on;

proc phreg plots(cl)=survival;
  model Time*Status(0)=X1-X5;
  baseline covariates=One;
run;

ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section "Enabling and Disabling ODS Graphics" on page 612 in Chapter 21, "Statistical Graphics Using ODS."

The *global-plot-options* include the following:

CL<=EQTAIL | HPD>
displays the pointwise interval limits for the specified curves. For the classical analysis, CL displays the confidence limits. For the Bayesian analysis, CL=EQTAIL displays the equal-tail credible limits and CL=HPD displays the HPD limits. Specifying just CL in a Bayesian analysis defaults to CL=HPD.

OVERLAY <=*overlay-option***>**
specifies how the curves for the various strata and covariate sets are overlaid. If the STRATA statement is not specified, specifying OVERLAY without any option will overlay the curves for all the covariate sets. The available *overlay-options* are as follows:

BYGROUP

GROUP
overlays, for each stratum, all curves for the covariate sets that have the same GROUP= value in the COVARIATES= data set in the same plot.

INDIVIDUAL

IND
displays, for each stratum, a separate plot for each covariate set.

BYROW

ROW

displays, for each covariate set, a separate plot containing the curves for all the strata.

BYSTRATUM

STRATUM

displays, for each stratum, a separate plot containing the curves for all sets of covariates.

The default is OVERLAY=BYGROUP if the GROUP= option is specified in the BASELINE statement or if the COVARIATES= data set contains the _GROUP_ variable; otherwise the default is OVERLAY=INDIVIDUAL.

TIMERANGE=(< *min* > < *,max* >**)**

TIMERANGE=< *min* > < *,max* >

RANGE=(< *min* > < *,max* >**)**

RANGE=< *min* > < *,max* >

specifies the range of values on the time axis to clip the display. The *min* and *max* values are the lower and upper bounds of the range. By default, *min* is 0 and *max* is the largest event time.

The *plot-requests* include the following:

CUMHAZ

plots the estimated cumulative hazard function for each set of covariates in the COVARIATES= data set in the BASELINE statement. If the COVARIATES= data set is not specified, the estimated cumulative hazard function is plotted for the reference set of covariates consisting of reference levels for the CLASS variables and average values for the continuous variables.

MCF

plots the estimated mean cumulative function for each set of covariates in the COVARIATES= data set in the BASELINE statement. If the COVARIATES= data set is not specified, the estimated mean cumulative function is plotted for the reference set of covariates consisting of reference levels for the CLASS variables and average values for the continuous variables.

NONE

suppresses all the plots in the procedure. Specifying this option is equivalent to disabling ODS Graphics for the entire procedure.

SURVIVAL

plots the estimated survivor function for each set of covariates in the COVARIATES= data set in the BASELINE statement. If COVARIATES= data set is not specified, the estimated survivor function is plotted for the reference set of covariates consisting of reference levels for the CLASS variables and average values for the continuous variables.

SIMPLE

displays simple descriptive statistics (mean, standard deviation, minimum, and maximum) for each explanatory variable in the MODEL statement.

ASSESS Statement

ASSESS < **VAR=***(list)* > < **PH** > < */options* > **;**

The ASSESS statement performs the graphical and numerical methods of Lin, Wei, and Ying (1993) for checking the adequacy of the Cox regression model. The methods are derived from cumulative sums of martingale residuals over follow-up times or covariate values. You can assess the functional form of a covariate or you can check the proportional hazards assumption for each covariate in the Cox model. PROC PHREG uses ODS Graphics for the graphical displays. You must specify at least one of the following options to create an analysis.

VAR=(*variable-list***)**

specifies the list of explanatory variables for which their functional forms are assessed. For each variable on the list, the observed cumulative martingale residuals are plotted against the values of the explanatory variable along with 20 (or *n* if NPATHS=*n* is specified) simulated residual patterns.

PROPORTIONALHAZARDS

PH

requests the checking of the proportional hazards assumption. For each explanatory variable in the model, the observed score process component is plotted against the follow-up time along with 20 (or *n* if NPATHS=*n* is specified) simulated patterns.

The following options can be specified after a slash (/):

NPATHS=*n*

specifies the number of simulated residual patterns to be displayed in a cumulative martingale residual plot or a score process plot. The default is *n*=20.

CRPANEL

requests that a plot with four panels, each containing the observed cumulative martingale residuals and two simulated residual patterns, be created.

RESAMPLE < =*n* **>**

requests that the Kolmogorov-type supremum test be computed on 1,000 simulated patterns or on *n* simulated patterns if *n* is specified.

SEED=*n*

specifies an integer seed for the random number generator used in creating simulated realizations for plots and for the Kolmogorov-type supremum tests. Specifying a seed enables you to reproduce identical graphs and *p*-values for the model assessments from the same PHREG specification. If the SEED= option is not specified, or if you specify a nonpositive seed, a random seed is derived from the time of day.

BASELINE Statement

BASELINE <**OUT=***SAS-data-set*> <**COVARIATES=***SAS-data-set*> <**TIMELIST=***list*> < *keyword=name . . . keyword=name* > </*options*> **;**

The BASELINE statement creates a new SAS data set that contains the baseline function estimates at the event times of each stratum for every set of covariates (**x**) given in the COVARIATES= data set. If the COVARIATES= data set is not specified, a reference set of covariates consisting of the reference levels for the CLASS variables and the average values for the continuous variables is used. No BASELINE data set is created if the model contains a time-dependent variable defined by means of programming statement.

The following options are available in the BASELINE statement.

OUT=*SAS-data-set*

names the output BASELINE data set. If you omit the OUT= option, the data set is created and given a default name by using the DATA*n* convention. See the section "OUT= Output Data Set in the BASELINE Statement" on page 5483 for more information.

COVARIATES=*SAS-data-set*

names the SAS data set that contains the sets of explanatory variable values for which the quantities of interest are estimated. All variables in the COVARIATES= data set are copied to the OUT= data set. Thus, any variable in the COVARIATES= data set can be used to identify the covariate sets in the OUT= data set.

TIMELIST=*list*

specifies a list of time points at which the survival function estimates, cumulative function estimates, or MCF estimates are computed. The following specifications are equivalent:

```
timelist=5,20 to 50 by 10
timelist=5 20 30 40 50
```

If the TIMELIST= option is not specified, the default is to carry out the prediction at all event times and at time 0. This option can be used only for the Bayesian analysis.

keyword=name

specifies the statistics to be included in the OUT= data set and assigns names to the variables that contain these statistics. Specify a *keyword* for each desired statistic, an equal sign, and the name of the variable for the statistic. Not all *keywords* listed in Table 66.1 (and discussed in the text that follows) are appropriate for both the classical analysis and the Bayesian analysis; and the table summaries the choices for each analysis.

Table 66.1 Summary of the Keyword Choices

Keyword	Classical	Bayesian
Survivor Function		
SURVIVAL	x	x
STDERR	x	x
LOWER	x	x

Table 66.1 *continued*

Options	Classical	Bayesian
UPPER	x	x
LOWERHPD		x
UPPERHPD		x
Cumulative Hazard Function		
CUMHAZ	x	x
STDCUMHAZ	x	x
LOWERCUMHAZ	x	x
UPPERCUMHAZ	x	x
LOWERHPDCUMHAZ		x
UPPERHPDCUMHAZ		x
Cumulative Mean Function		
CMF	x	
STDCMF	x	
LOWERCMF	x	
UPPERCMF	x	
Others		
XBETA	x	x
STDXBETA	x	x
LOGSURV	x	
LOGLOGS	x	

The available *keywords* are as follows.

CMF
MCF

specifies the cumulative mean function estimate for recurrent events data. Specifying CMF=_ALL_ is equivalent to specifying CMF=CMF, STDCMF=StdErrCMF, LOWERCMF=LowerCMF, and UPPERCMF=UpperCMF. Nelson (2002) refers to the mean function estimate as MCF (mean cumulative function).

CUMHAZ

specifies the cumulative hazard function estimate. Specifying CUMHAZ=_ALL_ is equivalent to specifying CUMHAZ=CumHaz, STDCUMHAZ=StdErrCumHaz, LOWERCUMHAZ=LowerCumHaz, and UPPERCUMHAZ=UpperCumHaz. For a Bayesian analysis, CUMHAZ=_ALL_ also includes LOWERHPDCUMHAZ= LowerHPDCumHaz and UpperHPDCUMHAZ=UpperHPDCumHaz.

LOGLOGS

specifies the log of the negative log of SURVIVAL.

LOGSURV

specifies the log of SURVIVAL.

LOWER

L

specifies the lower pointwise confidence limit for the survivor function. For a Bayesian analysis, this is the lower limit of the equal-tail credible interval for the survivor function. The confidence level is determined by the ALPHA= option.

LOWERCMF

LOWERMCF

specifies the lower pointwise confidence limit for the cumulative mean function. The confidence level is determined by the ALPHA= option.

LOWERHPD

specifies the lower limit of the HPD interval for the survivor function. The confidence level is determined by the ALPHA= option.

LOWERHPDCUMHAZ

specifies the lower limit of the HPD interval for the cumulative hazard function. The confidence level is determined by the ALPHA= option.

LOWERCUMHAZ

specifies the lower pointwise confidence limit for the cumulative hazard function. For a Bayesian analysis, this is the lower limit of the equal-tail credible interval for the cumulative hazard function. The confidence level is determined by the ALPHA= option.

STDERR

specifies the standard error of the survivor function estimator. For a Bayesian analysis, this is the standard deviation of the posterior distribution of the survivor function.

STDCMF

STDMCF

specifies the estimated standard error of the cumulative mean function estimator.

STDCUMHAZ

specifies the estimated standard error of the cumulative hazard function estimator. For a Bayesian analysis, this is the standard deviation of the posterior distribution of the cumulative hazard function.

STDXBETA

specifies the estimated standard error of the linear predictor estimator. For a Bayesian analysis, this is the standard deviation of the posterior distribution of the linear predictor.

SURVIVAL

specifies the survivor function ($S(t) = [S_0(t)]^{\exp(\boldsymbol{\beta}'\mathbf{x})}$) estimate. Specifying SURVIVAL=_ALL_ is equivalent to specifying SURVIVAL=Survival, STDERR=StdErrSurvival, LOWER=LowerSurvival, and UPPER=UpperSurvival; and for a Bayesian analyis, SURVIVAL=_ALL_ also specifies LOWERHPD= LowerHPDSurvival and UPPERHPD=UpperHPDSurvival.

UPPER

U

specifies the upper pointwise confidence limit for the survivor function. For a Bayesian analysis, this is the upper limit of the equal-tail credible interval for the survivor function. The confidence level is determined by the ALPHA= option.

UPPERCMF

UPPERMCF

specifies the upper pointwise confidence limit for the cumulative mean function. The confidence level is determined by the ALPHA= option.

UPPERCUMHAZ

specifies the upper pointwise confidence limit for the cumulative hazard function. For a Bayesian analysis, this is the upper limit of the equal-tail credible interval for the cumulative hazard function. The confidence level is determined by the ALPHA= option.

UPPERHPD

specifies the upper limit of the equal-tail credible interval for the survivor function. The confidence level is determined by the ALPHA= option.

UPPERHPDCUMHAZ

specifies the upper limit of the equal-tail credible interval for the cumulative hazard function. The confidence level is determined by the ALPHA= option.

XBETA

specifies the estimate of the linear predictor $\mathbf{x}'\boldsymbol{\beta}$.

The following options can appear in the BASELINE statement after a slash (/). The METHOD= and CLTYPE= options apply only to the estimate of the survivor function in the classical analysis. For the Bayesian analysis, the survivor function is estimated by the Breslow (1972) method.

ALPHA=*value*

specifies the significance level of the confidence interval for the survivor function. The value must be between 0 and 1. The default is the value of the ALPHA= option in the PROC PHREG statement, or 0.05 if that option is not specified.

CLTYPE=*method*

specifies the method used to compute the confidence limits for $S(t,\mathbf{z})$, the survivor function for a subject with a fixed covariate vector $\mathbf{z}$ at event time t. The CLTYPE= option can take the following values:

LOG

specifies that the confidence limits for $\log(S(t,\mathbf{z}))$ be computed using the normal theory approximation. The confidence limits for $S(t,\mathbf{z})$ are obtained by back-transforming the confidence limits for $\log(S(t,\mathbf{z}))$. The default is CLTYPE=LOG.

LOGLOG

specifies that the confidence limits for the $\log(-\log(S(t,\mathbf{z})))$ be computed using normal theory approximation. The confidence limits for $S(t,\mathbf{z})$ are obtained by back-transforming the confidence limits for $\log(-\log(S(t,\mathbf{z})))$.

NORMAL
specifies that the confidence limits for $S(t, \mathbf{z})$ be computed directly using normal theory approximation.

GROUP=*variable*
names a numeric variable in the COVARIATES= data set to group the baseline function curves for the observations into separate plots. This option has no effect if the PLOTS= option in the PROC PHREG statement is not specified. Curves for the covariate sets with the same value of the GROUP= variable are overlaid in the same plot.

METHOD=*method*
specifies the method used to compute the survivor function estimates. The two available methods are as follows:

CH

EMP
specifies that the Breslow (1972) method be used to compute the survivor function—that is, that the survivor function be estimated by exponentiating the negative empirical cumulative hazard function.

PL
specifies that the product-limit estimate of the survivor function be computed.

The default is METHOD=BRESLOW.

ROWID=*variable*

ID=*variable*

ROW=*variable*
names a variable in the COVARIATES= data set for identifying the baseline function curves in the plots. This option has no effect if the PLOTS= option in the PROC PHREG statement is not specified. Values of this variable are used to label the curves for the corresponding rows in the COVARIATES= data set. You can specify ROWID=_OBS_ to use the observation numbers in the COVARIATES= data set for identification.

For recurrent events data, both CMF= and CUMHAZ= statistics are the Nelson estimators, but their standard error are not the same. Confidence limits for the cumulative mean function and cumulative hazard function are based on the log transform.

BAYES Statement

BAYES < *options* > **;**

The BAYES statement requests a Bayesian analysis of the regression model by using Gibbs sampling. The Bayesian posterior samples (also known as the chain) for the regression parameters can be output to a SAS data set. Table 66.2 summarizes the options available in the BAYES statement.

Table 66.2 BAYES Statement Options

Option	Description
Monte Carlo Options	
INITIAL=	Specifies initial values of the chain
NBI=	Specifies the number of burn-in iterations
NMC=	Specifies the number of iterations after burn-in
SAMPLING=	Specifies the sampling algorithm
SEED=	Specifies the random number generator seed
THINNING=	Sontrols the thinning of the Markov chain
Model and Prior Options	
COEFFPRIOR=	Specifies the prior of the regression coefficients
PIECEWISE=	Specifies details of the piecewise exponential model
Summaries and Diagnostics of the Posterior Samples	
DIAGNOSTICS=	Displays convergence diagnostics
PLOTS=	Displays diagnostic plots
STATISTICS=	Displays summary statistics
Posterior Samples	
OUTPOST=	Names a SAS data set for the posterior samples

The following list describes these options and their suboptions.

COEFFPRIOR=UNIFORM | NORMAL <(*normal-option*)> | ZELLNER <(*zellner-option*)>
CPRIOR=UNIFORM | NORMAL <(*normal-option*)> | ZELLNER <(*zellner-option*)>
COEFF=UNIFORM | NORMAL <(*normal-option*)> | ZELLNER <(*zellner-option*)>

specifies the prior distribution for the regression coefficients. The default is COEFFPRIOR=UNIFORM. The following prior distributions are available:

UNIFORM

specifies a flat prior—that is, the prior that is proportional to a constant ($p(\beta_1, \ldots, \beta_k) \propto 1$ for all $-\infty < \beta_i < \infty$).

NORMAL<(*normal-option*)>

specifies a normal distribution. The *normal-options* include the following:

INPUT=*SAS-data-set*

specifies a SAS data set that contains the mean and covariance information of the normal prior. The data set must contain the _TYPE_ variable to identify the observation type, and it must contain a variable to represent each regression coefficient. If the data set also contains the _NAME_ variable, values of this variable are used to identify the covariances for the _TYPE_='COV' observations; otherwise, the _TYPE_='COV' observations are assumed to be in the same order as the explanatory variables in the MODEL statement. PROC PHREG reads the mean vector from the observation with _TYPE_='MEAN' and the covariance matrix from observations with _TYPE_='COV'. For an independent normal prior, the variances can be specified with _TYPE_='VAR'; alternatively, the precisions (inverse of the variances) can be specified with _TYPE_='PRECISION'.

RELVAR < =*c* >
specifies a normal prior $N(\mathbf{0}, c\mathbf{J})$, where $\mathbf{J}$ is a diagonal matrix with diagonal elements equal to the variances of the corresponding ML estimator. By default, *c*=$1E6$.

VAR=*c*
specifies the normal prior $N(\mathbf{0}, c\mathbf{I})$, where $\mathbf{I}$ is the identity matrix.

If you do not specify a *normal-option*, the normal prior $N(\mathbf{0}, 10^6\mathbf{I})$, where $\mathbf{I}$ is the identity matrix, is used. See the section "Normal Prior" on page 5476 for details.

ZELLNER< (*zellner-option*) >
specifies the Zellner g-prior for the regression coefficients. The g-prior is a normal prior distribution with mean zero and covariance matrix equal to $(gX'X)^{-1}$, where X is the design matrix and g can be a constant or a parameter with a gamma prior. The *zellner-options* include the following:

G=*number*
specifies a constant *number* for g.

GAMMA < (SHAPE=*a* ISCALE=*b*) >
specifies that g has a gamma prior distribution $G(a, b)$ with density $f(t) = \frac{b(bt)^{a-1}e^{-bt}}{\Gamma(a)}$. By default, *a*=*b*=1E–4.

If you do not specify a *zellner-option*, the default is ZELLNER(g=1E–6).

DIAGNOSTICS=ALL | NONE | *keyword* | *(keyword-list)*
DIAG=ALL | NONE | *keyword* | *(keyword-list)*
controls the number of diagnostics produced. You can request all the diagnostics in the following list by specifying DIAGNOSTICS=ALL. If you do not want any of these diagnostics, you specify DIAGNOSTICS=NONE. If you want some but not all of the diagnostics, or if you want to change certain settings of these diagnostics, you specify a subset of the following keywords. The default is DIAGNOSTICS=(AUTOCORR GEWEKE ESS).

AUTOCORR < (LAGS= *numeric-list*) >
computes the autocorrelations of lags given by LAGS= list for each parameter. Elements in the list are truncated to integers and repeated values are removed. If the LAGS= option is not specified, autocorrections of lags 1, 5, 10, and 50 are computed for each variable. See the section "Autocorrelations" on page 158 for details.

ESS
computes the effective sample size of Kass et al. (1998), the correlation time, and the efficiency of the chain for each parameter. See the section "Effective Sample Size" on page 158 for details.

MCSE
MCERROR
computes the Monte Carlo standard error for each parameter. The Monte Caro standard error, which measures the simulation accuracy, is the standard error of the posterior mean estimate and is calculated as the posterior standard deviation divided by the square root of the effective sample size. See the section "Standard Error of the Mean Estimate" on page 159 for details.

HEIDELBERGER < *(heidel-options)* >

computes the Heidelberger and Welch tests for each parameter. See the section "Heidelberger and Welch Diagnostics" on page 154 for details. The tests consist of a stationary test and a halfwidth test. The former tests the null hypothesis that the sample values form a stationary process. If the stationarity test is passed, a halfwidth test is then carried out. Optionally, you can specify one or more of the following *heidel-options*:

SALPHA=*value*

specifies the α level ($0 < \alpha < 1$) for the stationarity test. The default is the value of the ALPHA= option in the PROC PHREG statement, or 0.05 if that option is not specified.

HALPHA=*value*

specifies the α level ($0 < \alpha < 1$) for the halfwidth test. The default is the value of the ALPHA= option in the PROC PHREG statement, or 0.05 if that option is not specified.

EPS=*value*

specifies a small positive number ϵ such that if the halfwidth is less than ϵ times the sample mean of the retaining samples, the halfwidth test is passed.

GELMAN < **(***gelman-options***)** >

computes the Gelman and Rubin convergence diagnostics. See the section "Gelman and Rubin Diagnostics" on page 150 for details. You can specify one or more of the following *gelman-options*:

NCHAIN=*number*

N=*number*

specifies the number of parallel chains used to compute the diagnostic and has to be 2 or larger. The default is NCHAIN=3. The NCHAIN= option is ignored when the INITIAL= option is specified in the BAYES statement, and in such a case, the number of parallel chains is determined by the number of valid observations in the INITIAL= data set.

ALPHA=*value*

specifies the significance level for the upper bound. The default is the value of the ALPHA= option in the PROC PHREG statement, or 0.05 if that option is not specified (resulting in a 97.5% bound).

GEWEKE < *geweke-options* >

computes the Geweke diagnostics. See the section "Geweke Diagnostics" on page 152 for details. The diagnostic is essentially a two-sample t-test between the first f_1 portion and the last f_2 portion of the chain. The default is f_1=0.1 and f_2=0.5, but you can choose other fractions by using the following *geweke-options*:

FRAC1=*value*

specifies the early f_1 fraction of the Markov chain.

FRAC2=*value*

specifies the latter f_2 fraction of the Markov chain.

RAFTERY <(*raftery-options*)>

computes the Raftery and Lewis diagnostics. See the section "Raftery and Lewis Diagnostics" on page 155 for details. The diagnostic evaluates the accuracy of the estimated quantile ($\hat{\theta}_Q$ for a given $Q \in (0,1)$) of a chain. $\hat{\theta}_Q$ can achieve any degree of accuracy when the chain is allowed to run for a long time. A stopping criterion is when the estimated probability $\hat{P}_Q = \Pr(\theta \leq \hat{\theta}_Q)$ reaches within $\pm R$ of the value Q with probability S; that is, $\Pr(Q - R \leq \hat{P}_Q \leq Q + R) = S$. The following *raftery-options* enable you to specify Q, R, S, and a precision level ϵ for a stationary test.

QUANTILE=*value*

Q=*value*

specifies the order (a value between 0 and 1) of the quantile of interest. The default is 0.025.

ACCURACY=*value*

R=*value*

specifies a small positive number as the margin of error for measuring the accuracy of estimation of the quantile. The default is 0.005.

PROBABILITY=*value*

P=*value*

specifies the probability of attaining the accuracy of the estimation of the quantile. The default is 0.95.

EPSILON=*value*

EPS=*value*

specifies the tolerance level (a small positive number) for the test. The default is 0.001.

INITIAL=*SAS-data-set*

specifies the SAS data set that contains the initial values of the Markov chains. The INITIAL= data set must contain a variable for each parameter in the model. You can specify multiple rows as the initial values of the parallel chains for the Gelman-Rubin statistics, but posterior summary statistics, diagnostics, and plots are computed only for the first chain.

NBI=*number*

specifies the number of burn-in iterations before the chains are saved. The default is 2000.

NMC=*number*

specifies the number of iterations after the burn-in. The default is 10000.

OUTPOST=*SAS-data-set*

OUT=*SAS-data-set*

names the SAS data set that contains the posterior samples. See the section "OUTPOST= Output Data Set in the BAYES Statement" on page 5483 for more information. Alternatively, you can output the posterior samples into a data set, as shown in the following example in which the data set is named PostSamp.

```
ODS OUTPUT PosteriorSample = PostSamp;
```

PIECEWISE <=*keyword* **<(<NINTERVAL=***number***><INTERVAL=(***numeric-list***)><PRIOR=***option***>)>>**

specifies that the piecewise constant baseline hazard model be used in the Bayesian analysis. You can specify one of the following two *keywords*:

HAZARD
models the baseline hazard parameters in the original scale. The hazard parameters are named Lambda1, Lambda2, . . ., and so on.

LOGHAZARD
models the baseline hazard parameters in the log scale. The log-hazard parameters are named Alpha1, Alpha2, . . ., and so on.

Specifying PIECEWISE by itself is the same as specifying PIECEWISE=LOGHAZARD.

You can choose one of the following two options to specify the partition of the time axis into intervals of constant baseline hazards:

NINTERVAL=*number*

N=*number*
specifies the number of intervals with constant baseline hazard rates. PROC PHREG partitions the time axis into the given number of intervals with approximately equal number of events in each interval.

INTERVAL=*(numeric-list)*
specifies the list of numbers that partition the time axis into disjoint intervals with constant baseline hazard in each interval. For example, INTERVAL=(100, 150, 200, 250, 300) specifies a model with a constant hazard in the intervals [0,100), [100,150), [150,200), [200,250), [250,300), and [300,∞). Each interval must contain at least one event; otherwise, the posterior distribution can be improper, and inferences cannot be derived from an improper posterior distribution.

If neither NINTERVAL= nor INTERVAL= is specified, the default is NINTERVAL=8.

To specify the prior for the baseline hazards $(\lambda_1, \ldots, \lambda_J)$ in the original scale, you specify the following:

PRIOR = IMPROPER | UNIFORM | GAMMA<(*gamma-option***)> | ARGAMMA<(***argamma-option***)>**

The default is PRIOR=IMPROPER. The available prior options include the following:

IMPROPER
specifies the noninformative and improper prior $p(\lambda_1, \ldots, \lambda_J) \propto \prod_i {\lambda_i}^{-1}$ for all $\lambda_i > 0$.

UNIFORM
specifies a uniform prior on the real line; that is, $p(\lambda_i) \propto 1$ for all $\lambda_i > 0$.

GAMMA <(*gamma-option***)>**
specifies an independent gamma prior $G(a, b)$ with density $f(t) = \frac{b(bt)^{a-1}\mathrm{e}^{-bt}}{\Gamma(a)}$, which

can be followed by one of the following *gamma-options* enclosed in parentheses. The hyperparameters a and b are the shape and inverse-scale parameters of the gamma distribution, respectively. See the section "Independent Gamma Prior" on page 5475 for details. The default is $G(10^{-4}, 10^{-4})$ for each λ_j, setting the prior mean to 1 with variance 1E4. This prior is proper and reasonably noninformative.

INPUT=*SAS-data-set*
specifies a data set containing the hyperparameters of the independent gamma prior. The data set must contain the _TYPE_ variable to identify the observation type, and it must contain the variables named Lambda1, Lambda2, ..., and so forth, to represent the hazard parameters. The observation with _TYPE_='SHAPE' identifies the shape parameters, and the observation with _TYPE_='ISCALE' identifies the inverse-scale parameters.

RELSHAPE< =*c* **>**
specifies independent $G(c\hat{\lambda}_j, c)$ distribution, where $\hat{\lambda}_j$'s are the MLEs of the hazard rates. This prior has mean $\hat{\lambda}_j$ and variance $\frac{\hat{\lambda}_j}{c}$. By default, *c*=1E–4.

SHAPE=*a* **and ISCALE=***b*
together specify the $G(a, b)$ prior.

SHAPE=*c*
ISCALE=*c*
specifies the $G(c, c)$ prior.

ARGAMMA < (*argamma-option***) >**
specifies an autoregressive gamma prior of order 1, which can be followed by one of the following *argamma-options*. See the section "AR1 Prior" on page 5475 for details.

INPUT=*SAS-data-set*
specifies a data set containing the hyperparameters of the correlated gamma prior. The data set must contain the _TYPE_ variable to identify the observation type, and it must contain the variables named Lambda1, Lambda2, ..., and so forth, to represent the hazard parameters. The observation with _TYPE_='SHAPE' identifies the shape parameters, and the observation with _TYPE_='ISCALE' identifies the *relative* inverse-scale parameters; that is, if a_j and b_j are, respectively, the SHAPE and ISCALE values for $\lambda_j, 1 \le j \le J$, then $\lambda_1 \sim G(a_1, b_1)$, and $\lambda_j \sim G(a_j, b_j/\lambda_{j-1})$ for $2 \le j \le J$.

SHAPE=*a* **and SCALE=***b*
together specify that $\lambda_1 \sim G(a, b)$ and $\lambda_j \sim G(a, b/\lambda_{j-1})$ for $2 \le j \le J$.

SHAPE=*c*
ISCALE=*c*
specifies that $\lambda_1 \sim G(c, c)$ and $\lambda_j \sim G(c, c/\lambda_{j-1})$ for $2 \le j \le J$.

To specify the prior for $\alpha_1, \ldots, \alpha_J$, the hazard parameters in the log scale, you specifying the following:

PRIOR=UNIFORM | NORMAL< (*normal-option***) >**
specifies the prior for the loghazard parameters. The default is PRIOR=UNIFORM. The available PRIOR= options are as follows:

UNIFORM

specifies the uniform prior on the real line; that is, $\alpha_i \propto 1$ for all $-\infty < \alpha_i < \infty$.

NORMAL<(*normal-option*)>

specifies a normal prior distribution on the log-hazard parameters. The *normal-options* include the following. If you do not specify a *normal-option*, the normal prior $N(\mathbf{0}, 10^6\mathbf{I})$, where $\mathbf{I}$ is the identity matrix, is used.

INPUT=*SAS-data-set*

specifies a SAS data set containing the mean and covariance information of the normal prior. The data set must contain the _TYPE_ variable to identify the observation type, and it must contain variables named Alpha1, Alpha2, ..., and so forth, to represent the log-hazard parameters. If the data set also contains the _NAME_ variable, the value of this variable will be used to identify the covariances for the _TYPE_='COV' observations; otherwise, the _TYPE_='COV' observations are assumed to be in the same order as the explanatory variables in the MODEL statement. PROC PHREG reads the mean vector from the observation with _TYPE_='MEAN' and the covariance matrix from observations with _TYPE_='COV'. See the section "Normal Prior" on page 5476 for details. For an independent normal prior, the variances can be specified with _TYPE_='VAR'; alternatively, the precisions (inverse of the variances) can be specified with _TYPE_='PRECISION'.

If you have a joint normal prior for the log-hazard parameters and the regression coefficients, specify the same data set containing the mean and covariance information of the multivariate normal distribution in both the COEFFPRIOR=NORMAL(INPUT=) and the PIECEWISE=LOGHAZARD(PRIOR=NORMAL(INPUT=)) options. See the section "Joint Multivariate Normal Prior for Log-Hazards and Regression Coefficients" on page 5476 for details.

RELVAR<=*c*>

specifies the normal prior $N(\mathbf{0}, c\mathbf{J})$, where $\mathbf{J}$ is a diagonal matrix with diagonal elements equal to the variances of the corresponding ML estimator. By default, *c*=1E6.

VAR=*c*

specifies the normal prior $N(\mathbf{0}, c\mathbf{I})$, where $\mathbf{I}$ is the identity matrix.

PLOTS<(*global-plot-options*)>= *plot-request*

PLOTS<(*global-plot-options*)>=(*plot-requests***)**

controls the diagnostic plots produced through ODS Graphics. Three types of plots can be requested: trace plots, autocorrelation function plots, and kernel density plots. By default, the plots are displayed in panels unless the global plot option UNPACK is specified. If you specify more than one type of plots, the plots are displayed by parameters unless the global plot option GROUPBY=TYPE is specified. When you specify only one plot request, you can omit the parentheses around the plot request. For example:

```
plots=none
plots(unpack)=trace
plots=(trace autocorr)
```

ODS Graphics must be enabled before requesting plots. For example:

```
ods graphics on;
proc phreg;
   model y=x;
   bayes plots=trace;
   run;
end;
ods graphics off;
```

If ODS Graphics is enabled but you do not specify the PLOTS= option in the BAYES statement, then PROC PHREG produces, for each parameter, a panel that contains the trace plot, the autocorrelation function plot, and the density plot. This is equivalent to specifying **plots=(trace autocorr density)**.

The *global-plot-options* include the following:

FRINGE
creates a fringe plot on the X axis of the density plot.

GROUPBY = PARAMETER | TYPE
specifies how the plots are to be grouped when there is more than one type of plots. The choices are as follows:

TYPE
specifies that the plots be grouped by type.

PARAMETER
specifies that the plots be grouped by parameter.

GROUPBY=PARAMETER is the default.

SMOOTH
displays a fitted penalized B-spline curve each trace plot.

UNPACKPANEL
UNPACK
specifies that all paneled plots be unpacked, meaning that each plot in a panel is displayed separately.

The *plot-requests* include the following:

ALL
specifies all types of plots. PLOTS=ALL is equivalent to specifying PLOTS=(TRACE AUTOCORR DENSITY).

AUTOCORR
displays the autocorrelation function plots for the parameters.

DENSITY
displays the kernel density plots for the parameters.

NONE
suppresses all diagnostic plots.

TRACE
displays the trace plots for the parameters. See the section "Visual Analysis via Trace Plots" on page 145 for details.

Consider a model with four parameters, X1–X4. Displays for various specification are depicted as follows.

1. PLOTS=(TRACE AUTOCORR) displays the trace and autocorrelation plots for each parameter side by side with two parameters per panel:

Display 1	Trace(X1)	Autocorr(X1)
	Trace(X2)	Autocorr(X2)
Display 2	Trace(X3)	Autocorr(X3)
	Trace(X4)	Autocorr(X4)

2. PLOTS(GROUPBY=TYPE)=(TRACE AUTOCORR) displays all the paneled trace plots, followed by panels of autocorrelation plots:

Display 1	Trace(X1)	
	Trace(X2)	
Display 2	Trace(X3)	
	Trace(X4)	
Display 3	Autocorr(X1)	Autocorr(X2)
	Autocorr(X3)	Autocorr(X4)

3. PLOTS(UNPACK)=(TRACE AUTOCORR) displays a separate trace plot and a separate correlation plot, parameter by parameter:

Display 1	Trace(X1)
Display 2	Autocorr(X1)
Display 3	Trace(X2)
Display 4	Autocorr(X2)
Display 5	Trace(X3)
Display 6	Autocorr(X3)
Display 7	Trace(X4)
Display 8	Autocorr(X4)

4. PLOTS(UNPACK GROUPBY=TYPE) = (TRACE AUTOCORR) displays all the separate trace plots followed by the separate autocorrelation plots:

Display 1	Trace(X1)
Display 2	Trace(X2)
Display 3	Trace(X3)
Display 4	Trace(X4)
Display 5	Autocorr(X1)
Display 6	Autocorr(X2)
Display 7	Autocorr(X3)
Display 8	Autocorr(X4)

SAMPLING=*keyword*

specifies the sampling algorithm used in the Markov chain Monte Carlo (MCMC) simulations. Two sampling algorithms are available:

ARMS

GIBBS

requests the use of the adaptive rejection Metropolis sampling (ARMS) algorithm to draw the Gibbs samples. ALGORITHM=ARMS is the default.

RWM

requests the use of the random walk Metropolis (RWM) algorithm to draw the samples.

For details about the MCMC sampling algorithms, see the section "Markov Chain Monte Carlo Method" on page 139 in Chapter 7, "Introduction to Bayesian Analysis Procedures."

SEED=*number*

specifies an integer seed ranging from 1 to $2^{31}-1$ for the random number generator in the simulation. Specifying a seed enables you to reproduce identical Markov chains for the same specification. If the SEED= option is not specified, or if you specify a nonpositive seed, a random seed is derived from the time of day.

STATISTICS <(*global-options***)> = ALL | NONE |** *keyword* **|** *(keyword-list)*

STATS <(*global-statoptions***)> = ALL | NONE |** *keyword* **|** *(keyword-list)*

controls the number of posterior statistics produced. Specifying STATISTICS=ALL is equivalent to specifying STATISTICS=(SUMMARY INTERVAL COV CORR). If you do not want any posterior statistics, you specify STATISTICS=NONE. The default is STATISTICS=(SUMMARY INTERVAL). See the section "Summary Statistics" on page 159 for details. The *global-options* include the following:

ALPHA=*numeric-list*
controls the probabilities of the credible intervals. The ALPHA= values must be between 0 and 1. Each ALPHA= value produces a pair of 100(1–ALPHA)% equal-tail and HPD intervals for each parameters. The default is the value of the ALPHA= option in the PROC PHREG statement, or 0.05 if that option is not specified (yielding the 95% credible intervals for each parameter).

PERCENT=*numeric-list*
requests the percentile points of the posterior samples. The PERCENT= values must be between 0 and 100. The default is PERCENT= 25, 50, 75, which yield the 25th, 50th, and 75th percentile points for each parameter.

You can specify the following values for a *keyword* or as part of a *keyword-list*. To specify a list, place parentheses around multiple keywords that are separated by spaces.

CORR
produces the posterior correlation matrix.

COV
produces the posterior covariance matrix.

SUMMARY
produces the means, standard deviations, and percentile points for the posterior samples. The default is to produce the 25th, 50th, and 75th percentile points, but you can use the global PERCENT= option to request specific percentile points.

INTERVAL
produces equal-tail credible intervals and HPD intervals. The defult is to produce the 95% equal-tail credible intervals and 95% HPD intervals, but you can use the global ALPHA= option to request intervals of any probabilities.

THINNING=*number*

THIN=*number*
controls the thinning of the Markov chain. Only one in every k samples is used when THINNING=k, and if NBI=n_0 and NMC=n, the number of samples kept is

$$\left[\frac{n_0 + n}{k}\right] - \left[\frac{n_0}{k}\right]$$

where $[a]$ represents the integer part of the number a. The default is THINNING=1.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC PHREG to obtain separate analyses on observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data

set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the PHREG procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variable* < *(options)* >. . .< *variable* < *(options)* > > < / *global-options* > **;**

The CLASS statement names the classification variables to be used as explanatory variables in the analysis. The CLASS statement must precede the MODEL statement. Most options can be specified either as individual variable *options* or as *global-options*. You can specify *options* for each variable by enclosing the options in parentheses after the variable name. You can also specify *global-options* for the CLASS statement by placing them after a slash (/). *Global-options* are applied to all the variables specified in the CLASS statement. If you specify more than one CLASS statement, the *global-options* specified in any one CLASS statement apply to all CLASS statements. However, individual CLASS variable *options* override the *global-options*. You can specify the following values for either an *option* or a *global-option*:

CPREFIX=*n*

specifies that, at most, the first *n* characters of a CLASS variable name be used in creating names for the corresponding design variables. The default is $32 - \min(32, \max(2, f))$, where f is the formatted length of the CLASS variable.

DESCENDING

DESC

reverses the sorting order of the classification variable. If both the DESCENDING and ORDER= options are specified, PROC PHREG orders the categories according to the ORDER= option and then reverses that order.

LPREFIX=*n*

specifies that, at most, the first *n* characters of a CLASS variable label be used in creating labels for the corresponding design variables. The default is $256 - \min(256, \max(2, f))$, where f is the formatted length of the CLASS variable.

MISSING

treats missing values (".", ".A", . . . , ".Z" for numeric variables and blanks for character variables) as valid values for the CLASS variable.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the sorting order for the levels of classification variables. This ordering determines which parameters in the model correspond to each level in the data, so the ORDER= option can be useful when you use the CONTRAST statement. By default, ORDER=FORMATTED. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine-dependent. When ORDER=FORMATTED is in effect for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values.

The following table shows how PROC PHREG interprets values of the ORDER= option.

Value of ORDER=	Levels Sorted By
DATA	Order of appearance in the input data set
FORMATTED	External formatted values, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) values
FREQ	Descending frequency count; levels with more observations come earlier in the order
INTERNAL	Unformatted value

For more information about sorting order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

PARAM=*keyword*

specifies the parameterization method for the classification variable or variables. You can specify any of the *keywords* shown in the following table; the default is PARAM=REF. Design matrix columns are created from CLASS variables according to the corresponding coding schemes:

Value of PARAM=	Coding
EFFECT	Effect coding
GLM	Less-than-full-rank reference cell coding (this *keyword* can be used only in a global option)
ORDINAL THERMOMETER	Cumulative parameterization for an ordinal CLASS variable
POLYNOMIAL POLY	Polynomial coding
REFERENCE REF	Reference cell coding
ORTHEFFECT	Orthogonalizes PARAM=EFFECT coding
ORTHORDINAL ORTHOTHERM	Orthogonalizes PARAM=ORDINAL coding
ORTHPOLY	Orthogonalizes PARAM=POLYNOMIAL coding
ORTHREF	Orthogonalizes PARAM=REFERENCE coding

All parameterizations are full rank, except for the GLM parameterization. The REF= option in the CLASS statement determines the reference level for EFFECT and REFERENCE coding and for their orthogonal parameterizations.

If PARAM=ORTHPOLY or PARAM=POLY and the classification variable is numeric, then the ORDER= option in the CLASS statement is ignored, and the internal unformatted values are used. See the section "Other Parameterizations" on page 402 of Chapter 19, "Shared Concepts and Topics," for further details.

REF=*'level'* | *keyword*
specifies the reference level for PARAM=EFFECT, PARAM=REFERENCE, and their orthogonalizations. For an individual (but not a global) variable REF= option, you can specify the *level* of the variable to use as the reference level. Specify the formatted value of the variable if a format is assigned. For a global or individual variable REF= option, you can use one of the following *keywords*. The default is REF=LAST.

FIRST designates the first ordered level as reference.

LAST designates the last ordered level as reference.

TRUNCATE<*=n*>
specifies the length *n* of CLASS variable values to use in determining CLASS variable levels. The default is to use the full formatted length of the CLASS variable. If you specify TRUNCATE without the length *n*, the first 16 characters of the formatted values are used. When formatted values are longer than 16 characters, you can use this option to revert to the levels as determined in releases before SAS 9. The TRUNCATE option is available only as a global option.

Class Variable Naming Convention

Parameter names for a CLASS predictor variable are constructed by concatenating the CLASS variable name with the CLASS levels. However, for the POLYNOMIAL and orthogonal parameterizations, parameter names are formed by concatenating the CLASS variable name and keywords that reflect the parameterization. See the section "Other Parameterizations" on page 402 in Chapter 19, "Shared Concepts and Topics," for examples and further details.

Class Variable Parameterization with Unbalanced Designs

PROC PHREG initially parameterizes the CLASS variables by looking at the levels of the variables across the complete data set. If you have an *unbalanced* replication of levels across variables or BY groups, then the design matrix and the parameter interpretation might be different from what you expect. For instance, suppose you have a model with one CLASS variable A with three levels (1, 2, and 3), and another CLASS variable B with two levels (1 and 2). If the third level of A occurs only with the first level of B, if you use the EFFECT parameterization, and if your model contains the effect A(B) and an intercept, then the design for A within the second level of B is not a differential effect. In particular, the design looks like the following:

		Design Matrix			
		A(B=1)		A(B=2)	
B	A	A1	A2	A1	A2
1	1	1	0	0	0
1	2	0	1	0	0
1	3	−1	−1	0	0
2	1	0	0	1	0
2	2	0	0	0	1

PROC PHREG detects linear dependency among the last two design variables and sets the parameter for A2(B=2) to zero, resulting in an interpretation of these parameters as if they were reference- or dummy-coded. The REFERENCE or GLM parameterization might be more appropriate for such problems.

CONTRAST Statement

CONTRAST *'label' row-description <,... row-description>< /options>* **;**

The CONTRAST statement provides a mechanism for obtaining customized hypothesis tests. It is similar to the CONTRAST statement in PROC GLM and PROC CATMOD, depending on the coding schemes used with any categorical variables involved.

The CONTRAST statement enables you to specify a matrix, $\mathbf{L}$, for testing the hypothesis $\mathbf{L}\boldsymbol{\beta} = \mathbf{0}$. You must be familiar with the details of the model parameterization that PROC PHREG uses (for more information, see the PARAM= option in the section "CLASS Statement" on page 5400). Optionally, the CONTRAST statement enables you to estimate each row, $\boldsymbol{l}_i'\boldsymbol{\beta}$, of $\mathbf{L}\boldsymbol{\beta}$ and test the hypothesis $\boldsymbol{l}_i'\boldsymbol{\beta} = 0$. Computed statistics are based on the asymptotic chi-square distribution of the Wald statistic.

There is no limit to the number of CONTRAST statements that you can specify, but they must appear after the MODEL statement.

The syntax of a *row-description* is:

effect values <,...,effect values>

The following parameters are specified in the CONTRAST statement:

label identifies the contrast on the output. A label is required for every contrast specified, and it must be enclosed in quotes.

effect identifies an effect that appears in the MODEL statement. You do not need to include all effects that are included in the MODEL statement.

values are constants that are elements of the $\mathbf{L}$ matrix associated with the effect. To correctly specify your contrast, it is crucial to know the ordering of parameters within each effect and the variable levels associated with any parameter. The "Class Level Information" table shows the ordering of levels within variables. The E option, described later in this section, enables you to verify the proper correspondence of *values* to parameters.

The rows of **L** are specified in order and are separated by commas. Multiple degree-of-freedom hypotheses can be tested by specifying multiple *row-descriptions*. For any of the full-rank parameterizations, if an effect is not specified in the CONTRAST statement, all of its coefficients in the **L** matrix are set to 0. If too many values are specified for an effect, the extra ones are ignored. If too few values are specified, the remaining ones are set to 0.

When you use effect coding (by specifying PARAM=EFFECT in the CLASS statement), all parameters are directly estimable (involve no other parameters). For example, suppose an effect coded CLASS variable A has four levels. Then there are three parameters $(\alpha_1, \alpha_2, \alpha_3)$ representing the first three levels, and the fourth parameter is represented by

$$-\alpha_1 - \alpha_2 - \alpha_3$$

To test the first versus the fourth level of A, you would test

$$\alpha_1 = -\alpha_1 - \alpha_2 - \alpha_3$$

or, equivalently,

$$2\alpha_1 + \alpha_2 + \alpha_3 = 0$$

which, in the form $\mathbf{L}\boldsymbol{\beta} = 0$, is

$$\begin{bmatrix} 2 & 1 & 1 \end{bmatrix} \begin{bmatrix} \alpha_1 \\ \alpha_2 \\ \alpha_3 \end{bmatrix} = 0$$

Therefore, you would use the following CONTRAST statement:

```
contrast '1 vs. 4' A 2 1 1;
```

To contrast the third level with the average of the first two levels, you would test

$$\frac{\alpha_1 + \alpha_2}{2} = \alpha_3$$

or, equivalently,

$$\alpha_1 + \alpha_2 - 2\alpha_3 = 0$$

Therefore, you would use the following CONTRAST statement:

```
contrast '1&2 vs. 3' A 1 1 -2;
```

Other CONTRAST statements involving classification variables with PARAM=EFFECT are constructed similarly. For example:

```
contrast '1 vs. 2    '  A  1 -1  0;
contrast '1&2 vs. 4  '  A  3  3  2;
contrast '1&2 vs. 3&4'  A  2  2  0;
contrast 'Main Effect'  A  1  0  0,
                        A  0  1  0,
                        A  0  0  1;
```

When you use the less-than-full-rank parameterization (by specifying PARAM=GLM in the CLASS statement), each row is checked for estimability. If PROC PHREG finds a contrast to be nonestimable, it displays missing values in corresponding rows in the results. PROC PHREG handles missing level combinations of categorical variables in the same manner as PROC GLM. Parameters corresponding to missing level combinations are not included in the model. This convention can affect the way in which you specify the **L** matrix in your CONTRAST statement. If the elements of **L** are not specified for an effect that contains a specified effect, then the elements of the specified effect are distributed over the levels of the higher-order effect just as the GLM procedure does for its CONTRAST and ESTIMATE statements. For example, suppose that the model contains effects A and B and their interaction A*B. If you specify a CONTRAST statement involving A alone, the **L** matrix contains nonzero terms for both A and A*B, since A*B contains A.

The Cox model contains no explicit intercept parameter, so it is not valid to specify one in the CONTRAST statement. As a consequence, you can test or estimate only homogeneous linear combinations (those with zero-intercept coefficients, such as contrasts that represent group differences) for the GLM parameterization.

The degrees of freedom are the number of linearly independent constraints implied by the CONTRAST statement—that is, the rank of **L**.

You can specify the following *options* after a slash (/).

ALPHA= *p*
: specifies the level of significance *p* for the $100(1-p)\%$ confidence interval for each contrast when the ESTIMATE option is specified. The value *p* must be between 0 and 1. By default, *p* is equal to the value of the ALPHA= option in the PROC PHREG statement, or 0.05 if that option is not specified.

E
: requests that the **L** matrix be displayed.

ESTIMATE=*keyword*
: requests that each individual contrast (that is, each row, $l_i'\boldsymbol{\beta}$, of $\mathbf{L}\boldsymbol{\beta}$) or exponentiated contrast ($e^{l_i'\boldsymbol{\beta}}$) be estimated and tested. PROC PHREG displays the point estimate, its standard error, a Wald confidence interval, and a Wald chi-square test for each contrast. The significance level of the confidence interval is controlled by the ALPHA= option. You can estimate the contrast or the exponentiated contrast ($e^{l_i'\boldsymbol{\beta}}$), or both, by specifying one of the following *keywords*:

PARM	specifies that the contrast itself be estimated.
EXP	specifies that the exponentiated contrast be estimated.
BOTH	specifies that both the contrast and the exponentiated contrast be estimated.

SINGULAR=*number*
: tunes the estimability check. This option is ignored when the full-rank parameterization is used. If $\boldsymbol{v}$ is a vector, define ABS($\boldsymbol{v}$) to be the largest absolute value of the elements of $\boldsymbol{v}$. For a row vector $\boldsymbol{l}'$ of the contrast matrix **L**, define c to be equal to ABS($\boldsymbol{l}$) if ABS($\boldsymbol{l}$) is greater than 0; otherwise, c equals 1. If ABS($\boldsymbol{l}' - \boldsymbol{l}'\mathbf{T}$) is greater than $c * \textit{number}$, then $\boldsymbol{l}$ is declared nonestimable. The **T** matrix is the Hermite form matrix $\mathbf{I}_0^-\mathbf{I}_0$, where $\mathbf{I}_0^-$ represents a generalized inverse of the information matrix $\mathbf{I}_0$ of the null model. The value for *number* must be between 0 and 1; the default value is 1E−4.

TEST<(*keywords*)>
requests a Type 3 test for each contrast. The default is to use the Wald statistic, but you can requests other statistics by specifying one or more of the following *keywords*:

ALL
requests the likelihood ratio tests, the score tests, and the Wald tests. Specifying TEST(ALL) is equivalent to specifying TEST=(LR SCORE WALD).

NONE
suppresses the Type 3 analysis. Even if the TEST option is not specified, PROC PHREG displays the Wald test results for each model effect if a CLASS variable is involved in a MODEL effect. The NONE option can be used to suppress such display.

LR
requests the likelihood ratio tests. This request is not honored if the COVS option is also specified.

SCORE
requests the score tests. This request is not honored if the COVS option is also specified.

WALD
requests the Wald tests.

EFFECT Statement

EFFECT *name = effect-type (variables </ options>)* **;**

The EFFECT statement enables you to construct special collections of columns for design matrices. These collections are referred to as *constructed effects* to distinguish them from the usual model effects formed from continuous or classification variables, as discussed in the section "GLM Parameterization of Classification Variables and Effects" on page 397 of Chapter 19, "Shared Concepts and Topics."

The following *effect-types* are available:

COLLECTION	is a collection effect that defines one or more variables as a single effect with multiple degrees of freedom. The variables in a collection are considered as a unit for estimation and inference.
LAG	is a classification effect in which the level that is used for a given period corresponds to the level in the preceding period. **Note:** The LAG *effect-type* is experimental in this release.
MULTIMEMBER | MM	is a multimember classification effect whose levels are determined by one or more variables that appear in a CLASS statement.
POLYNOMIAL | POLY	is a multivariate polynomial effect in the specified numeric variables.
SPLINE	is a regression spline effect whose columns are univariate spline expansions of one or more variables. A spline expansion replaces the original variable with an expanded or larger set of new variables.

Table 66.3 summarizes important options for each type of EFFECT statement.

Table 66.3 Important EFFECT Statement Options

Option	Description
Options for Collection Effects	
DETAILS	Displays the constituents of the collection effect
Options for Lag Effects	
DESIGNROLE=	Names a variable that controls to which lag design an observation is assigned
DETAILS	Displays the lag design of the lag effect
NLAG=	Specifies the number of periods in the lag
PERIOD=	Names the variable that defines the period
WITHIN=	Names the variable or variables that define the group within which each period is defined
Options for Multimember Effects	
NOEFFECT	Specifies that observations with all missing levels for the multimember variables should have zero values in the corresponding design matrix columns
WEIGHT=	Specifies the weight variable for the contributions of each of the classification effects
Options for Polynomial Effects	
DEGREE=	Specifies the degree of the polynomial
MDEGREE=	Specifies the maximum degree of any variable in a term of the polynomial
STANDARDIZE=	Specifies centering and scaling suboptions for the variables that define the polynomial
Options for Spline Effects	
BASIS=	Specifies the type of basis (B-spline basis or truncated power function basis) for the spline expansion
DEGREE=	Specifies the degree of the spline transformation
KNOTMETHOD=	Specifies how to construct the knots for spline effects

For further details about the syntax of these *effect-types* and how columns of constructed effects are computed, see the section "EFFECT Statement" on page 406 of Chapter 19, "Shared Concepts and Topics."

ESTIMATE Statement

ESTIMATE < *'label'* > *estimate-specification* < **(***divisor***=***n***)** >
< **,** < *'label'* > *estimate-specification* < **(***divisor***=***n***)** > > < **,** . . . >
< **/** *options* > **;**

The ESTIMATE statement provides a mechanism for obtaining custom hypothesis tests. Estimates are formed as linear estimable functions of the form $\mathbf{L}\boldsymbol{\beta}$. You can perform hypothesis tests for the estimable functions, construct confidence limits, and obtain specific nonlinear transformations.

Table 66.4 summarizes important *options* in the ESTIMATE statement. If the BAYES statement is specified, the ADJUST=, STEPDOWN, TESTVALUE, LOWER, UPPER, and JOINT options are ignored. The PLOTS= option is not available for the maximum likelihood anaysis. It is available only for the Bayesian analysis.

Table 66.4 Important ESTIMATE Statement Options

Option	Description
Construction and Computation of Estimable Functions	
DIVISOR=	Specifies a list of values to divide the coefficients
NOFILL	Suppresses the automatic fill-in of coefficients for higher-order effects
SINGULAR=	Tunes the estimability checking difference
Degrees of Freedom and *p*-values	
ADJUST=	Determines the method for multiple comparison adjustment of estimates
ALPHA=α	Determines the confidence level $(1-\alpha)$
LOWER	Performs one-sided, lower-tailed inference
STEPDOWN	Adjusts multiplicity-corrected p-values further in a step-down fashion
TESTVALUE=	Specifies values under the null hypothesis for tests
UPPER	Performs one-sided, upper-tailed inference
Statistical Output	
CL	Constructs confidence limits
CORR	Displays the correlation matrix of estimates
COV	Displays the covariance matrix of estimates
E	Prints the **L** matrix
JOINT	Produces a joint F or chi-square test for the estimable functions
PLOTS=	Requests ODS statistical graphics if the analysis is sampling-based
SEED=	Specifies the seed for computations that depend on random numbers

For details about the syntax of the ESTIMATE statement, see the section "ESTIMATE Statement" on page 451 of Chapter 19, "Shared Concepts and Topics."

FREQ Statement

FREQ *variable* < */option* > **;**

The FREQ statement identifies the *variable* (in the input data set) that contains the frequency of occurrence of each observation. PROC PHREG treats each observation as if it appears *n* times, where *n* is the value of the FREQ variable for the observation. If not an integer, the frequency value is truncated to an integer. If the frequency value is missing, the observation is not used in the estimation of the regression parameters.

The following option can be specified in the FREQ statement after a slash (/):

NOTRUNCATE
NOTRUNC
specifies that frequency values are not truncated to integers.

HAZARDRATIO Statement

HAZARDRATIO < *'label'* > *variable* < */ options* > **;**

The HAZARDRATIO statement enables you to request hazard ratios for any variable in the model at customized settings. For example, if the model contains the interaction of a CLASS variable A and a continuous variable X, the following specification displays a table of hazard ratios comparing the hazards of each pair of levels of A at X=3:

```
hazardratio A / at (X=3) diff=ALL;
```

The HAZARDRATIO statement identifies the variable whose hazard ratios are to be evaluated. If the variable is a continuous variable, the hazard ratio compares the hazards for a given change (by default, a increase of 1 unit) in the variable. For a CLASS variable, a hazard ratio compares the hazards of two levels of the variable. More than one HAZARDRATIO statement can be specified, and an optional label (specified as a quoted string) helps identify the output.

Options for the HAZARDRATIO statement are as follows.

ALPHA=*number*
specifies the alpha level of the interval estimates for the hazard ratios. The value must be between 0 and 1. The default is the value of the ALPHA= option in the PROC PHREG statement, or 0.05 if that option is not specified.

AT (*variable***=ALL | REF |** *list* **< . . .** *variable***=ALL | REF |** *list* **>)**
specifies the variables that interact with the variable of interest and the corresponding values of the interacting variables. If the interacting variable is continuous and a numeric list is specified after the equal sign, hazard ratios are computed for each value in the list. If the interacting variable is a CLASS variable, you can specify, after the equal sign, a list of quoted strings corresponding to various levels of the CLASS variable, or you can specify the keyword ALL or REF. Hazard ratios are computed at each value of the list if the list is specified, or at each level of the interacting variable if ALL is specified, or at the reference level of the interacting variable if REF is specified.

If this option is not specified, PROC PHREG finds all the variables that interact with the variable of interest. If an interacting variable is a CLASS variable, *variable*= ALL is the default; if the interacting variable is continuous, *variable*=*m* is the default, where *m* is the average of all the sampled values of the continuous variable.

Suppose the model contains two interactions: an interaction A*B of CLASS variables A and B, and another interaction A*X of A with a continuous variable X. If 3.5 is the average of the sampled values of X, the following two HAZARDRATIO statements are equivalent:

```
hazardratio A;
hazardratio A / at (B=ALL X=3.5);
```

CL=WALD | PL | BOTH
specifies whether to create the Wald or profile-likelihood confidence limits, or both for the classical analyis. By default, Wald confidence limits are produced. This option is not applicable to a Bayesian analysis.

DIFF=ALL | REF
specifies which differences to consider for the level comparisons of a CLASS variable. The default is DIFF=ALL. This option is ignored in the estimation of hazard ratios for a continuous variable. DIFF=ALL requests all differences, and DIFF=REF requests comparisons between the reference level and all other levels of the CLASS variable.

E
displays the vector $\mathbf{h}$ of linear coefficients such that $\mathbf{h}'\boldsymbol{\beta}$ is the log-hazard ratio, with $\boldsymbol{\beta}$ being the vector of regression coefficients.

PLCONV=*value*
controls the convergence criterion for the profile-likelihood confidence limits. The quantity *value* must be a positive number, with a default value of 1E–4. The PLCONV= option has no effect if profile-likelihood confidence intervals (CL=PL) are not requested.

PLMAXIT=*n*
specifies the maximum number of iterations to achieve the convergence of the profile-likelihood confidence limits. By default, PLMAXITER=25. If convergence is not attained in *n* iterations, the corresponding profile-likelihood confidence limit for the hazard ratio is set to missing. The PLMAXITER= option has no effect if profile-likelihood confidence intervals (CL=PL) are not requested.

PLSINGULAR=*value*
specifies the tolerance for testing the singularity of the Hessian matrix in the computation of the profile-likelihood confidence limits. The test requires that a pivot for sweeping this matrix be at least this number times a norm of the matrix. Values of the PLSINGULAR= option must be numeric. By default, *value* is the machine epsilon times 1E7, which is approximately 1E–9. The PLSINGULAR= option has no effect if profile-likelihood confidence intervals (CL=PL) are not requested.

UNITS=*value*
specifies the units of change in the continuous explanatory variable for which the customized hazard ratio is estimated. The default is UNITS=1. This option is ignored in the computation of the hazard ratios for a CLASS variable.

ID Statement

ID *variables* **;**

The ID statement specifies additional variables for identifying observations in the input data. These variables are placed in the OUT= data set created by the OUTPUT statement. In the computation of the COVSANDWICH estimate, you can aggregate over distinct values of these ID variables.

Only variables in the input data set can be included in the ID statement.

LSMEANS Statement

LSMEANS < *model-effects* > < / *options* > **;**

The LSMEANS statement compares least squares means (LS-means) of fixed effects. LS-means are *predicted population margins*—that is, they estimate the marginal means over a balanced population. In a sense, LS-means are to unbalanced designs as class and subclass arithmetic means are to balanced designs.

Table 66.5 summarizes important options in the LSMEANS statement. If the BAYES statement is specified, the ADJUST=, STEPDOWN, and LINES options are ignored. The PLOTS= option is not available for the maximum likelihood analysis. It is available only for the Bayesian analysis.

Table 66.5 Important LSMEANS Statement Options

Option	Description
Construction and Computation of LS-Means	
AT	Modifies the covariate value in computing LS-means
BYLEVEL	Computes separate margins
DIFF	Requests differences of LS-means
OM=	Specifies the weighting scheme for LS-means computation as determined by the input data set
SINGULAR=	Tunes estimability checking
Degrees of Freedom and *p*-values	
ADJUST=	Determines the method for multiple comparison adjustment of LS-means differences
ALPHA=α	Determines the confidence level ($1-\alpha$)
STEPDOWN	Adjusts multiple comparison *p*-values further in a step-down fashion

Table 66.5 *continued*

Option	Description
Statistical Output	
CL	Constructs confidence limits for means and mean differences
CORR	Displays the correlation matrix of LS-means
COV	Displays the covariance matrix of LS-means
E	Prints the **L** matrix
LINES	Produces a "Lines" display for pairwise LS-means differences
MEANS	Prints the LS-means
PLOTS=	Requests ODS statistical graphics of means and mean comparisons
SEED=	Specifies the seed for computations that depend on random numbers

For details about the syntax of the LSMEANS statement, see the section "LSMEANS Statement" on page 467 of Chapter 19, "Shared Concepts and Topics."

LSMESTIMATE Statement

LSMESTIMATE *model-effect* < *'label'* > *values* < *divisor*=*n* >
< , < *'label'* > *values* < *divisor*=*n* > > < , . . . >
< / *options* > ;

The LSMESTIMATE statement provides a mechanism for obtaining custom hypothesis tests among least squares means.

Table 66.6 summarizes important options in the LSMESTIMATE statement. If the BAYES statement is specified, the ADJUST=, STEPDOWN, TESTVALUE, LOWER, UPPER, and JOINT options are ignored. The PLOTS= option is not available for the maximum likelihood anaysis. It is available only for the Bayesian analysis.

Table 66.6 Important LSMESTIMATE Statement Options

Option	Description
Construction and Computation of LS-Means	
AT	Modifies covariate values in computing LS-means
BYLEVEL	Computes separate margins
DIVISOR=	Specifies a list of values to divide the coefficients
OM=	Specifies the weighting scheme for LS-means computation as determined by a data set
SINGULAR=	Tunes estimability checking

Table 66.6 *continued*

Option	Description
Degrees of Freedom and *p*-values	
ADJUST=	Determines the method for multiple comparison adjustment of LS-means differences
ALPHA=α	Determines the confidence level ($1-\alpha$)
LOWER	Performs one-sided, lower-tailed inference
STEPDOWN	Adjusts multiple comparison *p*-values further in a step-down fashion
TESTVALUE=	Specifies values under the null hypothesis for tests
UPPER	Performs one-sided, upper-tailed inference
Statistical Output	
CL	Constructs confidence limits for means and mean differences
CORR	Displays the correlation matrix of LS-means
COV	Displays the covariance matrix of LS-means
E	Prints the **L** matrix
ELSM	Prints the **K** matrix
JOINT	Produces a joint F or chi-square test for the LS-means and LS-means differences
PLOTS=	Requests ODS statistical graphics of means and mean comparisons
SEED=	Specifies the seed for computations that depend on random numbers

For details about the syntax of the LSMESTIMATE statement, see the section "LSMESTIMATE Statement" on page 483 of Chapter 19, "Shared Concepts and Topics."

MODEL Statement

MODEL *response* < **censor (list)* > = *effects* < */options* > **;**

MODEL *(t1, t2)* < **censor(list)* > = *effects* < */options* > **;**

The MODEL statement identifies the variables to be used as the failure time variables, the optional censoring variable, and the explanatory effects, including covariates, main effects, interactions, nested effects; see the section "Specification of Effects" on page 3209 of Chapter 41, "The GLM Procedure," for more information. A note of caution: specifying the effect T*A in the MODEL statement, where T is the time variable and A is a CLASS variable, does not make the effect time-dependent. See the section "Time and CLASS Variables Usage" on page 5431 for more information.

Two forms of MODEL syntax can be specified; the first form allows one time variable, and the second form allows two time variables for the counting process style of input (see the section "Counting Process Style of Input" on page 5437 for more information).

In the first MODEL statement, the name of the failure time variable precedes the equal sign. This name can optionally be followed by an asterisk, the name of the censoring variable, and a list of censoring values (separated by blanks or commas if there is more than one) enclosed in parentheses. If the censoring variable takes on one of these values, the corresponding failure time is considered to be censored. Following the equal sign are the explanatory effects (sometimes called independent variables or covariates) for the model.

Instead of a single failure-time variable, the second MODEL statement identifies a pair of failure-time variables. Their names are enclosed in parentheses, and they signify the endpoints of a semiclosed interval $(t1, t2]$ during which the subject is at risk. If the censoring variable takes on one of the censoring values, the time $t2$ is considered to be censored.

The censoring variable must be numeric and the failure-time variables must contain nonnegative values. Any observation with a negative failure time is excluded from the analysis, as is any observation with a missing value for any of the variables listed in the MODEL statement. Failure-time variables with a SAS date format are not recommended because the dates might be translated into negative numbers and consequently the corresponding observation would be discarded.

Table 66.7 summarizes the *options* available in the MODEL statement, which can be specified after a slash (/). Four convergence criteria are allowed for the maximum likelihood optimization: ABSFCONV=, FCONV=, GCONV=, and XCONV=. If you specify more than one convergence criterion, the optimization is terminated as soon as one of the criteria is satisfied. If none of the criteria is specified, the default is GCONV=1E–8.

Table 66.7 MODEL Statement Options

Option	Description
Model Specification Options	
NOFIT	Suppresses model fitting
OFFSET=	Specifies offset variable
SELECTION=	Specifies effect selection method
Effect Selection Options	
BEST=	Controls the number of models displayed for SCORE selection
DETAILS	Requests detailed results at each step
HIERARCHY=	Specifies whether and how hierarchy is maintained and whether a single effect or multiple effects are allowed to enter or leave the model per step
INCLUDE=	Specifies number of effects included in every model
MAXSTEP=	Specifies maximum number of steps for STEPWISE selection
SEQUENTIAL	Adds or deletes effects in sequential order
SLENTRY=	Specifies significance level for entering effects
SLSTAY=	Specifies significance level for removing effects
START=	Specifies number of variables in first model
STOP=	Specifies number of variables in final model
STOPRES	Adds or deletes variables by residual chi-square criterion
Maximum Likelihood Optimization Options	
ABSFCONV=	Specifies absolute function convergence criterion
FCONV=	Specifies relative function convergence criterion

Table 66.7 *continued*

Option	Description
FIRTH	Specifies Firth's penalized likelihood method
GCONV=	Specifies relative gradient convergence criterion
XCONV=	Specifies relative parameter convergence criterion
MAXITER=	Specifies maximum number of iterations
RIDGEINIT=	Specifies the initial ridging value
RIDGING=	Specifies the technique to improve the log likelihood function when its value is worse than that of the previous step
SINGULAR=	Specifies tolerance for testing singularity
Confidence Interval Options	
ALPHA=	Specifies α for the $100(1-\alpha)\%$ confidence intervals
PLCONV=	Specifies profile-likelihood convergence criterion
RISKLIMITS=	Computes confidence intervals for hazard ratios
Display Options	
CORRB	Displays correlation matrix
COVB	Displays covariance matrix
ITPRINT	Displays iteration history
NODUMMYPRINT	suppresses "Class Level Information" table
TYPE1	Displays Type 1 analysis
TYPE3	Displays Type 3 analysis
Miscellaneous Options	
ENTRYTIME=	Specifies the delayed entry time variable
TIES=	Specifies the method of handling ties in failure times

ALPHA=*value*

sets the significance level used for the confidence limits for the hazard ratios. The quantity *value* must be between 0 and 1. The default is the value of the ALPHA= option in the PROC PHREG statement, or 0.05 if that option is not specified. This option has no effect unless the RISKLIMITS option is specified.

ABSFCONV=*value*

CONVERGELIKE=*value*

specifies the absolute function convergence criterion. Termination requires a small change in the objective function (log partial likelihood function) in subsequent iterations,

$$|l_k - l_{k-1}| < value$$

where l_k is the value of the objective function at iteration k.

BEST=*n*

is used exclusively with the SCORE model selection method. The BEST=*n* option specifies that *n* models with the highest-score chi-square statistics are to be displayed for each model size. If the option is omitted and there are no more than 10 explanatory variables, then all possible models are listed for each model size. If the option is omitted and there are more than 10 explanatory variables,

then the number of models selected for each model size is, at most, equal to the number of explanatory variables listed in the MODEL statement.

See Example 66.2 for an illustration of the SCORE selection method and the BEST= option.

CORRB
displays the estimated correlation matrix of the parameter estimates.

COVB
displays the estimated covariance matrix of the parameter estimates.

DETAILS
produces a detailed display at each step of the model-building process. It produces an "Analysis of Variables Not in the Model" table before displaying the variable selected for entry for FORWARD or STEPWISE selection. For each model fitted, it produces the "Analysis of Maximum Likelihood Estimates" table.

See Example 66.1 for a discussion of these tables.

ENTRYTIME=*variable*
ENTRY=*variable*
specifies the name of the variable that represents the left-truncation time. This option has no effect when the counting process style of input is specified. See the section "Left-Truncation of Failure Times" on page 5438 for more information.

FCONV=*value*
specifies the relative function convergence criterion. Termination requires a small relative change in the objective function (log partial likelihood function) in subsequent iterations,

$$\frac{|l_k - l_{k-1}|}{|l_{k-1}| + 1\mathrm{E}-6} < \mathit{value}$$

where l_k is the value of the objective function at iteration k.

FIRTH
performs Firth's penalized maximum likelihood estimation to reduce bias in the parameter estimates (Heinze and Schemper 2001; Firth 1993). This method is useful when the likelihood is monotone—that is, the likelihood converges to finite value while at least one estimate diverges to infinity.

GCONV=*value*
specifies the relative gradient convergence criterion. Termination requires that the normalized prediction function reduction is small,

$$\frac{\mathbf{g}_k \mathbf{H}_k^{-1} \mathbf{g}_k}{|l_k| + 1\mathrm{E}-6} < \mathit{value}$$

where l_k is the log partial likelihood, $\mathbf{g}_k$ is the gradient vector (first partial derivatives of the log partial likelihood), and $\mathbf{H}_k$ is the negative Hessian matrix (second partial derivatives of the log partial likelihood), all at iteration k.

HIERARCHY=*keyword*
HIER=*keyword*

specifies whether and how the model hierarchy requirement is applied and whether a single effect or multiple effects are allowed to enter or leave the model in one step. You can specify that only CLASS variable effects, or both CLASS and continuous variable effects, be subject to the hierarchy requirement. The HIERARCHY= option is ignored unless you also specify the FORWARD, BACKWARD, or STEPWISE selection method.

Model hierarchy refers to the requirement that, for any term to be in the model, all effects contained in the term must be present in the model. For example, in order for the interaction A*B to enter the model, the main effects A and B must be in the model. Likewise, neither effect A nor B can leave the model while the interaction A*B is in the model.

You can specify any of the following *keywords* in the HIERARCHY= option:

NONE
indicates that the model hierarchy is not maintained. Any single effect can enter or leave the model at any given step of the selection process.

SINGLE
indicates that only one effect can enter or leave the model at one time, subject to the model hierarchy requirement. For example, suppose that you specify the main effects A and B and the interaction of A*B in the model. In the first step of the selection process, either A or B can enter the model. In the second step, the other main effect can enter the model. The interaction effect can enter the model only when both main effects have already been entered. Also, before A or B can be removed from the model, the A*B interaction must first be removed. All effects (CLASS and continuous variables) are subject to the hierarchy requirement.

SINGLECLASS
is the same as HIERARCHY=SINGLE except that only CLASS effects are subject to the hierarchy requirement.

MULTIPLE
indicates that more than one effect can enter or leave the model at one time, subject to the model hierarchy requirement. In a forward selection step, a single main effect can enter the model, or an interaction can enter the model together with all the effects that are contained in the interaction. In a backward elimination step, an interaction itself, or the interaction together with all the effects that the interaction contains, can be removed. All effects (CLASS and continuous variable) are subject to the hierarchy requirement.

MULTIPLECLASS
is the same as HIERARCHY=MULTIPLE except that only CLASS effects are subject to the hierarchy requirement.

The default value is HIERARCHY=SINGLE, which means that model hierarchy is to be maintained for all effects (that is, both CLASS and continuous variable effects) and that only a single effect can enter or leave the model at each step.

INCLUDE=*n*
includes the first *n* effects in the MODEL statement in every model. By default, INCLUDE=0. The INCLUDE= option has no effect when SELECTION=NONE.

ITPRINT
displays the iteration history, including the last evaluation of the gradient vector.

MAXITER=*n*
specifies the maximum number of iterations allowed. The default value for *n* is 25. If convergence is not attained in *n* iterations, the displayed output and all data sets created by PROC PHREG contain results that are based on the last maximum likelihood iteration.

MAXSTEP=*n*
specifies the maximum number of times the explanatory variables can move in and out of the model before the STEPWISE model-building process ends. The default value for *n* is twice the number of explanatory variables in the MODEL statement. The option has no effect for other model selection methods.

NODUMMYPRINT

NODESIGNPRINT

NODP
suppresses the "Class Level Information" table, which shows how the design matrix columns for the CLASS variables are coded.

NOFIT
performs the global score test, which tests the joint significance of all the explanatory variables in the MODEL statement. No parameters are estimated. If the NOFIT option is specified along with other MODEL statement options, NOFIT takes precedence, and all other options are ignored except the TIES= option.

OFFSET=*name*
specifies the name of an offset variable, which is an explanatory variable with a regression coefficient fixed as one. This option can be used to incorporate risk weights for the likelihood function.

PLCONV=*value*
controls the convergence criterion for confidence intervals based on the profile-likelihood function. The quantity *value* must be a positive number, with a default value of 1E−4. The PLCONV= option has no effect if profile-likelihood based confidence intervals are not requested.

RIDGING=*keyword*
specifies the technique to improve the log likelihood when its value is worse than that of the previous step. The available *keywords* are as follows:

ABSOLUTE
specifies that the diagonal elements of the negative (expected) Hessian be inflated by adding the ridge value.

RELATIVE
specifies that the diagonal elements be inflated by the factor equal to 1 plus the ridge value.

NONE
specifies the crude line-search method of taking half a step be used instead of ridging.

The default is RIDGING=RELATIVE.

RIDGEINIT=*value*

specifies the initial ridge value. The maximum ridge value is 2000 times the maximum of 1 and the initial ridge value. The initial ridge value is raised to 1E–4 if it is less than 1E–4. By default, RIDGEINIT=1E–4. This option has no effect for RIDGING=ABSOLUTE.

RISKLIMITS< =*keyword* **>**

RL< =*keyword* **>**

produces confidence intervals for hazard ratios of main effects not involved in interactions or nestings. Computation of these confidence intervals is based on the profile likelihood or based on individual Wald tests. The confidence coefficient can be specified with the ALPHA= option. You can specify one of the following keywords:

PL

requests profile-likelihood confidence limits.

WALD

requests confidence limits based on the Wald tests.

BOTH

request both profile-likelihood and Wald confidence limits.

Classification main effects that use parameterizations other than REF, EFFECT, or GLM are ignored. If you need to compute hazard ratios for an effect involved in interactions or nestings, or using some other parameterization, then you should specify a HAZARDRATIO statement for that effect.

SELECTION=*method*

specifies the method used to select the model. The *methods* available are as follows:

BACKWARD

B

requests backward elimination.

FORWARD

F

requests forward selection.

NONE

N

fits the complete model specified in the MODEL statement. This is the default value.

SCORE

requests best subset selection. It identifies a specified number of models with the highest-score chi-square statistic for all possible model sizes ranging from one explanatory variable to the total number of explanatory variables listed in the MODEL statement. This option is not allowed if an explanatory effect in the MODEL statement contains a CLASS variable.

STEPWISE

S

requests stepwise selection.

For more information, see the section "Effect Selection Methods" on page 5468.

SEQUENTIAL

forces variables to be added to the model in the order specified in the MODEL statement or to be eliminated from the model in the reverse order of that specified in the MODEL statement.

SINGULAR=*value*

specifies the singularity criterion for determining linear dependencies in the set of explanatory variables. The default value is 1E–12.

SLENTRY=*value*

SLE=*value*

specifies the significance level (a value between 0 and 1) for entering an explanatory variable into the model in the FORWARD or STEPWISE method. For all variables not in the model, the one with the smallest *p*-value is entered if the *p*-value is less than or equal to the specified significance level. The default value is 0.05.

SLSTAY=*value*

SLS=*value*

specifies the significance level (a value between 0 and 1) for removing an explanatory variable from the model in the BACKWARD or STEPWISE method. For all variables in the model, the one with the largest *p*-value is removed if the *p*-value exceeds the specified significance level. The default value is 0.05.

START=*n*

begins the FORWARD, BACKWARD, or STEPWISE selection process with the first *n* effects listed in the MODEL statement. The value of *n* ranges from 0 to *s*, where *s* is the total number of effects in the MODEL statement. The default value of *n* is *s* for the BACKWARD method and 0 for the FORWARD and STEPWISE methods. Note that START=*n* specifies only that the first *n* effects appear in the first model, while INCLUDE=*n* requires that the first *n* effects be included in every model. For the SCORE method, START=*n* specifies that the smallest models contain *n* effects, where *n* ranges from 1 to *s*; the default value is 1. The START= option has no effect when SELECTION=NONE.

STOP=*n*

specifies the maximum (FORWARD method) or minimum (BACKWARD method) number of effects to be included in the final model. The effect selection process is stopped when *n* effects are found. The value of *n* ranges from 0 to *s*, where *s* is the total number of effects in the MODEL statement. The default value of *n* is *s* for the FORWARD method and 0 for the BACKWARD method. For the SCORE method, STOP=*n* specifies that the smallest models contain *n* effects, where *n* ranges from 1 to *s*; the default value of *n* is *s*. The STOP= option has no effect when SELECTION=NONE or STEPWISE.

STOPRES

SR

specifies that the addition and deletion of variables be based on the result of the likelihood score test for testing the joint significance of variables not in the model. This score chi-square statistic is referred to as the residual chi-square. In the FORWARD method, the STOPRES option enters the explanatory variables into the model one at a time until the residual chi-square becomes insignificant (that is, until the *p*-value of the residual chi-square exceeds the SLENTRY= value). In the BACKWARD

method, the STOPRES option removes variables from the model one at a time until the residual chi-square becomes significant (that is, until the p-value of the residual chi-square becomes less than the SLSTAY= value). The STOPRES option has no effect for the STEPWISE method.

TYPE1

requests that a Type 1 (sequential) analysis of likelihood ratio test be performed. This consists of sequentially fitting models, beginning with the null model and continuing up to the model specified in the MODEL statement. The likelihood ratio statistic for each successive pair of models is computed and displayed in a table.

TYPE3 < (*keywords*) >

requests a Type 3 test for each effect that is specified in the MODEL statement. The default is to use the Wald statistic, but you can requests other statistics by specifying one or more of the following *keywords*:

ALL

requests the likelihood ratio tests, the score tests, and the Wald tests. Specifying TYPE3(ALL) is equivalent to specifying TYPE3=(LR SCORE WALD).

NONE

suppresses the Type 3 analysis. Even if the TYPE3 option is not specified, PROC PHREG displays the Wald test results for each model effect if a CLASS variable is involved in a MODEL effect. The NONE option can be used to suppress such display.

LR

requests the likelihood ratio tests. This request is not honored if the COVS option is also specified.

SCORE

requests the score tests. This request is not honored if the COVS option is also specified.

WALD

requests the Wald tests.

TIES=*method*

specifies how to handle ties in the failure time. The following *methods* are available:

BRESLOW

uses the approximate likelihood of Breslow (1974). This is the default value.

DISCRETE

replaces the proportional hazards model by the discrete logistic model

$$\frac{\lambda(t;\mathbf{z})}{1-\lambda(t;\mathbf{z})} = \frac{\lambda_0(t)}{1-\lambda_0(t)}\exp(\mathbf{z}'\boldsymbol{\beta})$$

where $\lambda_0(t)$ and $h(t;\mathbf{z})$ are discrete hazard functions.

EFRON

uses the approximate likelihood of Efron (1977).

EXACT

computes the exact conditional probability under the proportional hazards assumption that all tied event times occur before censored times of the same value or before larger values. This is equivalent to summing all terms of the marginal likelihood for $\boldsymbol{\beta}$ that are consistent with the observed data (Kalbfleisch and Prentice 1980; DeLong, Guirguis, and So 1994).

The EXACT method can take a considerable amount of computer resources. If ties are not extensive, the EFRON and BRESLOW methods provide satisfactory approximations to the EXACT method for the continuous time-scale model. In general, Efron's approximation gives results that are much closer to the EXACT method results than Breslow's approximation does. If the time scale is genuinely discrete, you should use the DISCRETE method. The DISCRETE method is also required in the analysis of case-control studies when there is more than one case in a matched set. If there are no ties, all four methods result in the same likelihood and yield identical estimates. The default, TIES=BRESLOW, is the most efficient method when there are no ties.

XCONV=*value*

CONVEREPARM=*value*

specifies the relative parameter convergence criterion. Termination requires a small relative parameter change in subsequent iterations,

$$\max_i |\delta_k^{(i)}| < value$$

where

$$\delta_k^{(i)} = \begin{cases} \theta_k^{(i)} - \theta_{k-1}^{(i)} & |\theta_{k-1}^{(i)}| < .01 \\ \frac{\theta_k^{(i)} - \theta_{k-1}^{(i)}}{\theta_{k-1}^{(i)}} & \text{otherwise} \end{cases}$$

where $\theta_k^{(i)}$ is the estimate of the ith parameter at iteration k.

OUTPUT Statement

OUTPUT *< OUT=SAS-data-set > < keyword=name . . . keyword=name > < /options >* **;**

The OUTPUT statement creates a new SAS data set containing statistics calculated for each observation. These can include the estimated linear predictor ($\mathbf{z}_j'\hat{\boldsymbol{\beta}}$) and its standard error, survival distribution estimates, residuals, and influence statistics. In addition, this data set includes the time variable, the explanatory variables listed in the MODEL statement, the censoring variable (if specified), and the BY, STRATA, FREQ, and ID variables (if specified).

For observations with missing values in the time variable or any explanatory variables, the output statistics are set to missing. However, for observations with missing values only in the censoring variable or the FREQ variable, survival estimates are still computed. Therefore, by adding observations with missing values in the FREQ variable or the censoring variable, you can compute the survivor function estimates for new observations or for settings of explanatory variables not present in the data without affecting the model fit.

No OUTPUT data set is created if the model contains a time-dependent variable defined by means of programming statements.

The following list explains specifications in the OUTPUT statement.

OUT=*SAS-data-set*

names the output data set. If you omit the OUT= option, the OUTPUT data set is created and given a default name by using the DATA*n* convention. See the section "OUT= Output Data Set in the OUTPUT Statement" on page 5483 for more information.

keyword=name

specifies the statistics included in the OUTPUT data set and names the new variables that contain the statistics. Specify a keyword for each desired statistic (see the following list of keywords), an equal sign, and either a variable or a list of variables to contain the statistic. The keywords that accept a list of variables are DFBETA, RESSCH, RESSCO, and WTRESSCH. For these keywords, you can specify as many names in *name* as the number of explanatory variables specified in the MODEL statement. If you specify k names and k is less than the total number of explanatory variables, only the changes for the first k parameter estimates are output. The keywords and the corresponding statistics are as follows:

ATRISK

specifies the number of subjects at risk at the observation time τ_j (or at the right endpoint of the at-risk interval when a counting process MODEL specification is used).

DFBETA

specifies the approximate changes in the parameter estimates $(\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(j)})$ when the jth observation is omitted. These variables are a weighted transform of the score residual variables and are useful in assessing local influence and in computing robust variance estimates.

LD

specifies the approximate likelihood displacement when the observation is left out. This diagnostic can be used to assess the impact of each observation on the overall fit of the model.

LMAX

specifies the relative influence of observations on the overall fit of the model. This diagnostic is useful in assessing the sensitivity of the fit of the model to each observation.

LOGLOGS

specifies the log of the negative log of SURVIVAL.

LOGSURV

specifies the log of SURVIVAL.

RESDEV

specifies the deviance residual $\hat{D}_j$. This is a transform of the martingale residual to achieve a more symmetric distribution.

RESMART

specifies the martingale residual $\hat{M}_j$. The residual at the observation time τ_j can be interpreted as the difference over $[0, \tau_j]$ in the observed number of events minus the expected number of events given by the model.

RESSCH
specifies the Schoenfeld residuals. These residuals are useful in assessing the proportional hazards assumption.

RESSCO
specifies the score residuals. These residuals are a decomposition of the first partial derivative of the log likelihood. They can be used to assess the leverage exerted by each subject in the parameter estimation. They are also useful in constructing robust sandwich variance estimators.

STDXBETA
specifies the standard error of the XBETA predictor, $\sqrt{\mathbf{z}_j' \hat{\mathbf{V}}(\hat{\boldsymbol{\beta}}) \mathbf{z}_j}$.

SURVIVAL
specifies the survivor function estimate $\hat{S}_j = [\hat{S}_0(\tau_j)]^{\exp(\mathbf{z}_j' \hat{\boldsymbol{\beta}})}$, where τ_j is the observation time.

WTRESSCH
specifies the weighted Schoenfeld residuals. These residuals are useful in investigating the nature of nonproportionality if the proportional hazard assumption does not hold.

XBETA
specifies the estimate of the linear predictor, $\mathbf{z}_j' \hat{\boldsymbol{\beta}}$.

The following *options* can appear in the OUTPUT statement after a slash (/) as follows:

ORDER=*value*
specifies the order of the observations in the OUTPUT data set. The following *values* are available:

DATA requests that the output observations be sorted the same as the input data set.

SORTED requests that the output observations be sorted by strata and descending order of the time variable within each stratum.

The default is ORDER=DATA.

METHOD=*method*
specifies the method used to compute the survivor function estimates. The following *methods* are as available:

CH

EMP
specifies that the empirical cumulative hazard function estimate of the survivor function be computed; that is, the survivor function is estimated by exponentiating the negative empirical cumulative hazard function.

PL
specifies that the product-limit estimate of the survivor function be computed.

The default is METHOD=BRESLOW.

Programming Statements

Programming statements are used to create or modify the values of the explanatory variables in the MODEL statement. They are especially useful in fitting models with time-dependent explanatory variables. Programming statements can also be used to create explanatory variables that are not time dependent. For example, you can create indicator variables from a categorical variable and incorporate them into the model. PROC PHREG programming statements cannot be used to create or modify the values of the response variable, the censoring variable, the frequency variable, or the strata variables.

The following DATA step statements are available in PROC PHREG:

```
ABORT
ARRAY
assignment statements
CALL
DO
iterative DO
DO UNTIL
DO WHILE
END
GOTO
IF-THEN/ELSE
LINK-RETURN
PUT
SELECT
SUM statement
```

By default, the PUT statement in PROC PHREG writes results to the Output window instead of the Log window. If you want the results of the PUT statements to go to the Log window, add the following statement before the PUT statements:

```
FILE LOG;
```

DATA step functions are also available. Use these programming statements the same way you use them in the DATA step. For detailed information, refer to *SAS Language Reference: Dictionary*.

Consider the following example of using programming statements in PROC PHREG. Suppose blood pressure is measured at multiple times during the course of a study investigating the effect of blood pressure on some survival time. By treating the blood pressure as a time-dependent explanatory variable, you are able to use the value of the most recent blood pressure at each specific point of time in the modeling process rather than using the initial blood pressure or the final blood pressure. The values of the following variables are recorded for each patient, if they are available. Otherwise, the variables contain missing values.

Time	survival time
Censor	censoring indicator (with 0 as the censoring value)
BP0	blood pressure on entry to the study
T1	time 1
BP1	blood pressure at T1
T2	time 2
BP2	blood pressure at T2

The following programming statements create a variable BP. At each time T, the value of BP is the blood pressure reading for that time, if available. Otherwise, it is the last blood pressure reading.

```
proc phreg;
   model Time*Censor(0)=BP;
   BP = BP0;
   if Time>=T1 and T1^=. then BP=BP1;
   if Time>=T2 and T2^=. then BP=BP2;
run;
```

For other illustrations of using programming statements, see the section "Classical Method of Maximum Likelihood" on page 5369 and Example 66.6.

RANDOM Statement

RANDOM *variable* < / *options* > **;**

The RANDOM statement enables you to fit a shared frailty model for clustered data with normal distributed random effects (see the section "The Frailty Model" on page 5439 for details). The *variable* that represents the clusters must be a CLASS variable (declared in the CLASS statement). Currently, Bayesian analysis is not available for the frailty model.

The following *options* can be specified in the RANDOM statement:

ABSPCONV=*r*

specifies an absolute variance estimate convergence criterion for the doubly iterative estimation process. The PHREG procedure applies this criterion to the variance parameter estimate of the random effects. Suppose $\hat{\theta}^{(j)}$ denotes the estimate of the variance parameter at the jth optimization. By default, PROC PHREG examines the relative change in the variance estimate between optimizations (see the PCONV= option). The purpose of the ABSPCONV= criterion is to stop the doubly iterative process when the absolute change $|\hat{\theta}^{(j)} - \hat{\theta}^{(j-1)}|$ is less than the tolerance criterion *r*. This convergence criterion does not affect the convergence criteria applied within any individual optimization. In order to change the convergence behavior within an individual optimization, you can use the ABSCONV=, ABSFCONV=, ABSGCONV=, ABSXCONV=, FCONV=, or GCONV= option in the NLOPTIONS statement.

ALPHA=*value*

specifies the α level of the confidence limits for the random effects. The default is the value of the ALPHA= option in the PROC PHREG statement, or 0.05 if that option is not specified. This option is ignored if the SOLUTION option is not also specified.

METHOD=REML | ML

specifies the estimation method for the variance parameter. The REML specifications performs the residual maximum likelihood; this is the default method. The ML specification performs maximum likelihood.

NOCLPRINT

suppresses the display of the "Class Level Information for Random Effects" table.

PCONV=*r*

specifies the variance estimate convergence criterion for the doubly iterative estimation process. The PHREG procedure applies this criterion to the variance estimate of the random effects. Suppose $\hat{\theta}^{(j)}$ denotes the estimate of variance at the j th optimization. The procedure terminates the doubly iterative process if the relative change

$$2 \times \frac{|\hat{\theta}^{(j)} - \hat{\theta}^{(j-1)}|}{|\hat{\theta}^{(j)}| + |\hat{\theta}^{(j-1)}|}$$

is less than *r*. To check an absolute convergence criterion in addition, you can specify the ABSPCONV= option in the RANDOM statement. The default value for *r* is 1E–4. This convergence criterion does not affect the convergence criteria applied within any individual optimization. In order to change the convergence behavior within an individual optimization, you can use the ABSCONV=, ABSFCONV=, ABSGCONV=, ABSXCONV=, FCONV=, or GCONV= option in the NLOPTIONS statement.

SOLUTION

displays estimates of the normal random effects. Also displayed are estimates of the lognormal frailites, which are the exponentiated estimates of the normal random effects.

INITIALVARIANCE=*value*

INITIAL=*value*

specifies an inital value of the variance estimate. The default is INITIAL=1.

STRATA Statement

STRATA *variable* < *(list)* > < *. . . variable* < *(list)* > > < */option* > **;**

The proportional hazards assumption might not be realistic for all data. If so, it might still be reasonable to perform a stratified analysis. The STRATA statement names the variables that determine the stratification. Strata are formed according to the nonmissing values of the STRATA variables unless the MISSING option is specified. In the STRATA statement, *variable* is a variable with values that are used to determine the strata levels, and *list* is an optional list of values for a numeric variable. Multiple variables can appear in the STRATA statement.

The values for *variable* can be formatted or unformatted. If the variable is a character variable, or if the variable is numeric and no list appears, then the strata are defined by the unique values of the variable. If the variable is numeric and is followed by a list, then the levels for that variable correspond to the intervals defined by the list. The corresponding strata are formed by the combination of levels and unique values. The list can include numeric values separated by commas or blanks, *value* to *value* by *value* range specifications, or combinations of these.

For example, the specification

```
strata age (5, 10 to 40 by 10) sex ;
```

indicates that the levels for age are to be less than 5, 5 to 10, 10 to 20, 20 to 30, 30 to 40, and greater than 40. (Note that observations with exactly the cutpoint value fall into the interval preceding the cutpoint.) Thus, with the sex variable, this STRATA statement specifies 12 strata altogether.

The following option can be specified in the STRATA statement after a slash (/):

MISSING
allows missing values ('.' for numeric variables and blanks for character variables) as valid STRATA variable values. Otherwise, observations with missing STRATA variable values are deleted from the analysis.

SLICE Statement

SLICE *model-effect* < / *options* > **;**

The SLICE statement provides a general mechanism for performing a partitioned analysis of the LS-means for an interaction. This analysis is also known as an analysis of simple effects.

The SLICE statement uses the same options as the LSMEANS statement, which are summarized in Table 19.19. For details about the syntax of the SLICE statement, see the section "SLICE Statement" on page 513 of Chapter 19, "Shared Concepts and Topics."

STORE Statement

STORE < **OUT=** >*item-store-name* < / **LABEL=***'label'* > **;**

The STORE statement requests that the procedure save the context and results of the statistical analysis. The resulting item store is a binary file format that cannot be modified. The contents of the item store can be processed with the PLM procedure.

For details about the syntax of the STORE statement, see the section "STORE Statement" on page 516 of Chapter 19, "Shared Concepts and Topics."

TEST Statement

< *label:* > **TEST** *equation* < *,. . . , equation* > < */options* > **;**

The TEST statement tests linear hypotheses about the regression coefficients. PROC PHREG performs a Wald test for the joint hypothesis specified in a single TEST statement. Each equation specifies a linear hypothesis; multiple equations (rows of the joint hypothesis) are separated by commas. The *label*, which must be a valid SAS name, is used to identify the resulting output and should always be included. You can submit multiple TEST statements.

The form of an equation is as follows:

term < ± *term* ... > <= < ± *term* < ± *term* ... >>>

where *term* is a variable or a constant or a constant times a variable. The variable is any explanatory variable in the MODEL statement. When no equal sign appears, the expression is set to 0. The following program illustrates possible uses of the TEST statement:

```
proc phreg;
   model time= A1 A2 A3 A4;
   Test1: test A1, A2;
   Test2: test A1=0,A2=0;
   Test3: test A1=A2=A3;
   Test4: test A1=A2,A2=A3;
run;
```

Note that the first and second TEST statements are equivalent, as are the third and fourth TEST statements.

The following *options* can be specified in the TEST statement after a slash (/):

AVERAGE

enables you to assess the average effect of the variables in the given TEST statement. An overall estimate of the treatment effect is computed as a weighted average of the treatment coefficients as illustrated in the following statement:

```
TREATMENT: test trt1, trt2, trt3, trt4 / average;
```

Let β_1, β_2, β_3, and β_4 be corresponding parameters for trt1, trt2, trt3, and trt4, respectively. Let $\hat{\boldsymbol{\beta}} = (\hat{\beta}_1, \hat{\beta}_2, \hat{\beta}_3, \hat{\beta}_4)'$ be the estimated coefficient vector and let $\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})$ be the corresponding variance estimate. Assuming $\beta_1 = \beta_2 = \beta_3 = \beta_4$, let $\bar{\beta}$ be the average treatment effect. The effect is estimated by $\mathbf{c}'\hat{\boldsymbol{\beta}}$, where $\mathbf{c} = [\mathbf{1}_4'\hat{\mathbf{V}}^{-1}(\hat{\boldsymbol{\beta}})\mathbf{1}_4]^{-1}\hat{\mathbf{V}}^{-1}(\hat{\boldsymbol{\beta}})\mathbf{1}_4$ and $\mathbf{1}_4 = (1,1,1,1)'$. A test of the null hypothesis $H_0 : \bar{\beta} = 0$ is also included, which is more sensitive than the multivariate test for testing the null hypothesis $H_0 : \beta 1 = \beta 2 = \beta 3 = \beta 4 = 0$.

E

specifies that the linear coefficients and constants be printed. When the AVERAGE option is specified along with the E option, the optimal weights of the average effect are also printed in the same tables as the coefficients.

PRINT

displays intermediate calculations. This includes $\mathbf{L}\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})\mathbf{L}'$ bordered by $(\mathbf{L}\hat{\boldsymbol{\beta}} - \mathbf{c})$, and $[\mathbf{L}\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})\mathbf{L}']^{-1}$ bordered by $[\mathbf{L}\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})\mathbf{L}']^{-1}(\mathbf{L}\hat{\boldsymbol{\beta}} - \mathbf{c})$, where $\mathbf{L}$ is a matrix of linear coefficients and $\mathbf{c}$ is a vector of constants.

See the section "Using the TEST Statement to Test Linear Hypotheses" on page 5452 for details.

WEIGHT Statement

WEIGHT *variable* < */option* > **;**

The *variable* in the WEIGHT statement identifies the variable in the input data set that contains the case weights. When the WEIGHT statement appears, each observation in the input data set is weighted by the value of the WEIGHT variable. The WEIGHT values can be nonintegral and are not truncated. Observations with negative, zero, or missing values for the WEIGHT variable are not used in the model fitting. When the WEIGHT statement is not specified, each observation is assigned a weight of 1. The WEIGHT statement is available for TIES=BRESLOW and TIES=EFRON only.

The following *option* can be specified in the WEIGHT statement after a slash (/):

NORMALIZE

NORM

causes the weights specified by the WEIGHT *variable* to be normalized so that they add up the actual sample size. With this option, the estimated covariance matrix of the parameter estimators is invariant to the scale of the WEIGHT variable.

Details: PHREG Procedure

Failure Time Distribution

Let T be a nonnegative random variable representing the failure time of an individual from a homogeneous population. The survival distribution function (also known as the survivor function) of T is written as

$$S(t) = \Pr(T \geq t)$$

A mathematically equivalent way of specifying the distribution of T is through its hazard function. The hazard function $\lambda(t)$ specifies the instantaneous failure rate at t. If T is a continuous random variable, $\lambda(t)$ is expressed as

$$\lambda(t) = \lim_{\Delta t \to 0^+} \frac{\Pr(t \leq T < t + \Delta t \mid T \geq t)}{\Delta t} = \frac{f(t)}{S(t)}$$

where $f(t)$ is the probability density function of T. If T is discrete with masses at $x_1 < x_2 < \ldots$, then survivor function is given by

$$S(t) = \sum_{x_j \leq t} \Pr(T = x_j) = \sum_j \Pr(T = j)\delta(t - x_j)$$

where $\delta(u)$=0 if $u < 0$ and $\delta(u)$=1 otherwise. The discrete hazards are given by

$$\lambda_j = \Pr(T = x_j \mid T \geq x_j) = \frac{\Pr(T = x_j)}{S(x_j)} \quad j = 1, 2, \ldots$$

Time and CLASS Variables Usage

The following DATA step creates an artificial data set, Test, to be used in this section. There are four variables in Test: the variable T contains the failure times; the variable Status is the censoring indicator variable with the value 1 for an uncensored failure time and the value 0 for a censored time; the variable A is a categorical variable with values 1, 2, and 3 representing three different categories; and the variable MirrorT is an exact copy of T.

```
Data Test;
   input T Status A @@;
   MirrorT = T;
   datalines;
 23        1      1    7        0      1
 23        1      1   10        1      1
 20        0      1   13        0      1
 24        1      1   10        1      1
 18        1      2    6        1      2
 18        0      2    6        1      2
 13        0      2   13        1      2
  9        0      2   15        1      2
  8        1      3    6        1      3
 12        0      3    4        1      3
 11        1      3    8        1      1
  6        1      3    7        1      3
  7        1      3   12        1      3
  9        1      2   15        1      2
  3        1      2   14        0      3
  6        1      1   13        1      2
  ;
```

Time Variable on the Right Side of the MODEL Statement

When the time variable is explicitly used in an explanatory effect in the MODEL statement, the effect is *not* time-dependent. In the following specification, T is the time variable, but T does not play the role of the time variable in the explanatory effect T*A:

```
proc phreg data=Test;
   class A;
   model T*Status(0)=T*A;
   run;
```

The parameter estimates of this model are shown in Figure 66.12.

Figure 66.12 T*A Effect

The PHREG Procedure

Analysis of Maximum Likelihood Estimates

Parameter		DF	Parameter Estimate	Standard Error	Chi-Square	Pr > ChiSq	Hazard Ratio	Label
T*A	1	1	-0.16549	0.05042	10.7734	0.0010	.	A 1 * T
T*A	2	1	-0.11852	0.04181	8.0344	0.0046	.	A 2 * T

To verify that the effect T*A in the MODEL statement is not time-dependent, T is replaced by MirrorT, which is an exact copy of T, as in the following statements:

```
proc phreg data=Test;
   class A;
   model T*Status(0)=A*MirrorT;
   run;
```

The results of fitting this model (Figure 66.13) are identical to those of the previous model (Figure 66.12), except for the parameter names and labels. The effect A*MirrorT is not time-dependent, so neither is A*T.

Figure 66.13 T*A Effect

The PHREG Procedure

Analysis of Maximum Likelihood Estimates

Parameter	DF	Parameter Estimate	Standard Error	Chi-Square	Pr > ChiSq
MirrorT*A 1	1	-0.16549	0.05042	10.7734	0.0010

MirrorT*A 1	.	A 1 * MirrorT
MirrorT*A 2	.	A 2 * MirrorT

CLASS Variables and Programming Statements

In PROC PHREG, the levels of CLASS variables are determined by the CLASS statement and the input data and are not affected by user-supplied programming statements. Consider the following statements, which produce the results in Figure 66.14. Variable A is declared as a CLASS variable in the CLASS statement. By default, the reference parameterization is used with A=3 as the reference level. Two regression coefficients are estimated for the two dummy variables of A.

```
proc phreg data=Test;
   class A;
   model T*Status(0)=A;
   run;
```

Figure 66.14 shows the dummy variables of A and the regression coefficients estimates.

Figure 66.14 Design Variable and Regression Coefficient Estimates

The PHREG Procedure

Class Level Information

Class	Value	Design Variables	
A	1	1	0
	2	0	1
	3	0	0

Analysis of Maximum Likelihood Estimates

Parameter		DF	Parameter Estimate	Standard Error	Chi-Square	Pr > ChiSq	Hazard Ratio	Label
A	1	1	-1.40925	0.64802	4.7293	0.0297	0.244	A 1
A	2	1	-0.65705	0.51764	1.6112	0.2043	0.518	A 2

Now consider the programming statement that attempts to change the value of the CLASS variable A as in the following specification:

```
proc phreg data=Test;
   class A;
   model T*Status(0)=A;
   if A=3 then A=2;
   run;
```

Results of this analysis are shown in Figure 66.15 and are identical to those in Figure 66.14. The `if A=3 then A=2` programming statement has no effects on the design variables for A, which have already been determined.

Figure 66.15 Design Variable and Regression Coefficient Estimates

The PHREG Procedure

Class Level Information

Class	Value	Design Variables	
A	1	1	0
	2	0	1
	3	0	0

Figure 66.15 *continued*

Analysis of Maximum Likelihood Estimates

Parameter		DF	Parameter Estimate	Standard Error	Chi-Square	Pr > ChiSq	Hazard Ratio	Label
A	1	1	-1.40925	0.64802	4.7293	0.0297	0.244	A 1
A	2	1	-0.65705	0.51764	1.6112	0.2043	0.518	A 2

Additionally any variable used in a programming statement that has already been declared in the CLASS statement is *not* treated as a collection of the corresponding design variables. Consider the following statements:

```
proc phreg data=Test;
   class A;
   model T*Status(0)=A X;
   X=T*A;
   run;
```

The CLASS variable A generates two design variables as explanatory variables. The variable X created by the **X=T*A** programming statement is a single time-dependent covariate whose values are evaluated using the exact values of A given in the data, not the dummy-coded values that represent the levels of A. In data set Test, A assumes the values of 1, 2, and 3, and these are the exact values that are used in producing X. If A were a character variable with values 'Bird', 'Cat', and 'Dog', the programming statement X=T*A would have produced an error in the attempt to multiply a number with a character value.

Figure 66.16 Single Time-Dependent Variable X*A

The PHREG Procedure

Analysis of Maximum Likelihood Estimates

Parameter		DF	Parameter Estimate	Standard Error	Chi-Square	Pr > ChiSq	Hazard Ratio	Label
A	1	1	0.15798	1.69338	0.0087	0.9257	1.171	A 1
A	2	1	0.00898	0.87573	0.0001	0.9918	1.009	A 2
X		1	0.09268	0.09535	0.9448	0.3311	1.097	

To generalize the simple test of proportional hazard assumption for the design variables of A (as in the section the "Classical Method of Maximum Likelihood" on page 5369), you specify the following statements, which are not the same as in the preceding program or as in the specification in the section "Time Variable on the Right Side of the MODEL Statement" on page 5431:

```
proc phreg data=Test;
   class A;
   model T*Status(0)=A X1 X2;
   X1= T*(A=1);
   X2= T*(A=2);
   run;
```

The Boolean parenthetical expressions (A=1) and (A=2) resolve to a value of 1 or 0, depending on whether the expression is true or false, respectively.

Results of this test are shown in Figure 66.17.

Figure 66.17 Simple Test of Proportional Hazards Assumption

The PHREG Procedure

Analysis of Maximum Likelihood Estimates

Parameter		DF	Parameter Estimate	Standard Error	Chi-Square	Pr > ChiSq	Hazard Ratio	Label
A	1	1	-0.00766	1.69435	0.0000	0.9964	0.992	A 1
A	2	1	-0.88132	1.64298	0.2877	0.5917	0.414	A 2
X1		1	-0.15522	0.20174	0.5920	0.4417	0.856	
X2		1	0.01155	0.18858	0.0037	0.9512	1.012	

In general, when your model contains a categorical explanatory variable that is time-dependent, it might be necessary to use hardcoded dummy variables to represent the categories of the categorical variable. Alternatively, you might consider using the counting-process style of input where you break up the covariate history of an individual into a number of records with nonoverlapping start and stop times and declare the categorical time-dependent variable in the CLASS statement.

Partial Likelihood Function for the Cox Model

Let $\mathbf{Z}_l(t)$ denote the vector explanatory variables for the lth individual at time t. Let $t_1 < t_2 < \ldots < t_k$ denote the k distinct, ordered event times. Let d_i denote the multiplicity of failures at t_i; that is, d_i is the size of the set $\mathcal{D}_i$ of individuals that fail at t_i. Let w_l be the weight associated with the lth individual. Using this notation, the likelihood functions used in PROC PHREG to estimate $\boldsymbol{\beta}$ are described in the following sections.

Continuous Time Scale

Let $\mathcal{R}_i$ denote the risk set just before the ith ordered event time t_i. Let $\mathcal{R}_i^*$ denote the set of individuals whose event or censored times exceed t_i or whose censored times are equal to t_i.

Exact Likelihood

$$L_1(\boldsymbol{\beta}) = \prod_{i=1}^{k} \left\{ \int_0^{\infty} \prod_{j \in \mathcal{D}_i} \left[1 - \exp\left(- \frac{e^{\boldsymbol{\beta}' \mathbf{Z}_j(t_i)}}{\sum_{l \in \mathcal{R}_i^*} e^{\boldsymbol{\beta}' \mathbf{Z}_l(t_i)}} t \right) \right] \exp(-t) dt \right\}$$

Breslow Likelihood

$$L_2(\boldsymbol{\beta}) = \prod_{i=1}^{k} \frac{e^{\boldsymbol{\beta}' \sum_{j \in \mathcal{D}_i} \mathbf{Z}_j(t_i)}}{\left[\sum_{l \in \mathcal{R}_i} e^{\boldsymbol{\beta}' \mathbf{Z}_l(t_i)} \right]^{d_i}}$$

Incorporating weights, the Breslow likelihood becomes

$$L_2(\boldsymbol{\beta}) = \prod_{i=1}^{k} \frac{e^{\boldsymbol{\beta}' \sum_{j \in \mathcal{D}_i} w_j \mathbf{Z}_j(t_i)}}{\left[\sum_{l \in \mathcal{R}_i} w_l e^{\boldsymbol{\beta}' \mathbf{Z}_l(t_i)} \right]^{\sum_{j \in \mathcal{D}_i} w_i}}$$

Efron Likelihood

$$L_3(\boldsymbol{\beta}) = \prod_{i=1}^{k} \frac{e^{\boldsymbol{\beta}' \sum_{j \in \mathcal{D}_i} \mathbf{Z}_j(t_i)}}{\prod_{j=1}^{d_i} \left(\sum_{l \in \mathcal{R}_i} e^{\boldsymbol{\beta}' \mathbf{Z}_l(t_i)} - \frac{j-1}{d_i} \sum_{l \in \mathcal{D}_i} e^{\boldsymbol{\beta}' \mathbf{Z}_l(t_i)} \right)}$$

Incorporating weights, the Efron likelihood becomes

$$L_3(\boldsymbol{\beta}) = \prod_{i=1}^{k} \frac{e^{\boldsymbol{\beta}' \sum_{j \in \mathcal{D}_i} w_j \mathbf{Z}_j(t_i)}}{\left[\prod_{j=1}^{d_i} \left(\sum_{l \in \mathcal{R}_i} w_l e^{\boldsymbol{\beta}' \mathbf{Z}_l(t_i)} - \frac{j-1}{d_i} \sum_{l \in \mathcal{D}_i} w_l e^{\boldsymbol{\beta}' \mathbf{Z}_l(t_i)} \right) \right]^{\frac{1}{d_i} \sum_{j \in \mathcal{D}_i} w_j}}$$

Discrete Time Scale

Let $\mathcal{Q}_i$ denote the set of all subsets of d_i individuals from the risk set $\mathcal{R}_i$. For each $\mathbf{q} \in \mathcal{Q}_i$, $\mathbf{q}$ is a d_i-tuple $(q_1, q_2, \ldots, q_{d_i})$ of individuals who might have failed at t_i.

Discrete Logistic Likelihood

$$L_4(\boldsymbol{\beta}) = \prod_{i=1}^{k} \frac{e^{\boldsymbol{\beta}' \sum_{j \in \mathcal{D}_i} \mathbf{Z}_j(t_i)}}{\sum_{\boldsymbol{q} \in \mathcal{Q}_i} e^{\boldsymbol{\beta}' \sum_{l=1}^{d_i} \mathbf{Z}_{q_l}(t_i)}}$$

The computation of $L_4(\boldsymbol{\beta})$ and its derivatives is based on an adaptation of the recurrence algorithm of Gail, Lubin, and Rubinstein (1981) to the logarithmic scale. When there are no ties on the event times (that is, $d_i \equiv 1$), all four likelihood functions $L_1(\boldsymbol{\beta})$, $L_2(\boldsymbol{\beta})$, $L_3(\boldsymbol{\beta})$, and $L_4(\boldsymbol{\beta})$ reduce to the same expression. In a stratified analysis, the partial likelihood is the product of the partial likelihood functions for the individual strata.

Counting Process Style of Input

In the counting process formulation, data for each subject are identified by a triple $\{N, Y, \mathbf{Z}\}$ of counting, at-risk, and covariate processes. Here, $N(t)$ indicates the number of events that the subject experiences over the time interval $(0, t]$; $Y(t)$ indicates whether the subject is at risk at time t (one if at risk and zero otherwise); and $\mathbf{Z}(t)$ is a vector of explanatory variables for the subject at time t. The sample path of N is a step function with jumps of size +1 at the event times, and $N(0) = 0$. Unless $\mathbf{Z}(t)$ changes continuously with time, the data for each subject can be represented by multiple observations, each identifying a semiclosed time interval $(t1, t2]$, the values of the explanatory variables over that interval, and the event status at $t2$. The subject remains at risk during the interval $(t1, t2]$, and an event might occur at $t2$. Values of the explanatory variables for the subject remain unchanged in the interval. This style of data input was originated by Therneau (1994).

For example, a patient has a tumor recurrence at weeks 3, 10, and 15 and is followed up to week 23. The explanatory variables are Trt (treatment), Z1 (initial tumor number), and Z2 (initial tumor size), and, for this patient, the values of Trt, Z1, and Z2 are (1,1,3). The data for this patient are represented by the following four observations:

T1	T2	Event	Trt	Z1	Z2
0	3	1	1	1	3
3	10	1	1	1	3
10	15	1	1	1	3
15	23	0	1	1	3

Here (T1,T2] contains the at-risk intervals. The variable Event is a censoring variable indicating whether a recurrence has occurred at T2; a value of 1 indicates a tumor recurrence, and a value of 0 indicates nonrecurrence. The PHREG procedure fits the multiplicative hazards model, which is specified as follows:

```
proc phreg;
   model (T1,T2) * Event(0) = Trt Z1 Z2;
run;
```

Another useful application of the counting process formulation is delayed entry of subjects into the risk set. For example, in studying the mortality of workers exposed to a carcinogen, the survival time is chosen to be the worker's age at death by malignant neoplasm. Any worker joining the workplace at a later age than a given event failure time is not included in the corresponding risk set. The variables of a worker consist of Entry (age at which the worker entered the workplace), Age (age at death or age censored), Status (an indicator of whether the observation time is censored, with the value 0 identifying a censored time), and X1

and X2 (explanatory variables thought to be related to survival). The specification for such an application is as follows:

```
proc phreg;
   model (Entry, Age) * Status(0) = X1 X2;
run;
```

Alternatively, you can use a time-dependent variable to control the risk set, as illustrated in the following specification:

```
proc phreg;
   model Age * Status(0) = X1 X2;
   if Age < Entry then X1= .;
run;
```

Here, X1 becomes a time-dependent variable. At a given death time t, the value of X1 is reevaluated for each subject with Age $\geq t$; subjects with Entry $> t$ are given a missing value in X1 and are subsequently removed from the risk set. Computationally, this approach is not as efficient as the one that uses the counting process formulation.

Left-Truncation of Failure Times

Left-truncation arises when individuals come under observation only some known time after the natural time origin of the phenomenon under study. The risk set just prior to an event time does not include individuals whose left-truncation times exceed the given event time. Thus, any contribution to the likelihood must be conditional on the truncation limit having been exceeded.

An alternative way to specify left-truncation in PROC PHREG is through the counting process style of input. The following specifications are equivalent:

```
proc phreg data=one;
   model t2*dead(0)=x1-x10/entry=t1;
   title 'The ENTRY= option is Specified';
run;

proc phreg data=one;
   model (t1,t2)*dead(0)=x1-x10;
   title 'Counting Process Style of Input';
run;
```

The Multiplicative Hazards Model

Consider a set of n subjects such that the counting process $N_i \equiv \{N_i(t), t \geq 0\}$ for the ith subject represents the number of observed events experienced over time t. The sample paths of the process N_i are step functions with jumps of size $+1$, with $N_i(0) = 0$. Let $\boldsymbol{\beta}$ denote the vector of unknown regression

coefficients. The multiplicative hazards function $\Lambda(t, \mathbf{Z}_i(t))$ for N_i is given by

$$Y_i(t)d\Lambda(t, \mathbf{Z}_i(t)) = Y_i(t)\exp(\boldsymbol{\beta}'\mathbf{Z}_i(t))d\Lambda_0(t)$$

where

- $Y_i(t)$ indicates whether the ith subject is at risk at time t (specifically, $Y_i(t) = 1$ if at risk and $Y_i(t) = 0$ otherwise)
- $\mathbf{Z}_i(t)$ is the vector of explanatory variables for the ith subject at time t
- $\Lambda_0(t)$ is an unspecified baseline hazard function

Refer to Fleming and Harrington (1991) and Andersen et al. (1992). The Cox model is a special case of this multiplicative hazards model, where $Y_i(t) = 1$ until the first event or censoring, and $Y_i(t) = 0$ thereafter.

The partial likelihood for n independent triplets $(N_i, Y_i, \mathbf{Z}_i), i = 1, \ldots, n$, has the form

$$\mathcal{L}(\boldsymbol{\beta}) = \prod_{i=1}^{n}\prod_{t\geq 0}\left\{\frac{Y_i(t)\exp(\boldsymbol{\beta}'\mathbf{Z}_i(t))}{\sum_{j=1}^{n} Y_j(t)\exp(\boldsymbol{\beta}'\mathbf{Z}_j(t))}\right\}^{\Delta N_i(t)}$$

where $\Delta N_i(t) = 1$ if $N_i(t) - N_i(t-) = 1$, and $\Delta N_i(t) = 0$ otherwise.

The Frailty Model

You can use the frailty model to model correlations between failures of the same cluster by using a random component for the hazard function. The hazard rate for the jth individual in the ith cluster is

$$\lambda_{ij}(t) = \lambda_0(t)\mathrm{e}^{\boldsymbol{\beta}'\mathbf{Z}_{ij}(t)+\gamma_i}$$

where $\lambda_0(t)$ is an arbitrary baseline hazard rate, $\mathbf{Z}_{ij}$ is the vector of (fixed-effect) covariates, $\boldsymbol{\beta}$ is the vector of regression coefficients, and γ_i is the random effect for cluster i. The random components $\gamma_1, \ldots, \gamma_s$ are assumed to be independent and identically distributed as a normal random variable with mean 0 and an unknown variance θ.

In terms of the frailties $u_1, \ldots, u_s$, given by $\gamma_i = \log(u_i)$, the frailty model can be written as

$$\lambda_{ij}(t) = \lambda_0(t)u_i\mathrm{e}^{\boldsymbol{\beta}'\mathbf{Z}_{ij}(t)}$$

Each frailty has a lognormal distribution with median 1. This gives the interpretation that individuals in cluster i with $u_i > 1 (u_i < 1)$ tend to fail at a faster (slower) rate than that under an independence model.

The RANDOM statement in PROC PHREG enables you to fit a shared fraity model. However, the ASSESS, BASELINE, and OUTPUT statements, if specified, are ignored. Also ignored are the COVS options in the PROC PHREG statement and the following options in the MODEL statement: BEST=, DETAILS, HIERARCHY=, INCLUDE=, NOFIT, PLCONV=, SELECTION=, SEQUENTIAL, SLENTRY=, SLSTAY=, TYPE1, and TYPE3(ALL, LR, SCORE). Profile likelihood confidence intervals for the hazard ratios are not available for the frailty model analysis.

The Penalized Partial Likelihood Approach for Fitting Frailty Models

Let $\boldsymbol{\gamma} = (\gamma_1, \ldots, \gamma_s)'$ be the vector of random components for the s clusters. With each γ_i having a zero-mean normal distribution and a common variance θ, the joint log likelihood is

$$\frac{1}{2}\left[\frac{1}{\theta}\boldsymbol{\gamma}'\boldsymbol{\gamma} + s\log(2\pi\theta)\right]$$

Define the penalized partial log likelihood as

$$l_p(\boldsymbol{\beta}, \boldsymbol{\gamma}, \theta) = l_{\text{partial}}(\boldsymbol{\beta}, \boldsymbol{\gamma}) - \frac{1}{2\theta}\boldsymbol{\gamma}'\boldsymbol{\gamma}$$

where $l_{\text{partial}}(\boldsymbol{\beta}, \boldsymbol{\gamma})$ is the log of any of the partial likelihood in the sections "Partial Likelihood Function for the Cox Model" on page 5435 and "The Multiplicative Hazards Model" on page 5438.

For a given θ, let $\mathbf{H}$ be the negative Hessian of the penalized partial log likelihood $l_p(\boldsymbol{\beta}, \boldsymbol{\gamma}, \theta)$; that is,

$$\mathbf{H} = \mathbf{H}(\boldsymbol{\beta}, \boldsymbol{\gamma}) = \begin{bmatrix} \mathbf{H}_{11} & \mathbf{H}_{12} \\ \mathbf{H}_{21} & \mathbf{H}_{22} \end{bmatrix}$$

where $\mathbf{H}_{11} = -\frac{\partial^2 l_p(\boldsymbol{\beta},\boldsymbol{\gamma},\theta)}{\partial \boldsymbol{\beta}^2}$, $\mathbf{H}_{12} = \mathbf{H}'_{21} = -\frac{\partial^2 l_p(\boldsymbol{\beta},\boldsymbol{\gamma},\theta)}{\partial \boldsymbol{\beta}\partial \boldsymbol{\gamma}}$, and $\mathbf{H}_{22} = -\frac{\partial^2 l_p(\boldsymbol{\beta},\boldsymbol{\gamma},\theta)}{\partial \boldsymbol{\gamma}^2}$.

The marginal log likelihood of this shared frailty model is

$$l_m(\boldsymbol{\beta}, \theta) = -\frac{1}{2}\log(\theta^s) + \log\left[\int e^{l_p(\boldsymbol{\beta},\boldsymbol{\gamma},\theta)} d\boldsymbol{\gamma}\right]$$

Using a Laplace approximation to the integral as in Breslow and Clayton (1993), an approximate marginal log likelihood (Ripatti and Palmgren 2000; Therneau and Grambsch 2000) is given by

$$l_m(\boldsymbol{\beta}, \theta) \approx -\frac{1}{2}\log(\theta^s) - \frac{1}{2}\log(|\mathbf{H}_{22}(\boldsymbol{\beta}, \tilde{\boldsymbol{\gamma}}, \theta)|) - l_p(\boldsymbol{\beta}, \tilde{\boldsymbol{\gamma}}, \theta)$$

The maximization of this approximate likelihood is a doubly iterative process that alternates between the following two steps:

- For a provisional value of θ, PROC PHREG computes the best linear unbiased predictors (BLUP) of $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$ by maximizing the penalized partial log likelihood $l_p(\boldsymbol{\beta}, \boldsymbol{\gamma}, \theta)$. This contitutes the inner loop.
- For $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$ fixed at the BLUP values, PROC PHREG estimates θ by maximizing the approximate marginal likelihood $l_m(\boldsymbol{\beta}, \theta)$. This constitutes the outer loop.

The outer loop is iterated until the difference between two successive estimates of θ is small.

The ML estimate of θ is

$$\hat{\theta} = \frac{\hat{\boldsymbol{\gamma}}'\hat{\boldsymbol{\gamma}} + \texttt{trace}(\mathbf{H}_{22}^{-1})}{s}$$

The variance for $\hat{\theta}$ is

$$\text{var}(\hat{\theta}) = 2\hat{\theta}\left[s + \frac{1}{\hat{\theta}^2}\texttt{trace}(\mathbf{H}_{22}^{-1}\mathbf{H}_{22}^{-1}) - \frac{2}{\hat{\theta}}\texttt{trace}(\mathbf{H}_{22}^{-1})\right]^{-1}$$

The REML estimation of θ is obtained by replacing $(\mathbf{H}_{22})^{-1}$ by $(\mathbf{H}^{-1})_{22}$.

The inverse of the final $\mathbf{H}$ matrix is used as the variance estimate of $(\hat{\boldsymbol{\beta}}, \hat{\boldsymbol{\gamma}})'$.

The final BLUP estimates of the random components $\gamma_1, \ldots, \gamma_s$ can be displayed using the SOLUTION option in the RANDOM statement. Also displayed are estimates of the lognormal frailties, which are the exponentiated estimates of the BLUP estimates.

Wald-Type Tests for Penalized Models

Let $\mathbf{I}$ be the negative Hessian of the partial log likelihood $l_{\text{partial}}(\boldsymbol{\beta}, \boldsymbol{\gamma})$:

$$\mathbf{I} = \begin{bmatrix} \mathbf{I}_{11} & \mathbf{I}_{12} \\ \mathbf{I}_{21} & \mathbf{I}_{22} \end{bmatrix}$$

where $\mathbf{I}_{11} = -\frac{\partial^2 l_{\text{partial}}(\boldsymbol{\beta},\boldsymbol{\gamma})}{\partial \boldsymbol{\beta}^2}$, $\mathbf{I}_{12} = \mathbf{I}_{21}' = -\frac{\partial^2 l_{\text{partial}}(\boldsymbol{\beta},\boldsymbol{\gamma})}{\partial \boldsymbol{\beta}\partial \boldsymbol{\gamma}}$, and $\mathbf{I}_{22} = -\frac{\partial^2 l_{\text{partial}}(\boldsymbol{\beta},\boldsymbol{\gamma})}{\partial \boldsymbol{\gamma}^2}$. Write $\boldsymbol{\tau}' = (\boldsymbol{\beta}', \boldsymbol{\gamma}')'$. The Wald-type chi-square statistic for testing $H_0 : \mathbf{C}\boldsymbol{\tau} = \mathbf{0}$ is

$$(\mathbf{C}\hat{\boldsymbol{\tau}})'(\mathbf{C}\mathbf{H}^{-1}\mathbf{C}')^{-1}(\mathbf{C}\hat{\boldsymbol{\tau}})$$

Let $\mathbf{V} = \mathbf{H}^{-1}\mathbf{I}\mathbf{H}^{-1}$. Gray (1992) recommends the following generalized degrees of freedom for the Wald test:

$$df = \texttt{trace}[(\mathbf{C}\mathbf{H}^{-1}\mathbf{C}')^{-1}\mathbf{C}\mathbf{V}\mathbf{C}')]$$

See Therneau and Grambsch (2000, Section 5.8) for a discussion of this Wald-type test.

PROC PHREG uses the label "Adjusted DF" to represent this generalized degrees of freedom in the output.

Hazard Ratios

Consider a dichotomous risk factor variable X that takes the value 1 if the risk factor is present and 0 if the risk factor is absent. The log-hazard function is given by

$$\log[\lambda(t|X)] = \log[\lambda_0(t)] + \beta_1 X$$

where $\lambda_0(t)$ is the baseline hazard function.

The hazard ratio ψ is defined as the ratio of the hazard for those with the risk factor ($X = 1$) to the hazard without the risk factor ($X = 0$). The log of the hazard ratio is given by

$$\log(\psi) \equiv \log[\psi(X = 1, X = 0)] = \log[\lambda(t|X = 1)] - \log[\lambda(t|X = 0)] = \beta_1$$

In general, the hazard ratio can be computed by exponentiating the difference of the log-hazard between any two population profiles. This is the approach taken by the HAZARDRATIO statement, so the computations are available regardless of parameterization, interactions, and nestings. However, as shown in the preceding equation for $\log(\psi)$, hazard ratios of main effects can be computed as functions of the parameter estimates, and the remainder of this section is concerned with this methodology.

The parameter, β_1, associated with X represents the change in the log-hazard from $X = 0$ to $X = 1$. So the hazard ratio is obtained by simply exponentiating the value of the parameter associated with the risk factor. The hazard ratio indicates how the hazard change as you change X from 0 to 1. For instance, $\psi = 2$ means that the hazard when $X = 1$ is twice the hazard when $X = 0$.

Suppose the values of the dichotomous risk factor are coded as constants a and b instead of 0 and 1. The hazard when $X = a$ becomes $\lambda(t)\exp(a\beta_1)$, and the hazard when $X = b$ becomes $\lambda(t)\exp(b\beta_1)$. The hazard ratio corresponding to an increase in X from a to b is

$$\psi = \exp[(b-a)\beta_1] = [\exp(\beta_1)]^{b-a} \equiv [\exp(\beta_1)]^c$$

Note that for any a and b such that $c = b - a = 1$, $\psi = \exp(\beta_1)$. So the hazard ratio can be interpreted as the change in the hazard for any increase of one unit in the corresponding risk factor. However, the change in hazard for some amount other than one unit is often of greater interest. For example, a change of one pound in body weight might be too small to be considered important, while a change of 10 pounds might be more meaningful. The hazard ratio for a change in X from a to b is estimated by raising the hazard ratio estimate for a unit change in X to the power of $c = b - a$ as shown previously.

For a polytomous risk factor, the computation of hazard ratios depends on how the risk factor is parameterized. For illustration, suppose that Cell is a risk factor with four categories: Adeno, Large, Small, and Squamous.

For the effect parameterization scheme (PARAM=EFFECT) with Squamous as the reference group, the design variables for Cell are as follows:

	Design Variables		
Cell	X_1	X_2	X_3
Adeno	1	0	0
Large	0	1	0
Small	0	0	1
Squamous	−1	−1	−1

The log-hazard for Adeno is

$$\begin{aligned}\log[\lambda(t|\text{Adeno})] &= \log[\lambda_0(t)] + \beta_1(X_1 = 1) + \beta_2(X_2 = 0) + \beta_3(X_3 = 0) \\ &= \lambda_0(t) + \beta_1\end{aligned}$$

The log-hazard for Squamous is

$$\begin{aligned}\log[\lambda(t|\text{Squamous})] &= \log[\lambda_0(t)] + \beta_1(X_1 = -1) + \beta_2(X_2 = -1) + \beta_3(X_3 = -1)) \\ &= \log[\lambda_0(t)] - \beta_1 - \beta_2 - \beta_3\end{aligned}$$

Therefore, the log-hazard ratio of Adeno versus Squamous

$$\begin{aligned}\log[\psi(\text{Adeno, Squamous})] &= \log[\lambda(t|\text{Adeno})] - \log[\lambda(t|\text{Squamous})] \\ &= 2\beta_1 + \beta_2 + \beta_3\end{aligned}$$

For the reference cell parameterization scheme (PARAM=REF) with Squamous as the reference cell, the design variables for Cell are as follows:

	Design Variables		
Cell	X_1	X_2	X_3
Adeno	1	0	0
Large	0	1	0
Small	0	0	1
Squamous	0	0	0

The log-hazard ratio of Adeno versus Squamous is given by

$$\begin{aligned}
&\log(\psi(\text{Adeno}, \text{Squamous})) \\
&\quad = \log[\lambda(t|\text{Adeno})] - \log[\lambda(t|\text{Squamous})] \\
&\quad = (\log[\lambda_0(t)] + \beta_1(X_1 = 1) + \beta_2(X_2 = 0) + \beta_3(X_3 = 0)) - \\
&\qquad (\log[\lambda_0(t)] + \beta_1(X_1 = 0) + \beta_2(X_2 = 0) + \beta_3(X_3 = 0)) \\
&\quad = \beta_1
\end{aligned}$$

For the GLM parameterization scheme (PARAM=GLM), the design variables are as follows:

	Design Variables			
Cell	X_1	X_2	X_3	X_4
Adeno	1	0	0	0
Large	0	1	0	0
Small	0	0	1	0
Squamous	0	0	0	1

The log-hazard ratio of Adeno versus Squamous is

$$\begin{aligned}
&\log(\psi(\text{Adeno}, \text{Squamous})) \\
&\quad = \log[\lambda(t|\text{Adeno})] - \log[\lambda(t|\text{Squamous})] \\
&\quad = \log[\lambda_0(t)] + \beta_1(X_1 = 1) + \beta_2(X_2 = 0) + \beta_3(X_3 = 0) + \beta_4(X_4 = 0)) - \\
&\qquad (\log(\lambda_0(t)) + \beta_1(X_1 = 0) + \beta_2(X_2 = 0) + \beta_3(X_3 = 0) + \beta_4(X_4 = 1)) \\
&\quad = \beta_1 - \beta_4
\end{aligned}$$

Consider Cell as the only risk factor in the Cox regression in Example 66.3. The computation of hazard ratio of Adeno versus Squamous for various parameterization schemes is tabulated in Table 66.8.

Table 66.8 Hazard Ratio Comparing Adeno to Squamous

	Parameter Estimates				
PARAM=	$\hat{\beta}_1$	$\hat{\beta}_2$	$\hat{\beta}_3$	$\hat{\beta}_4$	**Hazard Ratio Estimates**
EFFECT	0.5772	–0.2115	0.2454		$\exp(2 \times 0.5772 - 0.2115 + 0.2454) = 3.281$
REF	1.8830	0.3996	0.8565		$\exp(1.8830) = 3.281$
GLM	1.8830	0.3996	0.8565	0.0000	$\exp(1.8830) = 3.281$

The fact that the log-hazard ratio ($\log(\psi)$) is a linear function of the parameters enables the HAZARDRATIO statement to compute the hazard ratio of the main effect even in the presence of interactions and nest effects. The section "Hazard Ratios" on page 5441 details the estimation of the hazard ratios in a classical analysis.

To customize hazard ratios for specific units of change for a continuous risk factor, you can use the UNITS= option in a HAZARDRATIO statement to specify a list of relevant units for each explanatory variable in the model. Estimates of these customized hazard ratios are given in a separate table. Let (L_j, U_j) be a confidence interval for $\log(\psi)$. The corresponding lower and upper confidence limits for the customized hazard ratio $\exp(c\beta_j)$ are $\exp(cL_j)$ and $\exp(cU_j)$, respectively (for $c > 0$), or $\exp(cU_j)$ and $\exp(cL_j)$, respectively (for $c < 0$).

Specifics for Classical Analysis

Proportional Rates/Means Models for Recurrent Events

Let $N(t)$ be the number of events experienced by a subject over the time interval $(0, t]$. Let $dN(t)$ be the increment of the counting process N over $[t, t + dt)$. The rate function is given by

$$d\mu_{\mathbf{Z}}(t) = E[dN(t)|Z(t)] = e^{\boldsymbol{\beta}'\mathbf{Z}(t)} d\mu_0(t)$$

where $\mu_0(.)$ is an unknown continuous function. If the $\mathbf{Z}$ are time independent, the rate model is reduced to the mean model

$$\mu_Z(t) = e^{\boldsymbol{\beta}'Z}\mu_0(t)$$

The partial likelihood for n independent triplets $(N_i, Y_i, \mathbf{Z}_i), i = 1, \ldots, n$, of counting, at-risk, and covariate processes is the same as that of the multiplicative hazards model. However, a robust sandwich estimate is used for the covariance matrix of the parameter estimator instead of the model-based estimate.

Let T_{ki} be the kth event time of the ith subject. Let C_i be the censoring time of the ith subject. The at-risk indicator and the failure indicator are, respectively,

$$Y_i(t) = I(C_i \geq t) \text{and} \Delta_{ki} = I(T_{ki} \leq C_i)$$

Denote

$$S^{(0)}(\boldsymbol{\beta}, t) = \sum_{i=1}^{n} Y_i(t) e^{\boldsymbol{\beta}'\mathbf{Z}_i(t)} \text{and} \bar{\mathbf{Z}}(\boldsymbol{\beta}, t) = \frac{\sum_{i=1}^{n} Y_i(t) e^{\boldsymbol{\beta}'\mathbf{Z}_i(t)} \mathbf{Z}_i(t)}{S^{(0)}(\boldsymbol{\beta}, t)}$$

Let $\hat{\boldsymbol{\beta}}$ be the maximum likelihood estimate of $\boldsymbol{\beta}$, and let $\mathcal{I}(\hat{\boldsymbol{\beta}})$ be the observed information matrix. The robust sandwich covariance matrix estimate is given by

$$\mathcal{I}^{-1}(\hat{\boldsymbol{\beta}}) \sum_{i=1}^{n} \left[W_i(\hat{\boldsymbol{\beta}}) W_i'(\hat{\boldsymbol{\beta}}) \right] \mathcal{I}^{-1}(\hat{\boldsymbol{\beta}})$$

where

$$\begin{aligned} W_i(\boldsymbol{\beta}) &= \sum_k \Delta_{ki} \left\{ Z_i(T_{ki}) - \bar{\mathbf{Z}}(\boldsymbol{\beta}, T_{ki}) \right\} - \\ &\quad \sum_{i=1}^{n} \sum_l \frac{\Delta_{lj} Y_i(T_{lj}) \mathrm{e}^{\boldsymbol{\beta}' \mathbf{Z}_i(T_{lj})}}{S^0(\boldsymbol{\beta}, T_{lj})} \left\{ Z_i(T_{lj}) - \bar{\mathbf{Z}}(\boldsymbol{\beta}, T_{lj}) \right\} \end{aligned}$$

For a given realization of the covariates $\boldsymbol{\xi}$, the Nelson estimator is used to predict the mean function

$$\hat{\mu}_{\boldsymbol{\xi}}(t) = \mathrm{e}^{\hat{\boldsymbol{\beta}}' \boldsymbol{\xi}} \sum_{i=1}^{n} \sum_k \frac{I(T_{ki} \le t) \Delta_{ki}}{S^{(0)}(\hat{\boldsymbol{\beta}}, T_{ki})}$$

with standard error estimate given by

$$\hat{\sigma}^2(\hat{\mu}_{\boldsymbol{\xi}}(t)) = \sum_{i=1}^{n} \left(\frac{1}{n} \hat{\Psi}_i(t, \boldsymbol{\xi}) \right)^2$$

where

$$\begin{aligned} \frac{1}{n} \hat{\Psi}_i(\boldsymbol{\xi}, t) &= \mathrm{e}^{\hat{\boldsymbol{\beta}}' \boldsymbol{\xi}} \left\{ \sum_k \frac{I(T_{ki} \le t) \Delta_{ik}}{S^{(0)}(\hat{\boldsymbol{\beta}}, T_{ki})} - \sum_{j=1}^{n} \sum_k \frac{Y_i(T_{kj}) \mathrm{e}^{\hat{\boldsymbol{\beta}}' \mathbf{Z}_i(T_{kj})} I(T_{kj} \le t) \Delta_{kj}}{[S^{(0)}(\hat{\boldsymbol{\beta}}, T_{kj})]^2} - \right. \\ &\quad \left[\sum_{i=1}^{n} \sum_k \frac{I(T_{ki} \le t) \Delta_{ik} [\bar{\mathbf{Z}}(\hat{\boldsymbol{\beta}}, T_{ki}) - \boldsymbol{\xi}]}{S^{(0)}(\hat{\boldsymbol{\beta}}, T_{ki})} \right] \\ &\quad \left. \times \mathcal{I}^{-1}(\hat{\boldsymbol{\beta}}) \int_0^{\tau} [\mathbf{Z}_i(u) - \bar{\mathbf{Z}}(\hat{\boldsymbol{\beta}}, u)] d\hat{M}_i(u) \right\} \end{aligned}$$

Since the cumulative mean function is always nonnegative, the log transform is used to compute confidence intervals. The $100(1-\alpha)\%$ pointwise confidence limits for $\mu_{\boldsymbol{\xi}}(t)$ are

$$\hat{\mu}_{\boldsymbol{\xi}}(t) \mathrm{e}^{\pm z_{\alpha/2} \frac{\hat{\sigma}(\hat{\mu}_{\boldsymbol{\xi}}(t))}{\hat{\mu}_{\boldsymbol{\xi}}(t)}}$$

where $z_{\alpha/2}$ is the upper $100\alpha/2$ percentage point of the standard normal distribution.

Newton-Raphson Method

Let $L(\boldsymbol{\beta})$ be one of the likelihood functions described in the previous subsections. Let $l(\boldsymbol{\beta}) = \log L(\boldsymbol{\beta})$. Finding $\boldsymbol{\beta}$ such that $L(\boldsymbol{\beta})$ is maximized is equivalent to finding the solution $\hat{\boldsymbol{\beta}}$ to the likelihood equations

$$\frac{\partial l(\boldsymbol{\beta})}{\partial \boldsymbol{\beta}} = 0$$

With $\hat{\boldsymbol{\beta}}^0 = \mathbf{0}$ as the initial solution, the iterative scheme is expressed as

$$\hat{\boldsymbol{\beta}}^{j+1} = \hat{\boldsymbol{\beta}}^{j} - \left[\frac{\partial^2 l(\hat{\boldsymbol{\beta}}^{j})}{\partial \boldsymbol{\beta}^2}\right]^{-1} \frac{\partial l(\hat{\boldsymbol{\beta}}^{j})}{\partial \boldsymbol{\beta}}$$

The term after the minus sign is the Newton-Raphson step. If the likelihood function evaluated at $\hat{\boldsymbol{\beta}}^{j+1}$ is less than that evaluated at $\hat{\boldsymbol{\beta}}^{j}$, then $\hat{\boldsymbol{\beta}}^{j+1}$ is recomputed using half the step size. The iterative scheme continues until convergence is obtained—that is, until $\hat{\boldsymbol{\beta}}_{j+1}$ is sufficiently close to $\hat{\boldsymbol{\beta}}_{j}$. Then the maximum likelihood estimate of $\boldsymbol{\beta}$ is $\hat{\boldsymbol{\beta}} = \hat{\boldsymbol{\beta}}_{j+1}$.

The model-based variance estimate of $\hat{\boldsymbol{\beta}}$ is obtained by inverting the information matrix $\mathcal{I}(\hat{\boldsymbol{\beta}})$

$$\hat{\mathbf{V}}_m(\hat{\boldsymbol{\beta}}) = \mathcal{I}^{-1}(\hat{\boldsymbol{\beta}}) = -\left[\frac{\partial^2 l(\hat{\boldsymbol{\beta}})}{\partial \boldsymbol{\beta}^2}\right]^{-1}$$

Firth's Modification for Maximum Likelihood Estimation

In fitting a Cox model, the phenomenon of monotone likelihood is observed if the likelihood converges to a finite value while at least one parameter diverges (Heinze and Schemper 2001).

Let $\mathbf{x}_l(t)$ denote the vector explanatory variables for the lth individual at time t. Let $t_1 < t_2 < \ldots < t_m$ denote the k distinct, ordered event times. Let d_j denote the multiplicity of failures at t_j; that is, d_j is the size of the set $\mathcal{D}_j$ of individuals that fail at t_j. Let $\mathcal{R}_j$ denote the risk set just before t_j. Let $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_k)'$ be the vector of regression parameters. The Breslow log partial likelihood is given by

$$l(\boldsymbol{\beta}) = \log L(\boldsymbol{\beta}) = \sum_{j=1}^{m} \left\{ \boldsymbol{\beta}' \sum_{l \in \mathcal{D}_j} \mathbf{x}_l(t_j) - d_j \log \sum_{h \in \mathcal{R}j} \mathrm{e}^{\boldsymbol{\beta}' \mathbf{x}_h(t_j)} \right\}$$

Denote

$$\mathbf{S}_j^{(a)}(\boldsymbol{\beta}) = \sum_{h \in \mathcal{R}j} \mathrm{e}^{\boldsymbol{\beta}' \mathbf{x}_h(t_j)} [\mathbf{x}_h(t_j)]^{\otimes a} \qquad a = 0, 1, 2$$

Then the score function is given by

$$\begin{aligned} \mathbf{U}(\boldsymbol{\beta}) &\equiv (U(\beta_1), \ldots, U(\beta_k))' \\ &= \frac{\partial l(\boldsymbol{\beta})}{\partial \boldsymbol{\beta}} \\ &= \sum_{j=1}^{m} \left\{ \sum_{l \in \mathcal{D}j} \mathbf{x}_l(t_j) - d_j \frac{\mathbf{S}_j^{(1)}(\boldsymbol{\beta})}{S_j^0(\boldsymbol{\beta})} \right\} \end{aligned}$$

and the Fisher information matrix is given by

$$\begin{aligned}\mathcal{I}(\boldsymbol{\beta}) &= -\frac{\partial^2 l(\boldsymbol{\beta})}{\partial \boldsymbol{\beta}^2} \\ &= \sum_{j=1}^{m} d_j \left\{ \frac{\mathbf{S}_j^{(2)}(\boldsymbol{\beta})}{S_j^{(0)}(\boldsymbol{\beta})} - \left[\frac{\mathbf{S}_j^{(1)}(\boldsymbol{\beta})}{\mathbf{S}_j^{(0)}(\boldsymbol{\beta})}\right]\left[\frac{\mathbf{S}_j^{(1)}(\boldsymbol{\beta})}{\mathbf{S}_j^{(0)}(\boldsymbol{\beta})}\right]' \right\}\end{aligned}$$

Heinze (1999); Heinze and Schemper (2001) applied the idea of Firth (1993) by maximizing the penalized partial likelihood

$$l^*(\boldsymbol{\beta}) = l(\boldsymbol{\beta}) + 0.5 \log(|\mathcal{I}(\boldsymbol{\beta})|)$$

The score function $\mathbf{U}(\boldsymbol{\beta})$ is replaced by the modified score function by $\mathbf{U}^*(\boldsymbol{\beta}) \equiv (U^*(\beta_1), \ldots, U^*(\beta_k))'$, where

$$U^*(\beta_r) = U(\beta_r) + 0.5\mathrm{tr}\left\{\mathcal{I}^{-1}(\boldsymbol{\beta})\frac{\partial \mathcal{I}(\boldsymbol{\beta})}{\partial \beta_r}\right\} \qquad r = 1, \ldots, k$$

The Firth estimate is obtained iteratively as

$$\boldsymbol{\beta}^{(s+1)} = \boldsymbol{\beta}^{(s)} + \mathcal{I}^{-1}(\boldsymbol{\beta}^{(s)})\mathbf{U}^*(\boldsymbol{\beta}^{(s)})$$

The covariance matrix $\hat{\mathbf{V}}$ is computed as $\mathcal{I}^{-1}(\hat{\boldsymbol{\beta}})$, where $\hat{\boldsymbol{\beta}}$ is the maximum penalized partial likelihood estimate.

Explicit formulae for $\frac{\partial \mathcal{I}(\boldsymbol{\beta})}{\partial \beta_r}, r = 1, \ldots, k$

Denote

$$\begin{aligned}\mathbf{x}_h(t) &= (x_{h1}(t), \ldots, x_{hk}(t))' \\ \mathbf{Q}_{jr}^{(a)}(\boldsymbol{\beta}) &= \sum_{h \in \mathcal{R}j} \mathrm{e}^{\boldsymbol{\beta}'\mathbf{x}_h(t_j)} x_{hr}(t_j)[\mathbf{x}_h(t_j)]^{\otimes a} \qquad a = 0, 1, 2; r = 1, \ldots, k\end{aligned}$$

Then

$$\begin{aligned}\frac{\partial \mathcal{I}(\boldsymbol{\beta})}{\partial \beta_r} = \sum_{j=1}^{m} d_j \Bigg\{ &\left[\frac{\mathbf{Q}_{jr}^{(2)}(\boldsymbol{\beta})}{S_j^{(0)}(\boldsymbol{\beta})} - \frac{\mathbf{Q}_{jr}^{(0)}(\boldsymbol{\beta})}{S_j^{(0)}(\boldsymbol{\beta})}\frac{\mathbf{S}_j^{(2)}(\boldsymbol{\beta})}{S_j^{(0)}(\boldsymbol{\beta})}\right] - \\ &\left[\frac{\mathbf{Q}_{jr}^{(1)}(\boldsymbol{\beta})}{S_j^{(0)}(\boldsymbol{\beta})} - \frac{\mathbf{Q}_{jr}^{(0)}(\boldsymbol{\beta})}{S_j^{(0)}(\boldsymbol{\beta})}\frac{\mathbf{S}_j^{(1)}(\boldsymbol{\beta})}{S_j^{(0)}(\boldsymbol{\beta})}\right]\left[\frac{\mathbf{S}_j^{(1)}(\boldsymbol{\beta})}{S_j^{(0)}(\boldsymbol{\beta})}\right]' - \\ &\left[\frac{\mathbf{S}_j^{(1)}(\boldsymbol{\beta})}{S_j^{(0)}(\boldsymbol{\beta})}\right]\left[\frac{\mathbf{Q}_{jr}^{(1)}(\boldsymbol{\beta})}{S_j^{(0)}(\boldsymbol{\beta})} - \frac{\mathbf{Q}_{jr}^{(0)}(\boldsymbol{\beta})}{S_j^{(0)}(\boldsymbol{\beta})}\frac{\mathbf{S}_j^{(1)}(\boldsymbol{\beta})}{S_j^{(0)}(\boldsymbol{\beta})}\right]' \Bigg\} \qquad r = 1, \ldots, k\end{aligned}$$

Robust Sandwich Variance Estimate

For the ith subject, $i = 1, \ldots, n$, let X_i, w_i, and $\mathbf{Z}_i(t)$ be the observed time, weight, and the covariate vector at time t, respectively. Let Δ_i be the event indicator and let $Y_i(t) = I(X_i \geq t)$. Let

$$S^{(r)}(\boldsymbol{\beta}, t) = \sum_{j=1}^{n} w_j Y_j(t) \mathrm{e}^{\boldsymbol{\beta}' \mathbf{Z}_j(t)} \mathbf{Z}_j^{\otimes r}(t), r = 0, 1$$

Let $\bar{\mathbf{Z}}(\boldsymbol{\beta}, t) = \frac{S^{(1)}(\boldsymbol{\beta},t)}{S^{(0)}(\boldsymbol{\beta},t)}$. The score residual for the ith subject is

$$\mathbf{L}_i(\boldsymbol{\beta}) = \Delta_i \left\{ \mathbf{Z}_i(X_i) - \bar{\mathbf{Z}}(\beta, X_i) \right\} - \sum_{j=1}^{n} \Delta_j \frac{w_j Y_i(X_j) \mathrm{e}^{\boldsymbol{\beta}' \mathbf{Z}_i(X_j)}}{S^{(0)}(\boldsymbol{\beta}, X_j)} \left\{ \mathbf{Z}_i(X_j) - \bar{\mathbf{Z}}(\boldsymbol{\beta}, X_j) \right\}$$

For TIES=EFRON, the computation of the score residuals is modified to comply with the Efron partial likelihood. See the section "Residuals" on page 5462 for more information.

The robust sandwich variance estimate of $\hat{\boldsymbol{\beta}}$ derived by Binder (1992), who incorporated weights into the analysis, is

$$\hat{\mathbf{V}}_s(\hat{\boldsymbol{\beta}}) = \mathcal{I}^{-1}(\hat{\boldsymbol{\beta}}) \left[\sum_{j=1}^{n} (w_j \mathbf{L}_j(\hat{\boldsymbol{\beta}}))^{\otimes 2} \right] \mathcal{I}^{-1}(\hat{\boldsymbol{\beta}})$$

where $\mathcal{I}(\hat{\boldsymbol{\beta}})$ is the observed information matrix, and $\mathbf{a}^{\otimes 2} = \mathbf{a}\mathbf{a}'$. Note that when $w_i \equiv 1$,

$$\hat{\mathbf{V}}_s(\hat{\boldsymbol{\beta}}) = \mathbf{D}'\mathbf{D}$$

where $\mathbf{D}$ is the matrix of DFBETA residuals. This robust variance estimate was proposed by Lin and Wei (1989) and Reid and Crèpeau (1985).

Testing the Global Null Hypothesis

The following statistics can be used to test the global null hypothesis H_0: $\boldsymbol{\beta}$=$\mathbf{0}$. Under mild assumptions, each statistic has an asymptotic chi-square distribution with p degrees of freedom given the null hypothesis. The value p is the dimension of $\boldsymbol{\beta}$. For clustered data, the likelihood ratio test, the score test, and the Wald test assume independence of observations within a cluster, while the robust Wald test and the robust score test do not need such an assumption.

Likelihood Ratio Test

$$\chi^2_{LR} = 2 \left[l(\hat{\boldsymbol{\beta}}) - l(\mathbf{0}) \right]$$

Score Test

$$\chi^2_S = \left[\frac{\partial l(\mathbf{0})}{\partial \boldsymbol{\beta}}\right]' \left[-\frac{\partial^2 l(\mathbf{0})}{\partial \boldsymbol{\beta}^2}\right]^{-1} \left[\frac{\partial l(\mathbf{0})}{\partial \boldsymbol{\beta}}\right]$$

Wald's Test

$$\chi^2_W = \hat{\boldsymbol{\beta}}' \left[-\frac{\partial^2 l(\hat{\boldsymbol{\beta}})}{\partial \boldsymbol{\beta}^2}\right] \hat{\boldsymbol{\beta}}$$

Robust Score Test

$$\chi^2_{RS} = \left[\sum_i \mathbf{L}_i^0\right]' \left[\sum_i \mathbf{L}_i^0 \mathbf{L}_i^{0\prime}\right]^{-1} \left[\sum_i \mathbf{L}_i^0\right]$$

where $\mathbf{L}_i^0$ is the score residual of the ith subject at $\boldsymbol{\beta}$=$\mathbf{0}$; that is, $\mathbf{L}_i^0$=$\mathbf{L}_i(\mathbf{0}, \infty)$, where the score process $\mathbf{L}_i(\boldsymbol{\beta}, t)$ is defined in the section "Residuals" on page 5462.

Robust Wald's Test

$$\chi^2_{RW} = \hat{\boldsymbol{\beta}}' [\hat{\mathbf{V}}_s(\hat{\boldsymbol{\beta}})]^{-1} \hat{\boldsymbol{\beta}}$$

where $\hat{\mathbf{V}}_s(\hat{\boldsymbol{\beta}})$ is the sandwich variance estimate (see the section "Robust Sandwich Variance Estimate" on page 5448 for details).

Type 3 Tests

The following statistics can be used to test the null hypothesis H_{0L}: $\mathbf{L}\boldsymbol{\beta}$=$\mathbf{0}$, where $\mathbf{L}$ is a matrix of known coefficients. Under mild assumptions, each of the following statistics has an asymptotic chi-square distribution with p degrees of freedom, where p is the rank of $\mathbf{L}$. Let $\tilde{\boldsymbol{\beta}}_{\mathbf{L}}$ be the maximum likelihood of $\boldsymbol{\beta}$ under the null hypothesis $H_{0\mathbf{L}}$; that is,

$$l(\tilde{\boldsymbol{\beta}}_{\mathbf{L}}) = \max_{\mathbf{L}\boldsymbol{\beta}=\mathbf{0}} l(\boldsymbol{\beta})$$

Likelihood Ratio Statistic

$$\chi^2_{LR} = 2\left[l(\hat{\boldsymbol{\beta}}) - l(\tilde{\boldsymbol{\beta}}_{\mathbf{L}})\right]$$

Score Statistic

$$\chi^2_S = \left[\frac{\partial l(\tilde{\boldsymbol{\beta}}_{\mathbf{L}})}{\partial \boldsymbol{\beta}}\right]' \left[-\frac{\partial^2 l(\tilde{\boldsymbol{\beta}}_{\mathbf{L}})}{\partial \boldsymbol{\beta}^2}\right]^{-1} \left[\frac{\partial l(\tilde{\boldsymbol{\beta}}_{\mathbf{L}})}{\partial \boldsymbol{\beta}}\right]$$

Wald's Statistic

$$\chi^2_W = \left(\mathbf{L}\hat{\boldsymbol{\beta}}\right)' \left[\mathbf{L}\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})\mathbf{L}'\right]^{-1} \left(\mathbf{L}\hat{\boldsymbol{\beta}}\right)$$

where $\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})$ is the estimated covariance matrix, which can be the model-based covariance matrix $\left[-\frac{\partial^2 l(\hat{\boldsymbol{\beta}})}{\partial \boldsymbol{\beta}^2}\right]^{-1}$ or the sandwich covariance matrix $V_S(\hat{\boldsymbol{\beta}})$ (see the section "Robust Sandwich Variance Estimate" on page 5448 for details).

Confidence Limits for a Hazard Ratio

Let $\mathbf{e}_j$ be the jth unit vector—that is, the jth entry of the vector is 1 and all other entries are 0. The hazard ratio for the explanatory variable with regression coefficient $\beta_j = \mathbf{e}'_j\boldsymbol{\beta}$ is defined as $\exp(\beta_j)$. In general, a log-hazard ratio can be written as $\mathbf{h}'\boldsymbol{\beta}$, a linear combination of the regression coefficients, and the hazard ratio $\exp(\mathbf{h}'\boldsymbol{\beta})$ is obtained by replacing $\mathbf{e}_j$ with $\mathbf{h}$.

Point Estimate

The hazard ratio $\exp(\mathbf{e}'_j\boldsymbol{\beta})$ is estimated by $\exp(\mathbf{e}'_j\hat{\beta})$, where $\hat{\boldsymbol{\beta}}$ is the maximum likelihood estimate of the $\boldsymbol{\beta}$.

Wald's Confidence Limits

The $100(1-\alpha)\%$ confidence limits for the hazard ratio are calculated as

$$\exp\left(\mathbf{e}'_j\hat{\beta} \pm z_{\alpha/2}\sqrt{\mathbf{e}'_j\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})\mathbf{e}_j}\right)$$

where $\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})$ is estimated covariance matrix, and $z_{\alpha/2}$ is the $100(1-\alpha/2)$ percentile point of the standard normal distribution.

Profile-Likelihood Confidence Limits

The construction of the profile-likelihood-based confidence interval is derived from the asymptotic χ^2 distribution of the generalized likelihood ratio test of Venzon and Moolgavkar (1988). Suppose that the parameter vector is $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_k)'$ and you want to compute a confidence interval for β_j. The profile-likelihood function for $\beta_j = \gamma$ is defined as

$$l_j^*(\gamma) = \max_{\boldsymbol{\beta} \in \mathcal{B}_j(\gamma)} l(\boldsymbol{\beta})$$

where $\mathcal{B}_j(\gamma)$ is the set of all $\boldsymbol{\beta}$ with the jth element fixed at γ, and $l(\boldsymbol{\beta})$ is the log-likelihood function for $\boldsymbol{\beta}$. If $l_{\max} = l(\hat{\boldsymbol{\beta}})$ is the log likelihood evaluated at the maximum likelihood estimate $\hat{\boldsymbol{\beta}}$, then $2(l_{\max} - l_j^*(\beta_j))$ has a limiting chi-square distribution with one degree of freedom if β_j is the true parameter value. Let $l_0 = l_{\max} - 0.5\chi_1^2(1-\alpha)$, where $\chi_1^2(1-\alpha)$ is the $100(1-\alpha)$ percentile of the chi-square distribution with one degree of freedom. A $100(1-\alpha)\%$ confidence interval for β_j is

$$\{\gamma : l_j^*(\gamma) \geq l_0\}$$

The endpoints of the confidence interval are found by solving numerically for values of β_j that satisfy equality in the preceding relation. To obtain an iterative algorithm for computing the confidence limits, the log-likelihood function in a neighborhood of $\boldsymbol{\beta}$ is approximated by the quadratic function

$$\tilde{l}(\boldsymbol{\beta} + \boldsymbol{\delta}) = l(\boldsymbol{\beta}) + \boldsymbol{\delta}'\mathbf{g} + \frac{1}{2}\boldsymbol{\delta}'\mathbf{V}\boldsymbol{\delta}$$

where $\mathbf{g} = \mathbf{g}(\boldsymbol{\beta})$ is the gradient vector and $\mathbf{V} = \mathbf{V}(\boldsymbol{\beta})$ is the Hessian matrix. The increment $\boldsymbol{\delta}$ for the next iteration is obtained by solving the likelihood equations

$$\frac{d}{d\boldsymbol{\delta}}\{\tilde{l}(\boldsymbol{\beta} + \boldsymbol{\delta}) + \lambda(\mathbf{e}_j'\boldsymbol{\delta} - \gamma)\} = \mathbf{0}$$

where λ is the Lagrange multiplier, $\mathbf{e}_j$ is the jth unit vector, and γ is an unknown constant. The solution is

$$\boldsymbol{\delta} = -\mathbf{V}^{-1}(\mathbf{g} + \lambda\mathbf{e}_j)$$

By substituting this $\boldsymbol{\delta}$ into the equation $\tilde{l}(\boldsymbol{\beta} + \boldsymbol{\delta}) = l_0$, you can estimate λ as

$$\lambda = \pm\left(\frac{2(l_0 - l(\boldsymbol{\beta}) + \frac{1}{2}\mathbf{g}'\mathbf{V}^{-1}\mathbf{g})}{\mathbf{e}_j'\mathbf{V}^{-1}\mathbf{e}_j}\right)^{\frac{1}{2}}$$

The upper confidence limit for β_j is computed by starting at the maximum likelihood estimate of $\boldsymbol{\beta}$ and iterating with positive values of λ until convergence is attained. The process is repeated for the lower confidence limit, using negative values of λ.

Convergence is controlled by value ϵ specified with the PLCONV= option in the MODEL statement (the default value of ϵ is 1E−4). Convergence is declared on the current iteration if the following two conditions are satisfied:

$$|l(\boldsymbol{\beta}) - l_0| \leq \epsilon$$

and

$$(\mathbf{g} + \lambda\mathbf{e}_j)'\mathbf{V}^{-1}(\mathbf{g} + \lambda\mathbf{e}_j) \leq \epsilon$$

The profile-likelihood confidence limits for the hazard ratio $\exp(\mathbf{e}_j'\boldsymbol{\beta})$ are obtained by exponentiating these confidence limits.

Using the TEST Statement to Test Linear Hypotheses

Linear hypotheses for $\boldsymbol{\beta}$ are expressed in matrix form as

$$H_0: \mathbf{L}\boldsymbol{\beta} = \mathbf{c}$$

where $\mathbf{L}$ is a matrix of coefficients for the linear hypotheses, and $\mathbf{c}$ is a vector of constants. The Wald chi-square statistic for testing H_0 is computed as

$$\chi^2_W = \left(\mathbf{L}\hat{\boldsymbol{\beta}} - \mathbf{c}\right)' \left[\mathbf{L}\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})\mathbf{L}'\right]^{-1} \left(\mathbf{L}\hat{\boldsymbol{\beta}} - \mathbf{c}\right)$$

where $\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})$ is the estimated covariance matrix. Under H_0, χ^2_W has an asymptotic chi-square distribution with r degrees of freedom, where r is the rank of $\mathbf{L}$.

Optimal Weights for the AVERAGE option in the TEST Statement

Let $\boldsymbol{\beta}_0 = (\beta_{i_1}, \ldots, \beta_{i_s})'$, where $\{\beta_{i_1}, \ldots, \beta_{i_s}\}$ is a subset of s regression coefficients. For any vector $\mathbf{e} = (e_1, \ldots, e_s)'$ of length s,

$$\mathbf{e}'\hat{\boldsymbol{\beta}}_0 \sim N(\mathbf{e}'\boldsymbol{\beta}_0, \mathbf{e}'\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}}_0)\mathbf{e})$$

To find $\mathbf{e}$ such that $\mathbf{e}'\hat{\boldsymbol{\beta}}_0$ has the minimum variance, it is necessary to minimize $\mathbf{e}'\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}}_0)\mathbf{e}$ subject to $\sum_{i=1}^{k} e_i = 1$. Let $\mathbf{1}_s$ be a vector of 1's of length s. The expression to be minimized is

$$\mathbf{e}'\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}}_0)\mathbf{e} - \lambda(\mathbf{e}'\mathbf{1}_s - 1)$$

where λ is the Lagrange multipler. Differentiating with respect to $\mathbf{e}$ and λ, respectively, yields

$$\begin{aligned} \hat{\mathbf{V}}(\hat{\boldsymbol{\beta}}_0)\mathbf{e} - \lambda\mathbf{1}_s &= \mathbf{0} \\ \mathbf{e}'\mathbf{1}_s - 1 &= 0 \end{aligned}$$

Solving these equations gives

$$\mathbf{e} = [\mathbf{1}_s'\hat{\mathbf{V}}^{-1}(\hat{\boldsymbol{\beta}}_0)\mathbf{1}_s]^{-1}\hat{\mathbf{V}}^{-1}(\hat{\boldsymbol{\beta}}_0)\mathbf{1}_s$$

This provides a one degree-of-freedom test for testing the null hypothesis $H_0 : \beta_{i_1} = \ldots = \beta_{i_s} = 0$ with normal test statistic

$$Z = \frac{\mathbf{e}'\hat{\boldsymbol{\beta}}_0}{\sqrt{\mathbf{e}'\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}}_0)\mathbf{e}}}$$

This test is more sensitive than the multivariate test specified by the TEST statement

```
Multivariate: test X1, ..., Xs;
```

where X1, ..., Xs are the variables with regression coefficients $\beta_{i_1}, \ldots, \beta_{i_s}$, respectively.

Analysis of Multivariate Failure Time Data

Multivariate failure time data arise when each study subject can potentially experience several events (for instance, multiple infections after surgery) or when there exists some natural or artificial clustering of subjects (for instance, a litter of mice) that induces dependence among the failure times of the same cluster. Data in the former situation are referred to as multiple events data, and data in the latter situation are referred to as clustered data. The multiple events data can be further classified into ordered and unordered data. For ordered data, there is a natural ordering of the multiple failures within a subject, which includes recurrent events data as a special case. For unordered data, the multiple event times result from several concurrent failure processes.

Multiple events data can be analyzed by the Wei, Lin, and Weissfeld (1989), or WLW, method based on the marginal Cox models. For the special case of recurrent events data, you can fit the intensity model (Andersen and Gill 1982), the proportional rates/means model (Pepe and Cai 1993; Lawless and Nadeau 1995; Lin et al. 2000), or the stratified models for total time and gap time proposed by Prentice, Williams, and Peterson (1981), or PWP. For clustered data, you can carry out the analysis of Lee, Wei, and Amato (1992) based on the marginal Cox model. To use PROC PHREG to perform these analyses correctly and effectively, you have to array your data in a specific way to produce the correct risk sets.

All examples described in this section can be found in the program *phrmult.sas* in the SAS/STAT sample library. Furthermore, the "Examples" section in this chapter contains two examples to illustrate the methods of analyzing recurrent events data and clustered data.

Marginal Cox Models for Multiple Events Data

Suppose there are n subjects and each subject can experience up to K potential events. Let $\mathbf{Z}_{ki}(.)$ be the covariate process associated with the kth event for the ith subject. The marginal Cox models are given by

$$\lambda_k(t;\mathbf{Z}_{ki}) = \lambda_{k0} e^{\boldsymbol{\beta}_k' \mathbf{Z}_{ki}(t)}, k = 1,\ldots,K; i = 1,\ldots,n$$

where $\lambda_{k0}(t)$ is the (event-specific) baseline hazard function for the kth event and $\boldsymbol{\beta}_k$ is the (event-specific) column vector of regression coefficients for the kth event. WLW estimates $\boldsymbol{\beta}_1,\ldots,\boldsymbol{\beta}_K$ by the maximum partial likelihood estimates $\hat{\boldsymbol{\beta}}_1,\ldots,\hat{\boldsymbol{\beta}}_K$, respectively, and uses a robust sandwich covariance matrix estimate for $(\hat{\boldsymbol{\beta}}_1',\ldots,\hat{\boldsymbol{\beta}}_K')'$ to account for the dependence of the multiple failure times.

By using a properly prepared input data set, you can estimate the regression parameters for all the marginal Cox models and compute the robust sandwich covariance estimates in one PROC PHREG invocation. For convenience of discussion, suppose each subject can potentially experience K=3 events and there are two explanatory variables Z1 and Z2. The event-specific parameters to be estimated are $\boldsymbol{\beta}_1 = (\beta_{11},\beta_{21})'$ for the first marginal model, $\boldsymbol{\beta}_2 = (\beta_{12},\beta_{22})'$ for the second marginal model, and $\boldsymbol{\beta}_3 = (\beta_{13},\beta_{23})'$ for the third marginal model. Inference of these parameters is based on the robust sandwich covariance matrix estimate of the parameter estimators. It is necessary that each row of the input data set represent the data for a potential event of a subject. The input data set should contain the following:

- an ID variable for identifying the subject so that all observations of the same subject have the same ID value
- an Enum variable to index the multiple events. For example, Enum=1 for the first event, Enum=2 for the second event, and so on.

- a Time variable to represent the observed time from some time origin for the event. For recurrence events data, it is the time from the study entry to each recurrence.
- a Status variable to indicate whether the Time value is a censored or uncensored time. For example, Status=1 indicates an uncensored time and Status=0 indicates a censored time.
- independent variables (Z1 and Z2)

The WLW analysis can be carried out by specifying the following:

```
proc phreg covs(aggregate);
   model Time*Status(0)=Z11 Z12 Z13 Z21 Z22 Z23;
   strata Enum;
   id ID;
   Z11= Z1 * (Enum=1);
   Z12= Z1 * (Enum=2);
   Z13= Z1 * (Enum=3);
   Z21= Z2 * (Enum=1);
   Z22= Z2 * (Enum=2);
   Z23= Z2 * (Enum=3);
   run;
```

The variable Enum is specified in the STRATA statement so that there is one marginal Cox model for each distinct value of Enum. The variables Z11, Z12, Z13, Z21, Z22, and Z23 in the MODEL statement are event-specific variables derived from the independent variables Z1 and Z2 by the given programming statements. In particular, the variables Z11, Z12, and Z13 are event-specific variables for the explanatory variable Z1; the variables Z21, Z22, and Z23 are event-specific variables for the explanatory variable Z2. For $j = 1, 2$, and $k = 1, 2, 3$, variable Zjk contains the same values as the explanatory variable Zj for the rows that correspond to kth marginal model and the value 0 for all other rows; as such, β_{jk} is the regression coefficient for Zjk. You can avoid using the programming statements in PROC PHREG if you create these event-specific variables in the input data set by using the same programming statements in a DATA step.

The option COVS(AGGREGATE) is specified in the PROC statement to obtain the robust sandwich estimate of the covariance matrix, and the score residuals used in computing the middle part of the sandwich estimate are aggregated over identical ID values. You can also include TEST statements in the PROC PHREG code to test various linear hypotheses of the regression parameters based on the robust sandwich covariance matrix estimate.

Consider the AIDS study data in Wei, Lin, and Weissfeld (1989) from a randomized clinical trial to assess the antiretroviral capacity of ribavirin over time in AIDS patients. Blood samples were collected at weeks 4, 8, and 12 from each patient in three treatment groups (placebo, low dose of ribavirin, and high dose). For each serum sample, the failure time is the number of days before virus positivity was detected. If the sample was contaminated or it took a longer period of time than was achievable in the laboratory, the sample was censored. For example:

- Patient #1 in the placebo group has uncensored times 9, 6, and 7 days (that is, it took 9 days to detect viral positivity in the first blood sample, 6 days for the second blood sample, and 7 days for the third blood sample).
- Patient #14 in the low-dose group of ribavirin has uncensored times of 16 and 17 days for the first and second sample, respectively, and a censored time of 21 days for the third blood sample.

- Patient #28 in the high-dose group has an uncensored time of 21 days for the first sample, no measurement for the second blood sample, and a censored time of 25 days for the third sample.

For a full-rank parameterization, two design variables are sufficient to represent three treatment groups. Based on the reference coding with placebo as the reference, the values of the two dummy explanatory variables Z1 and Z2 representing the treatments are as follows:

Treatment Group	Z1	Z2
Placebo	0	0
Low dose ribavirin	1	0
High dose ribavirin	0	1

The bulk of the task in using PROC PHREG to perform the WLW analysis lies in the preparation of the input data set. As discussed earlier, the input data set should contain the ID, Enum, Time, and Status variables, and event-specific independent variables Z11, Z12, Z13, Z21, Z22, and Z23. Data for the three patients described earlier are arrayed as follows:

ID	Time	Status	Enum	Z1	Z2
1	9	1	1	0	0
1	6	1	2	0	0
1	7	1	3	0	0
14	16	1	1	1	0
14	17	1	2	1	0
14	21	0	3	1	0
28	21	1	1	0	1
28	25	0	3	0	1

The first three rows are data for Patient #1 with event times at 9, 6, and 7 days, one row for each event. The next three rows are data for Patient #14, who has an uncensored time of 16 days for the first serum sample, an uncensored time of 17 days for the second sample, and a censored time of 21 days for the third sample. The last two rows are data for Patient #28 of the high-dose group (Z1=0 and Z2=1). Since the patient did not have a second serum sample, there are only two rows of data.

To perform the WLW analysis, you specify the following statements:

```
proc phreg covs(aggregate);
   model Time*Status(0)=Z11 Z12 Z13 Z21 Z22 Z23;
   strata Enum;
   id ID;
   Z11= Z1 * (Enum=1);
   Z12= Z1 * (Enum=2);
   Z13= Z1 * (Enum=3);
   Z21= Z2 * (Enum=1);
   Z22= Z2 * (Enum=2);
   Z23= Z2 * (Enum=3);
   EqualLowDose: test Z11=Z12, Z12=Z23;
   AverageLow: test Z11,Z12,Z13 / e average;
run;
```

Two linear hypotheses are tested using the TEST statements. The specification

```
EqualLowDose: test Z11=Z12, Z12=Z13;
```

tests the null hypothesis $\beta_{11} = \beta_{12} = \beta_{13}$ of identical low-dose effects across three marginal models. The specification

```
AverageLow: test Z11,Z12,Z13 / e average;
```

tests the null hypothesis of no low-dose effects (that is, $\beta_{11} = \beta_{12} = \beta_{13} = 0$). The AVERAGE option computes the optimal weights for estimating the average low-dose effect $\beta_1^* = \beta_{11} = \beta_{12} = \beta_{13}$ and performs a 1 DF test for testing the null hypothesis that $\beta_1^* = 0$. The E option displays the coefficients for the linear hypotheses, including the optimal weights.

Marginal Cox Models for Clustered Data

Suppose there are n clusters with K_i members in the ith cluster, $i = 1, \ldots, n$. Let $\mathbf{Z}_{ki}(.)$ be the covariate process associated with the kth member of the ith cluster. The marginal Cox model is given by

$$\lambda(t; \mathbf{Z}_{ki}) = \lambda_0(t) e^{\boldsymbol{\beta}' \mathbf{Z}_{ki}(t)} k = 1, \ldots, K_i; i = 1, \ldots, n$$

where $\lambda_0(t)$ is an arbitrary baseline hazard function and $\boldsymbol{\beta}$ is the vector of regression coefficients. Lee, Wei, and Amato (1992) estimate $\boldsymbol{\beta}$ by the maximum partial likelihood estimate $\hat{\boldsymbol{\beta}}$ under the independent working assumption, and use a robust sandwich covariance estimate to account for the intracluster dependence.

To use PROC PHREG to analyze the clustered data, each member of a cluster is represented by an observation in the input data set. The input data set to PROC PHREG should contain the following:

- an ID variable to identify the cluster so that members of the same cluster have the same ID value
- a Time variable to represent the observed survival time of a member of a cluster
- a Status variable to indicate whether the Time value is an uncensored or censored time. For example, Status=1 indicates an uncensored time and Status=0 indicates a censored time.
- the explanatory variables thought to be related to the failure time

Consider a tumor study in which one of three female rats of the same litter was randomly subjected to a drug treatment. The failure time is the time from randomization to the detection of tumor. If a rat died before the tumor was detected, the failure time was censored. For example:

- In litter #1, the drug-treated rat has an uncensored time of 101 days, one untreated rat has a censored time of 49 days, and the other untreated rat has a failure time of 104 days.
- In litter #3, the drug-treated rat has a censored time of 104 days, one untreated rat has a censored time of 102 days, and the other untreated rat has a censored time of 104 days.

In this example, a litter is a cluster and the rats of the same litter are members of the cluster. Let Trt be a 0-1 variable representing the treatment a rat received, with value 1 for drug treatment and 0 otherwise. Data for the two litters of rats described earlier contribute six observations to the input data set:

Litter	Time	Status	Trt
1	101	1	1
1	49	0	0
1	104	1	0
3	104	0	1
3	102	0	0
3	104	0	0

The analysis of Lee, Wei, and Amato (1992) can be performed by PROC PHREG as follows:

```
proc phreg covs(aggregate);
   model Time*Status(0)=Treatment;
   id Litter;
run;
```

Intensity and Rate/Mean Models for Recurrent Events Data

Suppose each subject experiences recurrences of the same phenomenon. Let $N(t)$ be the number of events a subject experiences over the interval $[0,t]$ and let $\mathbf{Z}(.)$ be the covariate process of the subject.

The intensity model (Andersen and Gill 1982) is given by

$$\lambda_{\mathbf{Z}}(t)dt = E\{dN(t)|\mathcal{F}_{t-}\} = \lambda_0(t)e^{\boldsymbol{\beta}'\mathbf{Z}(t)}dt$$

where $\mathcal{F}_t$ represents all the information of the processes N and $\mathbf{Z}$ up to time t, $\lambda_0(t)$ is an arbitrary baseline intensity function, and $\boldsymbol{\beta}$ is the vector of regression coefficients. This model consists of two components: (1) all the influence of the prior events on future recurrences, if there is any, is mediated through the time-dependent covariates, and (2) the covariates have multiplicative effects on the instantaneous rate of the counting process. If the covariates are time invariant, the risk of recurrences is unaffected by the past events.

The proportional rates and means models (Pepe and Cai 1993; Lawless and Nadeau 1995; Lin et al. 2000) assume that the covariates have multiplicative effects on the mean and rate functions of the counting process. The rate function is given by

$$d\mu_{\mathbf{Z}}(t) = E\{dN(t)|\mathbf{Z}(t)\} = e^{\boldsymbol{\beta}'\mathbf{Z}(t)}d\mu_0(t)$$

where $\mu_0(t)$ is an unknown continuous function and $\boldsymbol{\beta}$ is the vector of regression parameters. If $\mathbf{Z}$ is time invariant, the mean function is given by

$$\mu_{\mathbf{Z}}(t) = E\{N(t)|\mathbf{Z}\} = e^{\boldsymbol{\beta}'\mathbf{Z}}\mu_0(t)$$

For both the intensity and the proportional rates/means models, estimates of the regression coefficients are obtained by solving the partial likelihood score function. However, the covariance matrix estimate for the intensity model is computed as the inverse of the observed information matrix, while that for the proportional rates/means model is given by a sandwich estimate. For a given pattern of fixed covariates, the Nelson estimate for the cumulative intensity function is the same for the cumulative mean function, but their standard errors are not the same.

To fit the intensity or rate/mean model by using PROC PHREG, the counting process style of input is needed. A subject with K events contributes K+1 observations to the input data set. The kth observation of the subject identifies the time interval from the $(k-1)$th event or time 0 (if $k = 1$) to the kth event, $k = 1, \ldots, K$. The $(K+1)$th observation represents the time interval from the Kth event to time of censorship. The input data set should contain the following variables:

- a TStart variable to represent the $(k-1)$th recurrence time or the value 0 if $k = 1$
- a TStop variable to represent the kth recurrence time or the follow-up time if $k = K + 1$
- a Status variable indicating whether the TStop time is a recurrence time or a censored time; for example, Status=1 for a recurrence time and Status=0 for censored time
- explanatory variables thought to be related to the recurrence times

If the rate/mean model is used, the input data should also contain an ID variable for identifying the subjects.

Consider the chronic granulomatous disease (CGD) data listed in Fleming and Harrington (1991). The disease is a rare disorder characterized by recurrent pyrogenic infections. The study is a placebo-controlled randomized clinical trial conducted by the International CGD Cooperative Study to assess the effect of gamma interferon to reduce the rate of infection. For each study patient the times of recurrent infections along with a number of prognostic factors were collected. For example:

- Patient #17404, age 38, in the gamma interferon group had a follow-up time of 293 without any infection.
- Patient #204001, age 12, in the placebo group had an infection at 219 days, a recurrent infection at 373 days, and was followed up to 414 days.

Let Trt be the variable representing the treatment status with value 1 for gamma interferon and value 2 for placebo. Let Age be a covariate representing the age of the CGD patient. Data for the two CGD patients described earlier are given in the following table.

ID	TStart	TStop	Status	Trt	Age
174054	0	293	0	1	38
204001	0	219	1	2	12
204001	219	373	1	2	12
204001	373	414	0	2	12

Since Patient #174054 had no infection through the end of the follow-up period (293 days), there is only one observation representing the period from time 0 to the end of the follow-up. Data for Patient #204001 are broken into three observations, since there are two infections. The first observation represents the period from time 0 to the first infection, the second observation represents the period from the first infection to the second infection, and the third time period represents the period from the second infection to the end of the follow-up.

The following specification fits the intensity model:

```
proc phreg;
   model (TStart,TStop)*Status(0)=Trt Age;
   run;
```

You can predict the cumulative intensity function for a given pattern of fixed covariates by specifying the CUMHAZ= option in the BASELINE statement. Suppose you are interested in two fixed patterns, one for patients of age 30 in the gamma interferon group and the other for patients of age 1 in the placebo group. You first create the SAS data set as follows:

```
data Pattern;
   Trt=1; Age=30;
   output;
   Trt=2; Age=1;
   output;
   run;
```

You then include the following BASELINE statement in the PROC PHREG specification. The CUMHAZ=_all_ option produces the cumulative hazard function estimates, the standard error estimates, and the lower and upper pointwise confidence limits.

```
baseline covariates=Pattern out=out1 cumhaz=_all_;
```

The following specification of PROC PHREG fits the mean model and predicts the cumulative mean function for the two patterns of covariates in the Pattern data set:

```
proc phreg covs(aggregate);
   model (Tstart,Tstop)*Status(0)=Trt Age;
   baseline covariates=Pattern out=out2 cmf=_all_;
   id ID;
```

The COV(AGGREGATE) option, along with the ID statement, computes the robust sandwich covariance matrix estimate. The CMF=_ALL_ option adds the cumulative mean function estimates, the standard error estimates, and the lower and upper pointwise confidence limits to the OUT=Out2 data set.

PWP Models for Recurrent Events Data

Let $N(t)$ be the number of events a subject experiences by time t. Let $\mathbf{Z}(t)$ be the covariate vectors of the subject at time t. For a subject who has K events before censorship takes place, let $t_0 = 0$, let t_k be the kth recurrence time, $k = 1, \ldots, K$, and let t_{K+1} be the censored time. Prentice, Williams, and Peterson (1981) consider two time scales, a total time from the beginning of the study and a gap time from immediately preceding failure. The PWP models are stratified Cox-type models that allow the shape of the hazard function to depend on the number of preceding events and possibly on other characteristics of $\{N(t)$ and $\mathbf{Z}(t)\}$. The total time and gap time models are given, respectively, as follows:

$$\lambda(t|\mathcal{F}_{t-}) = \lambda_{0k}(t)e^{\boldsymbol{\beta}_k'\mathbf{Z}(t)}, \qquad t_{k-1} < t \le t_k$$
$$\lambda(t|\mathcal{F}_{t-}) = \lambda_{0k}(t - t_{k-1})e^{\boldsymbol{\beta}_k'\mathbf{Z}(t)}, \qquad t_{k-1} < t \le t_k$$

where λ_{0k} is an arbitrary baseline intensity functions, and $\boldsymbol{\beta}_k$ is a vector of stratum-specific regression coefficients. Here, a subject moves to the kth stratum immediately after his $(k-1)$th recurrence time and

remains there until the kth recurrence occurs or until censorship takes place. For instance, a subject who experiences only one event moves from the first stratum to the second stratum after the event occurs and remains in the second stratum until the end of the follow-up.

You can use PROC PHREG to carry out the analyses of the PWP models, but you have to prepare the input data set to provide the correct risk sets. The input data set for analyzing the total time is the same as the AG model with an additional variable to represent the stratum that the subject is in. A subject with K events contributes K+1 observations to the input data set, one for each stratum that the subject moves to. The input data should contain the following variables:

- a TStart variable to represent the $(k-1)$th recurrence time or the value 0 if $k = 1$
- a TStop variable to represent the kth recurrence time or the time of censorship if $k = K + 1$
- a Status variable with value 1 if the Time value is a recurrence time and value 0 if the Time value is a censored time
- an Enum variable representing the index of the stratum that the subject is in. For a subject who has only one event at t_1 and is followed to time t_c, Enum=1 for the first observation (where Time=t_1 and Status=1) and Enum=2 for the second observation (where Time=t_c and Status=0).
- explanatory variables thought to be related to the recurrence times

To analyze gap times, the input data set should also include a GapTime variable that is equal to (TStop − TStart).

Consider the data of two subjects in CGD data described in the previous section:

- Patients #174054, age 38, in the gamma interferon group had a follow-up time of 293 without any infection.
- Patient #204001, age 12, in the placebo group had an infection at 219 days, a recurrent infection at 373 days, and a follow-up time of 414 days.

To illustrate, suppose all subjects have at most two observed events. The data for the two subjects in the input data set are as follows:

ID	TStart	TStop	Gaptime	Status	Enum	Trt	Age
174054	0	293	293	0	1	1	38
204001	0	219	219	1	1	2	12
204001	219	373	154	1	2	2	12
204001	373	414	41	0	3	2	12

Subject #174054 contributes only one observation to the input data, since there is no observed event. Subject #204001 contributes three observations, since there are two observed events.

To fit the total time model of PWP with stratum-specific slopes, either you can create the stratum-specific explanatory variables (Trt1, Trt2, and Trt3 for Trt, and Age1, Age2, and Age3 for Age) in a DATA step, or you can specify them in PROC PHREG by using programming statements as follows:

```
proc phreg;
   model (TStart,TStop)*Status(0)=Trt1 Trt2 Trt3 Age1 Age2 Age3;
   strata Enum;
   Trt1= Trt * (Enum=1);
   Trt2= Trt * (Enum=2);
   Trt3= Trt * (Enum=3);
   Age1= Age * (Enum=1);
   Age2= Age * (Enum=2);
   Age3= Age * (Enum=3);
   run;
```

To fit the total time model of PWP with the common regression coefficients, you specify the following:

```
proc phreg;
   model (TStart,TStop)*Status(0)=Trt Age;
   strata Enum;
   run;
```

To fit the gap time model of PWP with stratum-specific regression coefficients, you specify the following:

```
proc phreg;
   model Gaptime*Status(0)=Trt1 Trt2 Trt3 Age1 Age2 Age3;
   strata Enum;
   Trt1= Trt * (Enum=1);
   Trt2= Trt * (Enum=2);
   Trt3= Trt * (Enum=3);
   Age1= Age * (Enum=1);
   Age2= Age * (Enum=2);
   Age3= Age * (Enum=3);
run;
```

To fit the gap time model of PWP with common regression coefficients, you specify the following:

```
proc phreg;
   model Gaptime*Status(0)=Trt Age;
   strata Enum;
   run;
```

Model Fit Statistics

Suppose the model contains p regression parameters. Let Δ_j and f_j be the event indicator and the frequency, respectively, of the jth observation. The three criteria displayed by the PHREG procedure are calculated as follows:

- -2 Log Likelihood:

  $$-2 \text{ Log L} = -2\log(L_n(\hat{\boldsymbol{\beta}}))$$

  where $L_n(.)$ is a partial likelihood function for the corresponding TIES= option as described in the section "Partial Likelihood Function for the Cox Model" on page 5435, and $\hat{\boldsymbol{\beta}}$ is the maximum likelihood estimate of the regression parameter vector.

- Akaike's Information Criterion:

$$\text{AIC} = -2\,\text{Log L} + 2p$$

- Schwarz Bayesian (Information) Criterion:

$$\text{SBC} = -2\,\text{Log L} + p\log(\sum_j f_j \Delta_j)$$

The -2 Log Likelihood statistic has a chi-square distribution under the null hypothesis (that all the explanatory effects in the model are zero) and the procedure produces a p-value for this statistic. The AIC and SBC statistics give two different ways of adjusting the -2 Log Likelihood statistic for the number of terms in the model and the number of observations used. These statistics should be used when comparing different models for the same data (for example, when you use the METHOD=STEPWISE option in the MODEL statement); lower values of the statistic indicate a more desirable model.

Residuals

This section describes the computation of residuals (RESMART=, RESDEV=, RESSCH=, and RESSCO=) in the OUTPUT statement.

First, consider TIES=BRESLOW. Let

$$\begin{aligned}
S^{(0)}(\boldsymbol{\beta}, t) &= \sum_i Y_i(t) \mathrm{e}^{\boldsymbol{\beta}' \mathbf{Z}_i(t)} \\
S^{(1)}(\boldsymbol{\beta}, t) &= \sum_i Y_i(t) \mathrm{e}^{\boldsymbol{\beta}' \mathbf{Z}_i(t)} \mathbf{Z}_i(t) \\
\bar{\mathbf{Z}}(\boldsymbol{\beta}, t) &= \frac{S^{(1)}(\boldsymbol{\beta}, t)}{S^{(0)}(\boldsymbol{\beta}, t)} \\
d\Lambda_0(\boldsymbol{\beta}, t) &= \sum_i \frac{dN_i(t)}{S^{(0)}(\boldsymbol{\beta}, t)} \\
dM_i(\boldsymbol{\beta}, t) &= dN_i(t) - Y_i(t) \mathrm{e}^{\boldsymbol{\beta}' \mathbf{Z}_i(t)} d\Lambda_0(\boldsymbol{\beta}, t)
\end{aligned}$$

The martingale residual at t is defined as

$$\hat{M}_i(t) = \int_0^t dM_i(\hat{\boldsymbol{\beta}}, s) = N_i(t) - \int_0^t Y_i(s) \mathrm{e}^{\hat{\boldsymbol{\beta}}' \mathbf{Z}_i(s)} d\Lambda_0(\hat{\boldsymbol{\beta}}, s)$$

Here $\hat{M}_i(t)$ estimates the difference over $(0, t]$ between the observed number of events for the ith subject and a conditional expected number of events. The quantity $\hat{M}_i \equiv \hat{M}_i(\infty)$ is referred to as the martingale residual for the ith subject. When the counting process MODEL specification is used, the RESMART= variable contains the component $(\hat{M}_i(t_2) - \hat{M}_i(t_1))$ instead of the martingale residual at t_2. The martingale residual for a subject can be obtained by summing up these component residuals within the subject. For the

Cox model with no time-dependent explanatory variables, the martingale residual for the ith subject with observation time t_i and event status Δ_i is

$$\hat{M}_i = \Delta_i - e^{\hat{\boldsymbol{\beta}}'\mathbf{Z}_i} \int_0^{t_i} d\Lambda_0(\hat{\boldsymbol{\beta}}, s)$$

The deviance residuals D_i are a transform of the martingale residuals:

$$D_i = \text{sign}(\hat{M}_i)\sqrt{2\left[-\hat{M}_i - N_i(\infty)\log\left(\frac{N_i(\infty) - \hat{M}_i}{N_i(\infty)}\right)\right]}$$

The square root shrinks large negative martingale residuals, while the logarithmic transformation expands martingale residuals that are close to unity. As such, the deviance residuals are more symmetrically distributed around zero than the martingale residuals. For the Cox model, the deviance residual reduces to the form

$$D_i = \text{sign}(\hat{M}_i)\sqrt{2[-\hat{M}_i - \Delta_i \log(\Delta_i - \hat{M}_i)]}$$

When the counting process MODEL specification is used, values of the RESDEV= variable are set to missing because the deviance residuals can be calculated only on a per-subject basis.

The Schoenfeld (1982) residual vector is calculated on a per-event-time basis. At the jth event time t_{i_j} of the ith subject, the Schoenfeld residual

$$\hat{\mathbf{U}}_i(t_{i_j}) = \mathbf{Z}_i(t_{i_j}) - \bar{\mathbf{Z}}(\hat{\boldsymbol{\beta}}, t_{i_j})$$

is the difference between the ith subject covariate vector at t_{i_j} and the average of the covariate vectors over the risk set at t_{i_j}. Under the proportional hazards assumption, the Schoenfeld residuals have the sample path of a random walk; therefore, they are useful in assessing time trend or lack of proportionality. Harrell (1886) proposed a z-transform of the Pearson correlation between these residuals and the rank order of the failure time as a test statistic for nonproportional hazards. Therneau, Grambsch, and Fleming (1990) considered a Kolmogorov-type test based on the cumulative sum of the residuals.

The score process for the ith subject at time t is

$$\mathbf{L}_i(\boldsymbol{\beta}, t) = \int_0^t [\mathbf{Z}_i(s) - \bar{\mathbf{Z}}(\boldsymbol{\beta}, s)] dM_i(\boldsymbol{\beta}, s)$$

The vector $\hat{\mathbf{L}}_i \equiv \mathbf{L}_i(\hat{\boldsymbol{\beta}}, \infty)$ is the score residual for the ith subject. When the counting process MODEL specification is used, the RESSCO= variables contain the components of $(\mathbf{L}_i(\hat{\boldsymbol{\beta}}, t_2) - \mathbf{L}_i(\hat{\boldsymbol{\beta}}, t_1))$ instead of the score process at t_2. The score residual for a subject can be obtained by summing up these component residuals within the subject.

The score residuals are a decomposition of the first partial derivative of the log likelihood. They are useful in assessing the influence of each subject on individual parameter estimates. They also play an important role in the computation of the robust sandwich variance estimators of Lin and Wei (1989) and Wei, Lin, and Weissfeld (1989).

For TIES=EFRON, the preceding computation is modified to comply with the Efron partial likelihood. Consider an uncensored time t. For a given time t, let $\Delta_i(t)$=1 if the t is an event time of the ith subject

and 0 otherwise. Let $d(t) = \sum_i \Delta_i(t)$, which is the number of subjects that have an event at t. For $1 \le k \le d(t)$, let

$$
\begin{aligned}
S^{(0)}(\boldsymbol{\beta}, k, t) &= \sum_i Y_i(t)\left\{1 - \frac{k-1}{d(t)}\Delta_i(t)\right\} \mathrm{e}^{\boldsymbol{\beta}'\mathbf{Z}_i(t)} \\
S^{(1)}(\boldsymbol{\beta}, k, t) &= \sum_i Y_i(t)\left\{1 - \frac{k-1}{d(t)}\Delta_i(t)\right\} \mathrm{e}^{\boldsymbol{\beta}'\mathbf{Z}_i(t)}\mathbf{Z}_i(t) \\
\bar{\mathbf{Z}}(\boldsymbol{\beta}, k, t) &= \frac{S^{(1)}(\boldsymbol{\beta}, k, t)}{S^{(0)}(\boldsymbol{\beta}, k, t)} \\
d\Lambda_0(\boldsymbol{\beta}, k, t) &= \sum_i \frac{dN_i(t)}{S^{(0)}(\boldsymbol{\beta}, k, t)} \\
dM_i(\boldsymbol{\beta}, k, t) &= dN_i(t) - Y_i(t)\left(1 - \Delta_i(t)\frac{k-1}{d(t)}\right)\mathrm{e}^{\boldsymbol{\beta}'\mathbf{Z}_i(t)} d\Lambda_0(\boldsymbol{\beta}, k, t)
\end{aligned}
$$

The martingale residual at t for the ith subject is defined as

$$
\hat{M}_i(t) = \int_0^t \frac{1}{d(s)} \sum_{k=1}^{d(s)} dM_i(\hat{\boldsymbol{\beta}}, k, s) = N_i(t) - \int_0^t \frac{1}{d(s)} \sum_{k=1}^{d(s)} Y_i(s)\left(1 - \Delta_i(s)\frac{k-1}{d(s)}\right)\mathrm{e}^{\hat{\boldsymbol{\beta}}'\mathbf{Z}_i(s)} d\Lambda_0(\hat{\boldsymbol{\beta}}, k, s)
$$

Deviance residuals are computed by using the same transform on the corresponding martingale residuals as in TIES=BRESLOW.

The Schoenfeld residual vector for the ith subject at event time t_{i_j} is

$$
\hat{\mathbf{U}}_i(t_{i_j}) = \mathbf{Z}_i(t_{i_j}) - \frac{1}{d(t_{i_j})} \sum_{k=1}^{d(t_{i_j})} \bar{\mathbf{Z}}(\hat{\boldsymbol{\beta}}, k, t_{i_j})
$$

The score process for the ith subject at time t is given by

$$
\mathbf{L}_i(\boldsymbol{\beta}, t) = \int_0^t \frac{1}{d(s)} \sum_{k=1}^{d(s)} \left(\mathbf{Z}_i(s) - \bar{\mathbf{Z}}(\boldsymbol{\beta}, k, s)\right) dM_i(\boldsymbol{\beta}, k, s)
$$

For TIES=DISCRETE or TIES=EXACT, it is difficult to come up with modifications that are consistent with the correponding partial likelihood. Residuals for these TIES= methods are computed by using the same formulae as in TIES=BRESLOW.

Diagnostics Based on Weighted Residuals

The vector of weighted Schoenfeld residuals, $\mathbf{r}_i$, is computed as

$$
\mathbf{r}_i = n_e \mathcal{I}^{-1}(\hat{\boldsymbol{\beta}}) \hat{\mathbf{U}}_i(t_i)
$$

where n_e is the total number of events and $\hat{\mathbf{U}}_i(t_i)$ is the vector of Schoenfeld residuals at the event time t_i. The components of $\mathbf{r}_i$ are output to the WTRESSCH= variables.

The weighted Schoenfeld residuals are useful in assessing the proportional hazards assumption. The idea is that most of the common alternatives to the proportional hazards can be cast in terms of a time-varying coefficient model

$$\lambda(t, \mathbf{Z}) = \lambda_0(t) \exp(\beta_1(t) Z_1 + \beta_2(t) Z_2 + \ldots)$$

where $\lambda(t, \mathbf{Z})$ and $\lambda_0(t)$ are hazard rates. Let $\hat{\beta}_j$ and r_{ij} be the jth component of $\hat{\boldsymbol{\beta}}$ and $\mathbf{r}_i$, respectively. Grambsch and Therneau (1994) suggest using a smoothed plot of $(\hat{\beta}_j + r_{ij})$ versus t_i to discover the functional form of the time-varying coefficient $\beta_j(t)$. A zero slope indicates that the coefficient is not varying with time.

The weighted score residuals are used more often than their unscaled counterparts in assessing local influence. Let $\hat{\boldsymbol{\beta}}_{(i)}$ be the estimate of $\boldsymbol{\beta}$ when the ith subject is left out, and let $\delta\hat{\boldsymbol{\beta}}_i = \hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(i)}$. The jth component of $\delta\hat{\boldsymbol{\beta}}_i$ can be used to assess any untoward effect of the ith subject on $\hat{\beta}_j$. The exact computation of $\delta\hat{\boldsymbol{\beta}}_i$ involves refitting the model each time a subject is omitted. Cain and Lange (1984) derived the following approximation of $\boldsymbol{\Delta}_i$ as weighted score residuals:

$$\delta\hat{\boldsymbol{\beta}}_i = \mathcal{I}^{-1}(\hat{\boldsymbol{\beta}})\hat{\mathbf{L}}_i$$

Here, $\hat{\mathbf{L}}_i$ is the vector of the score residuals for the ith subject. Values of $\delta\hat{\boldsymbol{\beta}}_i$ are output to the DFBETA= variables. Again, when the counting process MODEL specification is used, the DFBETA= variables contain the component $\mathcal{I}^{-1}(\hat{\boldsymbol{\beta}})(\mathbf{L}_i(\hat{\boldsymbol{\beta}}, t_2) - \mathbf{L}_i(\hat{\boldsymbol{\beta}}, t_1))$, where the score process $\mathbf{L}_i(\boldsymbol{\beta}, t)$ is defined in the section "Residuals" on page 5462. The vector $\delta\hat{\boldsymbol{\beta}}_i$ for the ith subject can be obtained by summing these components within the subject.

Note that these DFBETA statistics are a transform of the score residuals. In computing the robust sandwich variance estimators of Lin and Wei (1989) and Wei, Lin, and Weissfeld (1989), it is more convenient to use the DFBETA statistics than the score residuals (see Example 66.10).

Influence of Observations on Overall Fit of the Model

The LD statistic approximates the likelihood displacement, which is the amount by which minus twice the log likelihood ($-2 \log L(\hat{\boldsymbol{\beta}})$), under a fitted model, changes when each subject in turn is left out. When the ith subject is omitted, the likelihood displacement is

$$2 \log L(\hat{\boldsymbol{\beta}}) - 2 \log L(\hat{\boldsymbol{\beta}}_{(i)})$$

where $\hat{\boldsymbol{\beta}}_{(i)}$ is the vector of parameter estimates obtained by fitting the model without the ith subject. Instead of refitting the model without the ith subject, Pettitt and Bin Daud (1989) propose that the likelihood displacement for the ith subject be approximated by

$$LD_i = \hat{\mathbf{L}}_i' \mathcal{I}^{-1}(\hat{\boldsymbol{\beta}})\hat{\mathbf{L}}_i$$

wher $\hat{\mathbf{L}}_i$ is the score residual vector of the ith subject. This approximation is output to the LD= variable.

The LMAX statistic is another global influence statistic. This statistic is based on the symmetric matrix

$$\mathbf{B} = \mathbf{L}\mathcal{I}^{-1}(\hat{\boldsymbol{\beta}})\mathbf{L}'$$

where $\mathbf{L}$ is the matrix with rows that are the score residual vectors $\hat{\mathbf{L}}_i$. The elements of the eigenvector associated with the largest eigenvalue of the matrix $\mathbf{B}$, standardized to unit length, give a measure of the sensitivity of the fit of the model to each observation in the data. The influence of the ith subject on the global fit of the model is proportional to the magnitude of ζ_i, where ζ_i is the ith element of the vector $\boldsymbol{\zeta}$ that satisfies

$$\mathbf{B}\boldsymbol{\zeta} = \lambda_{\max}\boldsymbol{\zeta} \quad \text{and} \quad \boldsymbol{\zeta}'\boldsymbol{\zeta} = 1$$

with $\lambda_{\max}$ being the largest eigenvalue of $\mathbf{B}$. The sign of ζ_i is irrelevant, and its absolute value is output to the LMAX= variable.

When the counting process MODEL specification is used, the LD= and LMAX= variables are set to missing, because these two global influence statistics can be calculated on a per-subject basis only.

Survivor Function Estimation for the Cox Model

Two estimators of the survivor function are available: one is the product-limit estimator (Kalbfleisch and Prentice 1980, pp. 84–86) and the other is the Breslow (1972) estimator based on the empirical cumulative hazard function.

Product-Limit Estimates

Let $\mathcal{C}_i$ denote the set of individuals censored in the half-open interval $[t_i, t_{i+1})$, where $t_0 = 0$ and $t_{k+1} = \infty$. Let γ_l denote the censoring times in $[t_i, t_{i+1})$; l ranges over $\mathcal{C}_i$.

The likelihood function for all individuals is given by

$$\mathcal{L} = \prod_{i=0}^{k} \left\{ \prod_{l \in \mathcal{D}_i} \left([S_0(t_i)]^{\exp(\mathbf{z}_l'\boldsymbol{\beta})} - [S_0(t_i + 0)]^{\exp(\mathbf{z}_l'\boldsymbol{\beta})} \right) \prod_{l \in \mathcal{C}_i} [S_0(\gamma_l + 0)]^{\exp(\mathbf{z}_l'\boldsymbol{\beta})} \right\}$$

where $\mathcal{D}_0$ is empty. The likelihood $\mathcal{L}$ is maximized by taking $S_0(t) = S_0(t_i + 0)$ for $t_i < t \leq t_{i+1}$ and allowing the probability mass to fall only on the observed event times $t_1, \ldots, t_k$. By considering a discrete model with hazard contribution $1 - \alpha_i$ at t_i, you take $S_0(t_i) = S_0(t_{i-1} + 0) = \prod_{j=0}^{i-1} \alpha_j$, where $\alpha_0 = 1$. Substitution into the likelihood function produces

$$\mathcal{L} = \prod_{i=0}^{k} \left\{ \prod_{j \in \mathcal{D}_i} \left(1 - \alpha_i^{\exp(\mathbf{z}_j'\boldsymbol{\beta})} \right) \prod_{l \in \mathcal{R}_i - \mathcal{D}_i} \alpha_i^{\exp(\mathbf{z}_l'\boldsymbol{\beta})} \right\}$$

If you replace $\boldsymbol{\beta}$ with $\hat{\boldsymbol{\beta}}$ estimated from the partial likelihood function and then maximize with respect to $\alpha_1, \ldots, \alpha_k$, the maximum likelihood estimate $\hat{\alpha}_i$ of α_i becomes a solution of

$$\sum_{j \in \mathcal{D}_i} \frac{\exp(\mathbf{z}_j'\hat{\boldsymbol{\beta}})}{1 - \hat{\alpha}_i^{\exp(\mathbf{z}_j'\hat{\boldsymbol{\beta}})}} = \sum_{l \in \mathcal{R}_i} \exp(\mathbf{z}_l'\hat{\boldsymbol{\beta}})$$

When only a single failure occurs at t_i, $\hat{\alpha}_i$ can be found explicitly. Otherwise, an iterative solution is obtained by the Newton method.

The estimated baseline cumulative hazard function is

$$\hat{H}_0(t) = -\log(\hat{S}_0(t))$$

where $\hat{S}_0(t)$ is the estimated baseline survivor function given by

$$\hat{S}_0(t) = \hat{S}_0(t_{i-1} + 0) = \prod_{j=0}^{i-1} \hat{\alpha}_j, t_{i-1} < t \leq t_i$$

For details, refer to Kalbfleisch and Prentice (1980). For a given realization of the explanatory variables $\boldsymbol{\xi}$, the product-limit estimate of the survival function at $\mathbf{Z} = \boldsymbol{\xi}$ is

$$\hat{S}(t, \boldsymbol{\xi}) = [\hat{S}_0(t)]^{\exp(\boldsymbol{\beta}'\boldsymbol{\xi})}$$

Empirical Cumulative Hazards Function Estimates

Let $\boldsymbol{\xi}$ be a given realization of the explanatory variables. The empirical cumulative hazard function estimate at $\mathbf{Z} = \boldsymbol{\xi}$ is

$$\hat{\Lambda}(t, \boldsymbol{\xi}) = \sum_{i=1}^{n} \int_0^t \frac{dN_i(s)}{\sum_{j=1}^{n} Y_j(s) \exp(\hat{\boldsymbol{\beta}}'(\mathbf{z}_j - \boldsymbol{\xi}))}$$

The variance estimator of $\hat{\Lambda}(t, \boldsymbol{\xi})$ is given by the following (Tsiatis 1981):

$$\begin{aligned} & \hat{var}\{n^{\frac{1}{2}}(\hat{\Lambda}(t, \boldsymbol{\xi}) - \Lambda(t, \boldsymbol{\xi}))\} \\ = \; & n\left\{\sum_{i=1}^{n} \int_0^t \frac{dN_i(s)}{[\sum_{j=1}^{n} Y_j(s) \exp(\hat{\boldsymbol{\beta}}'(\mathbf{z}_j - \boldsymbol{\xi}))]^2} + \mathbf{H}'(t, \boldsymbol{\xi})\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})\mathbf{H}(t, \boldsymbol{\xi})\right\} \end{aligned}$$

where $\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})$ is the estimated covariance matrix of $\hat{\boldsymbol{\beta}}$ and

$$\mathbf{H}(t, \boldsymbol{\xi}) = \sum_{i=1}^{n} \int_0^t \frac{\sum_{l=1}^{n} Y_l(s)(\mathbf{Z}_l - \boldsymbol{\xi}) \exp(\hat{\boldsymbol{\beta}}'(\mathbf{z}_l - \boldsymbol{\xi}))}{[\sum_{j=1}^{n} Y_j(s) \exp(\hat{\boldsymbol{\beta}}'(\mathbf{z}_j - \boldsymbol{\xi}))]^2} dN_i(s)$$

For the marginal model, the variance estimator computation follows Spiekerman and Lin (1998).

The empirical cumulative hazard function (CH) estimate of the survivor function for $\mathbf{Z} = \boldsymbol{\xi}$ is

$$\tilde{S}(t, \boldsymbol{\xi}) = \exp(-\hat{\Lambda}(t, \boldsymbol{\xi}))$$

Confidence Intervals for the Survivor Function

Let $\hat{S}(t, \boldsymbol{\xi})$ and $\tilde{S}(t, \boldsymbol{\xi})$ correspond to the product-limit (PL) and empirical cumulative hazard function (CH) estimates of the survivor function for $\mathbf{Z} = \boldsymbol{\xi}$, respectively. Both the standard error of $\log(\hat{S}(t, \boldsymbol{\xi}))$ and the standard error of $\log(\tilde{S}(t, \boldsymbol{\xi}))$ are approximated by $\tilde{\sigma}_0(t, \boldsymbol{\xi})$, which is the square root of the variance

estimate of $\hat{\Lambda}(t,\boldsymbol{\xi})$; refer to Kalbfleisch and Prentice (1980, p. 116). By the delta method, the standard errors of $\hat{S}(t,\boldsymbol{\xi})$ and $\tilde{S}(t,\boldsymbol{\xi})$ are given by

$$\hat{\sigma}_1(t,\boldsymbol{\xi}) \doteq \hat{S}(t,\boldsymbol{\xi})\tilde{\sigma}_0(t,\boldsymbol{\xi}) \quad \text{and} \quad \tilde{\sigma}_1(t,\boldsymbol{\xi}) \doteq \tilde{S}(t,\boldsymbol{\xi})\tilde{\sigma}_0(t,\boldsymbol{\xi})$$

respectively. The standard errors of log[–log($\hat{S}(t,\boldsymbol{\xi})$)] and log[–log($\tilde{S}(t,\boldsymbol{\xi})$)] are given by

$$\hat{\sigma}_2(t,\boldsymbol{\xi}) \doteq \frac{-\tilde{\sigma}_0(t,\boldsymbol{\xi})}{\log(\hat{S}(t,\boldsymbol{\xi}))} \quad \text{and} \quad \tilde{\sigma}_2(t,\boldsymbol{\xi}) \doteq \frac{\tilde{\sigma}_0(t,\boldsymbol{\xi})}{\hat{\Lambda}(t,\boldsymbol{\xi})}$$

respectively.

Let $z_{\alpha/2}$ be the upper $100(1-\frac{\alpha}{2})$ percentile point of the standard normal distribution. A $100(1-\alpha)\%$ confidence interval for the survivor function $S(t,\boldsymbol{\xi})$ is given in the following table.

CLTYPE	Method	Confidence Limits
LOG	PL	$\exp[\log(\hat{S}(t,\boldsymbol{\xi})) \pm z_{\frac{\alpha}{2}}\tilde{\sigma}_0(t,\boldsymbol{\xi})]$
LOG	CH	$\exp[\log(\tilde{S}(t,\boldsymbol{\xi})) \pm z_{\frac{\alpha}{2}}\tilde{\sigma}_0(t,\boldsymbol{\xi})]$
LOGLOG	PL	$\exp\{-\exp[\log(-\log(\hat{S}(t,\boldsymbol{\xi}))) \pm z_{\frac{\alpha}{2}}\hat{\sigma}_2(t,\boldsymbol{\xi})]\}$
LOGLOG	CH	$\exp\{-\exp[\log(-\log(\tilde{S}(t,\boldsymbol{\xi}))) \pm z_{\frac{\alpha}{2}}\tilde{\sigma}_2(t,\boldsymbol{\xi})]\}$
NORMAL	PL	$\hat{S}(t,\boldsymbol{\xi}) \pm z_{\frac{\alpha}{2}}\hat{\sigma}_1(t,\boldsymbol{\xi})$
NORMAL	CH	$\tilde{S}(t,\boldsymbol{\xi}) \pm z_{\frac{\alpha}{2}}\tilde{\sigma}_1(t,\boldsymbol{\xi})$

Effect Selection Methods

Five effect selection methods are available. The simplest method (and the default) is SELECTION=NONE, for which PROC PHREG fits the complete model as specified in the MODEL statement. The other four methods are FORWARD for forward selection, BACKWARD for backward elimination, STEPWISE for stepwise selection, and SCORE for best subsets selection. These methods are specified with the SELECTION= option in the MODEL statement and are based on the score test or Wald test as described in the section "Type 3 Tests" on page 5449.

When SELECTION=FORWARD, PROC PHREG first estimates parameters for effects that are forced into the model. These are the first n effects in the MODEL statement, where n is the number specified by the START= or INCLUDE= option in the MODEL statement (n is zero by default). Next, the procedure computes the score statistic for each effect that is not in the model. Each score statistic is the chi-square statistic of the score test for testing the null hypothesis that the corresponding effect that is not in the model is null. If the largest of these statistics is significant at the SLSENTRY= level, the effect with the largest score statistic is added to the model. After an effect is entered in the model, it is never removed from the model. The process is repeated until none of the remaining effects meet the specified level for entry or until the STOP= value is reached.

When SELECTION=BACKWARD, parameters for the complete model as specified in the MODEL statement are estimated unless the START= option is specified. In that case, only the parameters for the first n effects in the MODEL statement are estimated, where n is the number specified by the START= option. Next, the procedure computes the Wald statistic of each effect in the model. Each Wald's statistic is the chi-square statistic of the Wald test for testing the null hypothesis that the corresponding effect is null. If the

smallest of these statistics is not significant at the SLSTAY= level, the effect with the smallest Wald statistic is removed. After an effect is removed from the model, it remains excluded. The process is repeated until no other variable in the model meets the specified level for removal or until the STOP= value is reached.

The SELECTION=STEPWISE option is similar to the SELECTION=FORWARD option except that effects already in the model do not necessarily remain. Effects are entered into and removed from the model in such a way that each forward selection step can be followed by one or more backward elimination steps. The stepwise selection process terminates if no further effect can be added to the model or if the effect just entered into the model is the only effect that is removed in the subsequent backward elimination.

For SELECTION=SCORE, PROC PHREG uses the branch-and-bound algorithm of Furnival and Wilson (1974) to find a specified number of models with the highest score (chi-square) statistic for all possible model sizes, from 1, 2, or 3 variables, and so on, up to the single model that contains all of the explanatory variables. The number of models displayed for each model size is controlled by the BEST= option. You can use the START= option to impose a minimum model size, and you can use the STOP= option to impose a maximum model size. For instance, with BEST=3, START=2, and STOP=5, the SCORE selection method displays the best three models (that is, the three models with the highest score chi-squares) that contain 2, 3, 4, and 5 variables. One of the limitations of the branch-and-bound algorithm is that it works only when each explanatory effect contains exactly one parameter—the SELECTION=SCORE option is not allowed when an explanatory effect in the MODEL statement contains a CLASS variable.

The SEQUENTIAL and STOPRES options can alter the default criteria for adding variables to or removing variables from the model when they are used with the FORWARD, BACKWARD, or STEPWISE selection method.

Assessment of the Proportional Hazards Model

The proportional hazards model specifies that the hazard function for the failure time T associated with a $p \times 1$ column covariate vector $\mathbf{Z}$ takes the form

$$\lambda(t;\mathbf{Z}) = \lambda_0(t)\exp^{\boldsymbol{\beta}'\mathbf{Z}}$$

where $\lambda_0(.)$ is an unspecified baseline hazard function and $\boldsymbol{\beta}$ is a $p \times 1$ column vector of regression parameters. Lin, Wei, and Ying (1993) present graphical and numerical methods for model assessment based on the cumulative sums of martingale residuals and their transforms over certain coordinates (such as covariate values or follow-up times). The distributions of these stochastic processes under the assumed model can be approximated by the distributions of certain zero-mean Gaussian processes whose realizations can be generated by simulation. Each observed residual pattern can then be compared, both graphically and numerically, with a number of realizations from the null distribution. Such comparisons enable you to assess objectively whether the observed residual pattern reflects anything beyond random fluctuation. These procedures are useful in determining appropriate functional forms of covariates and assessing the proportional hazards assumption. You use the ASSESS statement to carry out these model-checking procedures.

For a sample of n subjects, let $(X_i, \Delta_i, \mathbf{Z}_i)$ be the data of the ith subject; that is, X_i represents the observed failure time, Δ_i has a value of 1 if X_i is an uncensored time and 0 otherwise, and $\mathbf{Z}_i = (Z_{1i}, \ldots, Z_{pi})'$ is a p-vector of covariates. Let $N_i(t) = \Delta_i I(X_i \le t)$ and $Y_i(t) = I(X_i \ge t)$. Let

$$S^{(0)}(\boldsymbol{\beta}, t) = \sum_{i=1}^{n} Y_i(t)\exp^{\boldsymbol{\beta}'\mathbf{Z}_i} \quad \text{and} \quad \mathbf{Z}(\boldsymbol{\beta}, t) = \frac{\sum_{i=1}^{n} Y_i(t)\exp^{\boldsymbol{\beta}'\mathbf{Z}_i}\mathbf{Z}_i}{S^{(0)}(\boldsymbol{\beta}, t)}$$

Let $\hat{\boldsymbol{\beta}}$ be the maximum partial likelihood estimate of $\boldsymbol{\beta}$, and let $\mathcal{I}(\hat{\boldsymbol{\beta}})$ be the observed information matrix.

The martingale residuals are defined as

$$\hat{M}_i(t) = N_i(t) - \int_0^t Y_i(u)\mathrm{e}^{\hat{\boldsymbol{\beta}}'\mathbf{Z}_i}\, d\hat{\Lambda}_0(u), i = 1, \ldots, n$$

where $\hat{\Lambda}_0(t) = \int_0^t \frac{\sum_{i=1}^n dN_i(u)}{S^{(0)}(\hat{\boldsymbol{\beta}},u)}$.

The empirical score process $\mathbf{U}(\hat{\boldsymbol{\beta}}, t) = (U_1(\hat{\boldsymbol{\beta}}, t), \ldots, U_p(\hat{\boldsymbol{\beta}}, t))'$ is a transform of the martingale residuals:

$$\mathbf{U}(\hat{\boldsymbol{\beta}}, t) = \sum_{i=1}^n \mathbf{Z}_i \hat{M}_i(t)$$

Checking the Functional Form of a Covariate

To check the functional form of the jth covariate, consider the partial-sum process of $\hat{M}_i = \hat{M}_i(\infty)$:

$$W_j(z) = \sum_{i=1}^n I(Z_{ji} \le z)\hat{M}_i$$

Under that null hypothesis that the model holds, $W_j(z)$ can be approximated by the zero-mean Gaussian process

$$\begin{aligned}\hat{W}_j(z) \quad = \quad & \sum_{l=1}^n \Delta_l \left\{ I(Z_{jl} \le z) - \frac{\sum_{i=1}^n Y_i(X_l)\mathrm{e}^{\boldsymbol{\beta}'\mathbf{Z}_i} I(Z_{ij} \le z)}{S^{(0)}(\hat{\boldsymbol{\beta}}, X_l)} \right\} G_l - \\ & \sum_{k=1}^n \int_0^\infty Y_k(s)\mathrm{e}^{\hat{\boldsymbol{\beta}}'\mathbf{Z}_k} I(Z_{jk} \le z)[\mathbf{Z}_k - \bar{\mathbf{Z}}(\hat{\boldsymbol{\beta}}, s)]' d\hat{\Lambda}_0(s) \\ & \times \mathcal{I}^{-1}(\hat{\boldsymbol{\beta}}) \sum_{l=1}^n \Delta_l [\mathbf{Z}_l - \bar{\mathbf{Z}}(\hat{\boldsymbol{\beta}}, X_l)] G_l\end{aligned}$$

where $(G_1, \ldots, G_n)$ are independent standard normal variables that are independent of $(X_i, \Delta_i, \mathbf{Z}_i)$, $i = 1, \ldots, n$.

You can assess the functional form of the jth covariate by plotting a small number of realizations (the default is 20) of $\hat{W}_j(z)$ on the same graph as the observed $W_j(z)$ and visually comparing them to see how typical the observed pattern of $W_j(z)$ is of the null distribution samples. You can supplement the graphical inspection method with a Kolmogorov-type supremum test. Let s_j be the observed value of $S_j = \sup_z |W_j(z)|$ and let $\hat{S}_j = \sup_z |\hat{W}_j(z)|$. The p-value $\Pr(S_j \ge s_j)$ is approximated by $\Pr(\hat{S}_j \ge s_j)$, which in turn is approximated by generating a large number of realizations (1000 is the default) of $\hat{W}_j(.)$.

Checking the Proportional Hazards Assumption

Consider the standardized empirical score process for the jth component of $\mathbf{Z}$

$$U_j^*(t) = [\mathcal{I}^{-1}(\hat{\boldsymbol{\beta}})_{jj}]^{\frac{1}{2}} U_j(\hat{\boldsymbol{\beta}}, t),$$

Under the null hypothesis that the model holds, $U_j^*(t)$ can be approximated by

$$\begin{aligned}\hat{U}_j^*(t) &= [\mathcal{I}^{-1}(\hat{\boldsymbol{\beta}})_{jj}]^{\frac{1}{2}}\Bigg\{\sum_{l=1}^{n} I(X_l \le t)\Delta_l[Z_{jl} - \bar{Z}_j(\hat{\boldsymbol{\beta}}, t)]G_l - \\ &\quad \sum_{k=1}^{n}\int_0^t Y_k(s)\ominus^{\hat{\boldsymbol{\beta}}'\mathbf{Z}_k} Z_{jk}[\mathbf{Z}_k - \bar{\mathbf{Z}}(\hat{\boldsymbol{\beta}}, s)]' d\,\hat{\Lambda}_0(s) \\ &\quad \times\mathcal{I}^{-1}(\hat{\boldsymbol{\beta}})\sum_{l=1}^{n}\Delta_l[\mathbf{Z}_l - \bar{\mathbf{Z}}(\hat{\boldsymbol{\beta}}, X_l)]G_l\Bigg\}\end{aligned}$$

where $\bar{Z}_j(\hat{\boldsymbol{\beta}}, t)$ is the jth component of $\bar{\mathbf{Z}}(\hat{\boldsymbol{\beta}}, t)$, and $(G_1, \ldots, G_n)$ are independent standard normal variables that are independent of $(X_i, \Delta_i, \mathbf{Z}_i, (i = 1, \ldots, n)$.

You can assess the proportional hazards assumption for the jth covariate by plotting a few realizations of $\hat{U}_j^*(t)$ on the same graph as the observed $U_j^*(t)$ and visually comparing them to see how typical the observed pattern of $U_j^*(t)$ is of the null distribution samples. Again you can supplement the graphical inspection method with a Kolmogorov-type supremum test. Let s_j^* be the observed value of $S_j^* = \sup_t |U_j^*(t)|$ and let $\hat{S}_j^* = \sup_t |\hat{U}_j^*(t)|$. The p-value $\Pr[S_j^* \ge s_j^*]$ is approximated by $\Pr[\hat{S}_j^* \ge s_j^*]$, which in turn is approximated by generating a large number of realizations (1000 is the default) of $\hat{U}_j^*(.)$.

Specifics for Bayesian Analysis

To request a Bayesian analysis, you specify the new BAYES statement in addition to the PROC PHREG statement and the MODEL statement. You include a CLASS statement if you have effects that involve categorical variables. The FREQ or WEIGHT statement can be included if you have a frequency or weight variable, respectively, in the input data. The STRATA statement can be used to carry out a stratified analysis for the Cox model, but it is not allowed in the piecewise constant baseline hazard model. Programming statements can be used to create time-dependent covariates for the Cox model, but they are not allowed in the piecewise constant baseline hazard model. However, you can use the counting process style of input to accommodate time-dependent covariates that are not continuously changing with time for the piecewise constant baseline hazard model and the Cox model as well. The HAZARDRATIO statement enables you to request a hazard ratio analysis based on the posterior samples. The ASSESS, CONTRAST, ID, OUTPUT, and TEST statements, if specified, are ignored. Also ignored are the COVM and COVS options in the PROC PHREG statement and the following options in the MODEL statement: BEST=, CORRB, COVB, DETAILS, HIERARCHY=, INCLUDE=, MAXSTEP=, NOFIT, PLCONV=, SELECTION=, SEQUENTIAL, SLENTRY=, and SLSTAY=.

Piecewise Constant Baseline Hazard Model

Single Failure Time Variable

Let $\{(t_i, \mathbf{x}_i, \delta_i), i = 1, 2, \ldots, n\}$ be the observed data. Let $a_0 = 0 < a_1 < \ldots < a_{J-1} < a_J = \infty$ be a partition of the time axis.

Hazards in Original Scale

The hazard function for subject i is

$$h(t|\mathbf{x}_i;\boldsymbol{\theta}) = h_0(t)\exp(\boldsymbol{\beta}'\mathbf{x}_i)$$

where

$$h_0(t) = \lambda_j \text{ if } a_{j-1} \le t < a_j, j = 1,\ldots,J$$

The baseline cumulative hazard function is

$$H_0(t) = \sum_{j=1}^{J} \lambda_j \Delta_j(t)$$

where

$$\Delta_j(t) = \begin{cases} 0 & t < a_{j-1} \\ t - a_{j-1} & a_{j-1} \le t < a_j \\ a_j - a_{j-1} & t \ge a_j \end{cases}$$

The log likelihood is given by

$$\begin{aligned} l(\boldsymbol{\lambda},\boldsymbol{\beta}) &= \sum_{i=1}^{n}\delta_i\left[\sum_{j=1}^{J} I(a_{j-1} \le t_i < a_j)\log\lambda_j + \boldsymbol{\beta}'\mathbf{x}_i\right] - \sum_{i=1}^{n}\left[\sum_{j=1}^{J}\Delta_j(t_i)\lambda_j\right]\exp(\boldsymbol{\beta}'\mathbf{x}_i) \\ &= \sum_{j=1}^{J} d_j \log\lambda_j + \sum_{i=1}^{n}\delta_i\boldsymbol{\beta}'\mathbf{x}_i - \sum_{j=1}^{J}\lambda_j\left[\sum_{i=1}^{n}\Delta_j(t_i)\exp(\boldsymbol{\beta}'\mathbf{x}_i)\right] \end{aligned}$$

where $d_j = \sum_{i=1}^{n}\delta_i I(a_{j-1} \le t_i < a_j)$.

Note that for $1 \le j \le J$, the full conditional for λ_j is log-concave only when $d_j > 0$, but the full conditionals for the β's are always log-concave.

For a given $\boldsymbol{\beta}$, $\frac{\partial l}{\partial \boldsymbol{\lambda}} = 0$ gives

$$\tilde{\lambda}_j(\boldsymbol{\beta}) = \frac{d_j}{\sum_{i=1}^{n}\Delta_j(t_i)\exp(\boldsymbol{\beta}'\mathbf{x}_i)}, \quad j = 1,\ldots,J$$

Substituting these values into $l(\boldsymbol{\lambda},\boldsymbol{\beta})$ gives the profile log likelihood for $\boldsymbol{\beta}$

$$l_p(\boldsymbol{\beta}) = \sum_{i=1}^{n}\delta_i\boldsymbol{\beta}'\mathbf{x}_i - \sum_{j=1}^{J} d_j \log\left[\sum_{l=1}^{n}\Delta_j(t_l)\exp(\boldsymbol{\beta}'\mathbf{x}_l)\right] + c$$

where $c = \sum_j (d_j \log d_j - d_j)$. Since the constant c does not depend on $\boldsymbol{\beta}$, it can be discarded from $l_p(\boldsymbol{\beta})$ in the optimization.

The MLE $\hat{\boldsymbol{\beta}}$ of $\boldsymbol{\beta}$ is obtained by maximizing

$$l_p(\boldsymbol{\beta}) = \sum_{i=1}^{n} \delta_i \boldsymbol{\beta}' \mathbf{x}_i - \sum_{j=1}^{J} d_j \log\left[\sum_{l=1}^{n} \Delta_j(t_l) \exp(\boldsymbol{\beta}' \mathbf{x}_l)\right]$$

with respect to $\boldsymbol{\beta}$, and the MLE $\hat{\boldsymbol{\lambda}}$ of $\boldsymbol{\lambda}$ is given by

$$\hat{\boldsymbol{\lambda}} = \tilde{\boldsymbol{\lambda}}(\hat{\boldsymbol{\beta}})$$

For $j = 1, \ldots, J$, let

$$\begin{aligned} \mathbf{S}_j^{(r)}(\boldsymbol{\beta}) &= \sum_{l=1}^{n} \Delta_j(t_l) \mathrm{e}^{\boldsymbol{\beta}' \mathbf{x}_l} \mathbf{x}_l^{\otimes r}, \quad r = 0, 1, 2 \\ \mathbf{E}_j(\boldsymbol{\beta}) &= \frac{\mathbf{S}_j^{(1)}(\boldsymbol{\beta})}{S_j^{(0)}(\boldsymbol{\beta})} \end{aligned}$$

The partial derivatives of $l_p(\boldsymbol{\beta})$ are

$$\begin{aligned} \frac{\partial l_p(\boldsymbol{\beta})}{\partial \boldsymbol{\beta}} &= \sum_{i=1}^{n} \delta_i \mathbf{x}_i - \sum_{j=1}^{J} d_j \mathbf{E}_j(\boldsymbol{\beta}) \\ -\frac{\partial^2 l_p(\boldsymbol{\beta})}{\partial \boldsymbol{\beta}^2} &= \sum_{j=1}^{J} d_j \left\{ \frac{\mathbf{S}_j^{(2)}(\boldsymbol{\beta})}{S_j^{(0)}(\boldsymbol{\beta})} - \left[\mathbf{E}_j(\boldsymbol{\beta})\right]\left[\mathbf{E}_j(\boldsymbol{\beta})\right]' \right\} \end{aligned}$$

The asymptotic covariance matrix for $(\hat{\boldsymbol{\lambda}}, \hat{\boldsymbol{\beta}})$ is obtained as the inverse of the information matrix given by

$$\begin{aligned} -\frac{\partial^2 l(\hat{\boldsymbol{\lambda}}, \hat{\boldsymbol{\beta}})}{\partial \boldsymbol{\lambda}^2} &= \mathcal{D}\left(\frac{d_1}{\hat{\lambda}_1^2}, \ldots, \frac{d_J}{\hat{\lambda}_J^2}\right) \\ -\frac{\partial^2 l(\hat{\boldsymbol{\lambda}}, \hat{\boldsymbol{\beta}})}{\partial \boldsymbol{\beta}^2} &= \sum_{j=1}^{J} \hat{\lambda}_j \mathbf{S}_j^{(2)}(\hat{\boldsymbol{\beta}}) \\ -\frac{\partial^2 l(\hat{\boldsymbol{\lambda}}, \hat{\boldsymbol{\beta}})}{\partial \boldsymbol{\lambda} \partial \boldsymbol{\beta}} &= (\mathbf{S}_1^{(1)}(\hat{\boldsymbol{\beta}}), \ldots, \mathbf{S}_J^{(1)}(\hat{\boldsymbol{\beta}})) \end{aligned}$$

See Example 6.5.1 in Lawless (2003) for details.

Hazards in Log Scale

By letting

$$\alpha_j = \log(\lambda_j), \quad j = 1, \ldots, J$$

you can build a prior correlation among the λ_j's by using a correlated prior $\boldsymbol{\alpha} \sim N(\boldsymbol{\alpha}_0, \Sigma_{\alpha})$, where $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_J)'$.

The log likelihood is given by

$$l(\boldsymbol{\alpha}, \boldsymbol{\beta}) = \sum_{j=1}^{J} d_j \alpha_j + \sum_{i=1}^{n} \delta_i \boldsymbol{\beta}' \mathbf{x}_i - \sum_{j=1}^{J} \mathrm{e}^{\alpha_j} S_j^{(0)}(\boldsymbol{\beta})$$

Then the MLE of λ_j is given by

$$\mathrm{e}^{\hat{\alpha}_j} = \hat{\lambda}_j = \frac{d_j}{S_j^0(\hat{\boldsymbol{\beta}})}$$

Note that the full conditionals for α's and β's are always log-concave.

The asymptotic covariance matrix for $(\hat{\boldsymbol{\alpha}}, \hat{\boldsymbol{\beta}})$ is obtained as the inverse of the information matrix formed by

$$\begin{aligned}
-\frac{\partial^2 l(\hat{\boldsymbol{\alpha}}, \hat{\boldsymbol{\beta}})}{\partial \boldsymbol{\alpha}^2} &= \mathcal{D}\left(\mathrm{e}^{\hat{\alpha}_j} S_j^0(\hat{\boldsymbol{\beta}}), \ldots, \mathrm{e}^{\hat{\alpha}_J} S_J^0(\hat{\boldsymbol{\beta}})\right) \\
-\frac{\partial^2 l(\hat{\boldsymbol{\alpha}}, \hat{\boldsymbol{\beta}})}{\partial \boldsymbol{\beta}^2} &= \sum_{j=1}^{J} \mathrm{e}^{\hat{\alpha}_j} \mathbf{S}_j^{(2)}(\hat{\boldsymbol{\beta}}) \\
-\frac{\partial^2 l(\hat{\boldsymbol{\alpha}}, \hat{\boldsymbol{\beta}})}{\partial \boldsymbol{\alpha} \partial \boldsymbol{\beta}} &= (\mathrm{e}^{\hat{\alpha}_j} \mathbf{S}_1^{(1)}(\hat{\boldsymbol{\beta}}), \ldots, \mathrm{e}^{\hat{\alpha}_j} \mathbf{S}_J^{(1)}(\hat{\boldsymbol{\beta}}))
\end{aligned}$$

Counting Process Style of Input

Let $\{((s_j, t_i], \mathbf{x}_i, \delta_i), i = 1, 2, \ldots, n\}$ be the observed data. Let $a_0 = 0 < a_1 < \ldots < a_k$ be a partition of the time axis, where $a_k > t_i$ for all $i = 1, 2, \ldots, n$.

Replacing $\Delta_j(t_i)$ with

$$\Delta_j((s_i, t_i]) = \begin{cases} 0 & t_i < a_{j-1} \vee s_i > a_j \\ t_i - \max(s_i, a_{j-1}) & a_{j-1} \le t_i < a_j \\ a_j - \max(s_i, a_{j-1}) & t_i \ge a_j \end{cases}$$

the formulation for the single failure time variable applies.

Priors for Model Parameters

For a Cox model, the model parameters are the regression coefficients. For a piecewise exponential model, the model parameters consist of the regression coefficients and the hazards or log-hazards. The priors for the hazards and the priors for the regression coefficients are assumed to be independent, while you can have a joint multivariate normal prior for the log-hazards and the regression coefficients.

Hazard Parameters

Let $\lambda_1, \ldots, \lambda_J$ be the constant baseline hazards.

Improper Prior The joint prior density is given by

$$p(\lambda_1, \ldots, \lambda_J) = \prod_{j=1}^{J} \frac{1}{\lambda_j}. \forall \lambda_j > 0$$

This prior is improper (nonintegrable), but the posterior distribution is proper as long as there is at least one event time in each of the constant hazard intervals.

Uniform Prior The joint prior density is given by

$$p(\lambda_1, \ldots, \lambda_J) \propto 1, \forall \lambda_j > 0$$

This prior is improper (nonintegrable), but the posteriors are proper as long as there is at least one event time in each of the constant hazard intervals.

Gamma Prior The gamma distribution $G(a, b)$ has a pdf

$$f_{a,b}(t) = \frac{b(bt)^{a-1}\mathrm{e}^{-bt}}{\Gamma(a)}, t > 0$$

where a is the shape parameter and b^{-1} is the scale parameter. The mean is $\frac{a}{b}$ and the variance is $\frac{a}{b^2}$.

Independent Gamma Prior Suppose for $j = 1, \ldots, J$, λ_j has an independent $G(a_j, b_j)$ prior. The joint prior density is given by

$$p(\lambda_1, \ldots, \lambda_J) \propto \prod_{j=1}^{J} \left\{ \lambda_j^{a_j - 1} \mathrm{e}^{-b_j \lambda_j} \right\}, \forall \lambda_j > 0$$

AR1 Prior $\lambda_1, \ldots, \lambda_J$ are correlated as follows:

$$\begin{aligned}
\lambda_1 &\sim G(a_1, b_1) \\
\lambda_2 &\sim G\left(a_2, \frac{b_2}{\lambda_1}\right) \\
\ldots &\quad \ldots \\
\lambda_J &\sim G\left(a_J, \frac{b_J}{\lambda_{J-1}}\right)
\end{aligned}$$

The joint prior density is given by

$$p(\lambda_1, \ldots, \lambda_J) \propto \lambda_1^{a_1 - 1} \mathrm{e}^{-b_1 \lambda_1} \prod_{j=2}^{J} \left(\frac{b_j}{\lambda_{j-1}} \right)^{a_j} \lambda_j^{a_j - 1} \mathrm{e}^{-\frac{b_j}{\lambda_{j-1}} \lambda_j}$$

Log-Hazard Parameters

Write $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_J)' \equiv (\log\lambda_1, \ldots, \log\lambda_J)'$.

Uniform Prior The joint prior density is given by

$$p(\alpha_1 \ldots \alpha_J) \propto 1, \forall -\infty < \alpha_i < \infty$$

Note that the uniform prior for the log-hazards is the same as the improper prior for the hazards.

Normal Prior Assume $\boldsymbol{\alpha}$ has a multivariate normal prior with mean vector $\boldsymbol{\alpha}_0$ and covariance matrix $\boldsymbol{\Psi}_0$. The joint prior density is given by

$$p(\boldsymbol{\alpha}) \propto \mathrm{e}^{-\frac{1}{2}(\boldsymbol{\alpha}-\boldsymbol{\alpha}_0)'\boldsymbol{\Psi}_0^{-1}(\boldsymbol{\alpha}-\boldsymbol{\alpha}_0)}$$

Regression Coefficients

Let $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_k)'$ be the vector of regression coefficients.

Uniform Prior The joint prior density is given by

$$p(\beta_1, \ldots, \beta_k) \propto 1, \forall -\infty < \beta_i < \infty$$

This prior is improper, but the posterior distributions for $\boldsymbol{\beta}$ are proper.

Normal Prior Assume $\boldsymbol{\beta}$ has a multivariate normal prior with mean vector $\boldsymbol{\beta}_0$ and covariance matrix $\boldsymbol{\Sigma}_0$. The joint prior density is given by

$$p(\boldsymbol{\beta}) \propto \mathrm{e}^{-\frac{1}{2}(\boldsymbol{\beta}-\boldsymbol{\beta}_0)'\boldsymbol{\Sigma}_0^{-1}(\boldsymbol{\beta}-\boldsymbol{\beta}_0)}$$

Joint Multivariate Normal Prior for Log-Hazards and Regression Coefficients Assume $(\boldsymbol{\alpha}', \boldsymbol{\beta}')'$ has a multivariate normal prior with mean vector $(\alpha_0', \boldsymbol{\beta}_0')'$ and covariance matrix $\boldsymbol{\Phi}_0$. The joint prior density is given by

$$p(\boldsymbol{\alpha}, \boldsymbol{\beta}) \propto \mathrm{e}^{-\frac{1}{2}[(\boldsymbol{\alpha}-\boldsymbol{\alpha}_0)', (\boldsymbol{\beta}-\boldsymbol{\beta}_0)']\boldsymbol{\Phi}_0^{-1}[(\boldsymbol{\alpha}-\boldsymbol{\alpha}_0)', (\boldsymbol{\beta}-\boldsymbol{\beta}_0)']'}$$

Zellner's g-Prior Assume $\boldsymbol{\beta}$ has a multivariate normal prior with mean vector $\mathbf{0}$ and covariance matrix $(gX'X)^{-1}$, where X is the design matrix and g is either a constant or it follows a gamma prior with density $f(\tau) = \frac{b(b\tau)^{a-1}\mathrm{e}^{-b\tau}}{\Gamma(a)}$ where a and b are the SHAPE= and ISCALE= parameters. Let k be the rank of X. The joint prior density with g being a constant c is given by

$$p(\boldsymbol{\beta}) \propto c^{\frac{k}{2}}\mathrm{e}^{-\frac{1}{2}\boldsymbol{\beta}'(cX'X)^{-1}\boldsymbol{\beta}}$$

The joint prior density with g having a gamma prior is given by

$$p(\boldsymbol{\beta}, \tau) \propto \tau^{\frac{k}{2}}\mathrm{e}^{-\frac{1}{2}\boldsymbol{\beta}'(\tau X'X)^{-1}\boldsymbol{\beta}}\frac{b(b\tau)^{a-1}\mathrm{e}^{-b\tau}}{\Gamma(a)}$$

Posterior Distribution

Denote the observed data by D.

Cox Model

$$\pi(\boldsymbol{\beta}|D) \propto L_P(D|\boldsymbol{\beta})p(\boldsymbol{\beta})$$

where $L_P(D|\boldsymbol{\beta})$ is the partial likelihood function with regression coefficients $\boldsymbol{\beta}$ as parameters.

Piecewise Exponential Model

Hazard Parameters

$$\pi(\boldsymbol{\lambda}, \boldsymbol{\beta}|D) \propto L_H(D|\boldsymbol{\lambda}, \boldsymbol{\beta})p(\boldsymbol{\lambda})p(\boldsymbol{\beta})$$

where $L_H(D|\boldsymbol{\lambda}, \boldsymbol{\beta})$ is the likelihood function with hazards $\boldsymbol{\lambda}$ and regression coefficients $\boldsymbol{\beta}$ as parameters.

Log-Hazard Parameters

$$\pi(\boldsymbol{\alpha}, \boldsymbol{\beta}|D) \propto \begin{cases} L_{LH}(D|\boldsymbol{\alpha}, \boldsymbol{\beta})p(\boldsymbol{\alpha}, \boldsymbol{\beta}) & \text{if} \quad (\boldsymbol{\alpha}', \boldsymbol{\beta}')' \sim \text{MVN} \\ L_{LH}(D|\boldsymbol{\alpha}, \boldsymbol{\beta})p(\boldsymbol{\alpha})p(\boldsymbol{\beta}) & \text{otherwise} \end{cases}$$

where $L_{LH}(D|\boldsymbol{\alpha}, \boldsymbol{\beta})$ is the likelihood function with log-hazards $\boldsymbol{\alpha}$ and regression coefficients $\boldsymbol{\beta}$ as parameters.

Sampling from the Posterior Distribution

For the Gibbs sampler, PROC PHREG uses the ARMS (adaptive rejection Metropolis sampling) algorithm of Gilks, Best, and Tan (1995) to sample from the full conditionals. This is the default sampling scheme. Alternatively, you can requests the random walk Metropolis (RWM) algorithm to sample an entire parameter vector from the posterior distribution. For a general discussion of these algorithms, refer to section "Markov Chain Monte Carlo Method" on page 139.

You can output these posterior samples into a SAS data set by using the OUTPOST= option in the BAYES statement, or you can use the following SAS statement to output the posterior samples into the SAS data set Post:

```
ods output PosteriorSample=Post;
```

The output data set also includes the variables LogLike and LogPost, which represent the log of the likelihood and the log of the posterior log density, respectively.

Let $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_k)'$ be the parameter vector. For the Cox model, the θ_i's are the regression coefficients β_i's, and for the piecewise constant baseline hazard model, the θ_i's consist of the baseline hazards λ_i's (or log baseline hazards α_i's) and the regression coefficients β_j's. Let $L(D|\boldsymbol{\theta})$ be the likelihood function, where D is the observed data. Note that for the Cox model, the likelihood contains the infinite-dimensional

baseline hazard function, and the gamma process is perhaps the most commonly used prior process (Ibrahim, Chen, and Sinha 2001). However, Sinha, Ibrahim, and Chen (2003) justify using the partial likelihood as the likelihood function for the Bayesian analysis. Let $p(\boldsymbol{\theta})$ be the prior distribution. The posterior $f\pi(\boldsymbol{\theta}|D)$ is proportional to the joint distribution $L(D|\boldsymbol{\theta})p(\boldsymbol{\theta})$.

Gibbs Sampler

The full conditional distribution of θ_i is proportional to the joint distribution; that is,

$$\pi(\theta_i|\theta_j, i \neq j, D) \propto L(D|\boldsymbol{\theta})p(\boldsymbol{\theta})$$

For example, the one-dimensional conditional distribution of θ_1, given $\theta_j = \theta_j^*, 2 \leq j \leq k$, is computed as

$$\pi(\theta_1|\theta_j = \theta_j^*, 2 \leq j \leq k, D) = L(D|\boldsymbol{\theta} = (\theta_1, \theta_2^*, \ldots, \theta_k^*)')p(\boldsymbol{\theta} = (\theta_1, \theta_2^*, \ldots, \theta_k^*)')$$

Suppose you have a set of arbitrary starting values $\{\theta_1^{(0)}, \ldots, \theta_k^{(0)}\}$. Using the ARMS algorithm, an iteration of the Gibbs sampler consists of the following:

- draw $\theta_1^{(1)}$ from $\pi(\theta_1|\theta_2^{(0)}, \ldots, \theta_k^{(0)}, D)$
- draw $\theta_2^{(1)}$ from $\pi(\theta_2|\theta_1^{(1)}, \theta_3^{(0)}, \ldots, \theta_k^{(0)}, D)$
- $\vdots$
- draw $\theta_k^{(1)}$ from $\pi(\theta_k|\theta_1^{(1)}, \ldots, \theta_{k-1}^{(1)}, D)$

After one iteration, you have $\{\theta_1^{(1)}, \ldots, \theta_k^{(1)}\}$. After n iterations, you have $\{\theta_1^{(n)}, \ldots, \theta_k^{(n)}\}$. Cumulatively, a chain of n samples is obtained.

Random Walk Metropolis Algorithm

PROC PHREG uses a multivariate normal proposal distribution $q(.|\boldsymbol{\theta})$ centered at $\boldsymbol{\theta}$. With an initial parameter vector $\boldsymbol{\theta}^{(0)}$, a new sample $\boldsymbol{\theta}^{(1)}$ is obtained as follows:

- sample $\boldsymbol{\theta}^*$ from $q(.|\boldsymbol{\theta}^{(0)})$
- calculate the quantity $r = \min\left\{\frac{\pi(\boldsymbol{\theta}^*|D)}{\pi(\boldsymbol{\theta}^{(0)}|D)}, 1\right\}$
- sample u from the uniform distribution $U(0, 1)$
- set $\boldsymbol{\theta}^{(1)} = \boldsymbol{\theta}^*$ if $u < r$; otherwise set $\boldsymbol{\theta}^{(1)} = \boldsymbol{\theta}^{(0)}$

With $\boldsymbol{\theta}^{(1)}$ taking the role of $\boldsymbol{\theta}^{(0)}$, the previous steps are repeated to generate the next sample $\boldsymbol{\theta}^{(2)}$. After n iterations, a chain of n samples $\{\boldsymbol{\theta}^{(1)}, \ldots, \boldsymbol{\theta}^{(n)}\}$ is obtained.

Starting Values of the Markov Chains

When the BAYES statement is specified, PROC PHREG generates one Markov chain that contains the approximate posterior samples of the model parameters. Additional chains are produced when the Gelman-Rubin diagnostics are requested. Starting values (initial values) can be specified in the INITIAL= data set in the BAYES statement. If the INITIAL= option is not specified, PROC PHREG picks its own initial values for the chains based on the maximum likelihood estimates of $\boldsymbol{\theta}$ and the prior information of $\boldsymbol{\theta}$.

Denote $[x]$ as the integral value of x.

Constant Baseline Hazards λ_i's

For the first chain that the summary statistics and diagnostics are based on, the initial values are

$$\lambda_i^{(0)} = \hat{\lambda}_i$$

For subsequent chains, the starting values are picked in two different ways according to the total number of chains specified. If the total number of chains specified is less than or equal to 10, initial values of the rth chain ($2 \leq r \leq 10$) are given by

$$\lambda_i^{(0)} = \hat{\lambda}_i \mathrm{e}^{\pm\left([\frac{r}{2}]+2\right)\hat{s}(\hat{\lambda}_i)}$$

with the plus sign for odd r and minus sign for even r. If the total number of chains is greater than 10, initial values are picked at random over a wide range of values. Let u_i be a uniform random number between 0 and 1; the initial value for λ_i is given by

$$\lambda_i^{(0)} = \hat{\lambda}_i \mathrm{e}^{16(u_i-0.5)\hat{s}(\hat{\lambda}_i)}$$

Regression Coefficients and Log-Hazard Parameters θ_i's

The θ_i's are the regression coefficients β_i's, and in the piecewise exponential model, include the log-hazard parameters α_i's. For the first chain that the summary statistics and regression diagnostics are based on, the initial values are

$$\theta_i^{(0)} = \hat{\theta}_i$$

If the number of chains requested is less than or equal to 10, initial values for the rth chain ($2 \leq r \leq 10$) are given by

$$\theta_i^{(0)} = \hat{\theta}_i \pm \left(2 + \left[\frac{r}{2}\right]\right)\hat{s}(\hat{\theta}_i)$$

with the plus sign for odd r and minus sign for even r. When there are more than 10 chains, the initial value for the θ_i is picked at random over the range $(\hat{\theta}_i - 8\hat{s}(\hat{\theta}_i), \hat{\theta}_i + 8\hat{s}(\hat{\theta}_i))$; that is,

$$\theta_i^{(0)} = \hat{\theta}_i + 16(u_i - 0.5)\hat{s}(\hat{\theta}_i)$$

where u_i is a uniform random number between 0 and 1.

Fit Statistics

Denote the observed data by D. Let $\boldsymbol{\theta}$ be the vector of parameters of length k. Let $L(D|\boldsymbol{\theta})$ be the likelihood. The deviance information criterion (DIC) proposed in Spiegelhalter et al. (2002) is a Bayesian model assessment tool. Let $\text{Dev}(\boldsymbol{\theta}) = -2\log L(D|\boldsymbol{\theta})$. Let $\overline{\text{Dev}(\theta)}$ and $\bar{\boldsymbol{\theta}}$ be the corresponding posterior means of $\text{Dev}(\boldsymbol{\theta})$ and $\boldsymbol{\theta}$, respectively. The deviance information criterion is computed as

$$\text{DIC} = 2\overline{\text{Dev}(\boldsymbol{\theta})} - \text{Dev}(\bar{\boldsymbol{\theta}})$$

Also computed is

$$pD = \overline{\text{Dev}(\boldsymbol{\theta})} - \text{Dev}(\bar{\boldsymbol{\theta}})$$

where pD is interpreted as the effective number of parameters.

Note that $\text{Dev}(\boldsymbol{\theta})$ defined here does not have the standardizing term as in the section "Deviance Information Criterion (DIC)" on page 161. Nevertheless, the DIC calculated here is still useful for variable selection.

Posterior Distribution for Quantities of Interest

Let $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_k)'$ be the parameter vector. For the Cox model, the θ_i's are the regression coefficients β_i's; for the piecewise constant baseline hazard model, the θ_i's consist of the baseline hazards λ_i's (or log baseline hazards α_i's) and the regression coefficients β_j's. Let $\mathcal{S} = \{\boldsymbol{\theta}^{(r)}, r = 1, \ldots, N\}$ be the chain that represents the posterior distribution for $\boldsymbol{\theta}$.

Consider a quantity of interest τ that can be expressed as a function $f(\boldsymbol{\theta})$ of the parameter vector $\boldsymbol{\theta}$. You can construct the posterior distribution of τ by evaluating the function $f(\boldsymbol{\theta}^{(r)})$ for each $\boldsymbol{\theta}^{(r)}$ in $\mathcal{S}$. The posterior chain for τ is $\{f(\boldsymbol{\theta}^{(r)}), r = 1, \ldots, N\}$. Summary statistics such as mean, standard deviation, percentiles, and credible intervals are used to describe the posterior distribution of τ.

Hazard Ratio

As shown in the section "Hazard Ratios" on page 5441, a log-hazard ratio is a linear combination of the regression coefficients. Let $\mathbf{h}$ be the vector of linear coefficients. The posterior sample for this hazard ratio is the set $\{\exp(\text{h}'\boldsymbol{\beta}^{(r)}), r = 1, \ldots, N\}$.

Survival Distribution

Let x be a covariate vector of interest.

Cox Model Let $\{(t_i, \mathbf{z}_i, \delta_i), i = 1, 2, \ldots, n\}$ be the observed data. Define

$$Y_i(t) = \begin{cases} 1 & t < t_i \\ 0 & \text{otherwise} \end{cases}$$

Consider the rth draw $\boldsymbol{\beta}^{(r)}$ of $\mathcal{S}$. The baseline cumulative hazard function at time t is given by

$$H_0(t|\boldsymbol{\beta}^{(r)}) = \sum_{i:t_i \le t} \frac{\delta_i}{\sum_{l=1}^{n} Y_l(t_i)\exp(\mathbf{z}_l'\boldsymbol{\beta}^{(r)})}$$

For the given covariate vector x, the cumulative hazard function at time t is

$$H(t;\mathbf{x}|\boldsymbol{\beta}^{(r)}) = H_0(t|\boldsymbol{\beta}^{(r)})\exp(\mathbf{x}'\boldsymbol{\beta}^{(r)})$$

and the survival function at time t is

$$S(t;\mathbf{x}|\boldsymbol{\beta}^{(r)}) = \exp[-H^{(r)}(t;\mathbf{x}|\boldsymbol{\beta}^{(r)})]$$

Piecewise Exponential Model Let $0 = a_0 < a_1 < \ldots < a_J < \infty$ be a partition of the time axis. Consider the rth draw $\boldsymbol{\theta}^{(r)}$ in $\mathcal{S}$, where $\boldsymbol{\theta}^{(r)}$ consists of $\boldsymbol{\lambda}^{(r)} = (\lambda_1^{(r)},\ldots,\lambda_J^{(r)})'$ and $\boldsymbol{\beta}^{(r)}$. The baseline cumulative hazard function at time t is

$$H_0(t|\boldsymbol{\lambda}^{(r)}) = \sum_{j=1}^{J}\lambda_j^{(r)}\Delta_j(t)$$

where

$$\Delta_j(t) = \begin{cases} 0 & t < a_{j-1} \\ t - a_{j-1} & a_{j-1} \le t < a_j \\ a_j - a_{j-1} & t \ge a_j \end{cases}$$

For the given covariate vector $\mathbf{x}$, the cumulative hazard function at time t is

$$H(t;\mathbf{x}|\boldsymbol{\lambda}^{(r)},\boldsymbol{\beta}^{(r)}) = H_0(t|\boldsymbol{\lambda}^{(r)})\exp(\mathbf{x}'\boldsymbol{\beta}^{(r)})$$

and the survival function at time t is

$$S(t;\mathbf{x}|\boldsymbol{\lambda}^{(r)},\boldsymbol{\beta}^{(r)}) = \exp[-H(t;\mathbf{x}|\boldsymbol{\lambda}^{(r)},\boldsymbol{\beta}^{(r)})]$$

Computational Resources

Let n be the number of observations in a BY group. Let p be the number of explanatory variables. The minimum working space (in bytes) needed to process the BY group is

$$\max\{12n, 24p^2 + 160p\}$$

Extra memory is needed for certain TIES= options. Let k be the maximum multiplicity of tied times. The TIES=DISCRETE option requires extra memory (in bytes) of

$$4k(p^2 + 4p)$$

The TIES=EXACT option requires extra memory (in bytes) of

$$24(k^2 + 5k)$$

If sufficient space is available, the input data are also kept in memory. Otherwise, the input data are reread from the utility file for each evaluation of the likelihood function and its derivatives, with the resulting execution time substantially increased.

Input and Output Data Sets

OUTEST= Output Data Set

The OUTEST= data set contains one observation for each BY group containing the maximum likelihood estimates of the regression coefficients. If you also use the COVOUT option in the PROC PHREG statement, there are additional observations containing the rows of the estimated covariance matrix. If you specify SELECTION=FORWARD, BACKWARD, or STEPWISE, only the estimates of the parameters and covariance matrix for the final model are output to the OUTEST= data set.

Variables in the OUTEST= Data Set

The OUTEST= data set contains the following variables:

- any BY variables specified
- _TIES_, a character variable of length 8 with four possible values: BRESLOW, DISCRETE, EFRON, and EXACT. These are the four values of the TIES= option in the MODEL statement.
- _TYPE_, a character variable of length 8 with two possible values: PARMS for parameter estimates or COV for covariance estimates. If both the COVM and COVS options are specified in the PROC PHREG statement along with the COVOUT option, _TYPE_='COVM' for the model-based covariance estimates and _TYPE_='COVS' for the robust sandwich covariance estimates.
- _STATUS_, a character variable indicating whether the estimates have converged
- _NAME_, a character variable containing the name of the TIME variable for the row of parameter estimates and the name of each explanatory variable to label the rows of covariance estimates
- one variable for each regression coefficient and one variable for the offset variable if the OFFSET= option is specified. If an explanatory variable is not included in the final model in a variable selection process, the corresponding parameter estimates and covariances are set to missing.
- _LNLIKE_, a numeric variable containing the last computed value of the log likelihood

Parameter Names in the OUTEST= Data Set

For continuous explanatory variables, the names of the parameters are the same as the corresponding variables. For CLASS variables, the parameter names are obtained by concatenating the corresponding CLASS variable name with the CLASS category; see the PARAM= option in the CLASS statement for more details. For interaction and nested effects, the parameter names are created by concatenating the names of each component effect.

INEST= Input Data Set

You can specify starting values for the maximum likelihood iterative algorithm in the INEST= data set. The INEST= data set has the same structure as the OUTEST= data set but is not required to have all the variables or observations that appear in the OUTEST= data set.

The INEST= data set must contain variables that represent the regression coefficients of the model. If BY processing is used, the INEST= data set should also include the BY variables, and there must be one observation for each BY group. If the INEST= data set also contains the _TYPE_ variable, only observations with _TYPE_ value 'PARMS' are used as starting values.

OUT= Output Data Set in the OUTPUT Statement

The OUT= data set in the OUTPUT statement contains all the variables in the input data set, along with statistics you request by specifying *keyword=name* options. The new variables contain a variety of diagnostics that are calculated for each observation in the input data set.

OUT= Output Data Set in the BASELINE Statement

The OUT= data set in the BASELINE statement contains all the variables in the COVARIATES= data set, along with statistics you request by specifying *keyword=name* options. For unstratified input data, there are 1+n observations in the OUT= data set for each observation in the COVARIATES= data set, where n is the number of distinct event times in the input data. For input data that are stratified into k strata, with n_i distinct events in the ith stratum, $i = 1, \ldots, k$, there are 1+n_i observations for the ith stratum in the OUT= data set for each observation in the COVARIATES= data set.

OUTPOST= Output Data Set in the BAYES Statement

The OUTPOST= data set contains the generated posterior samples. There are 3+n variables, where n is the number of model parameters. The variable Iteration represents the iteration number, the variable LogLike contains the log-likelihood values, and the variable LogPost contains the log-posterior-density values. The other n variables represent the draws of the Markov chain for the model parameters.

Displayed Output

If you use the NOPRINT option in the PROC PHREG statement, the procedure does not display any output. Otherwise, PROC PHREG displays results of the analysis in a collection of tables. The tables are listed separately for the maximum likelihood analysis and for the Bayesian analysis.

Maximum Likelihood Analysis Displayed Output

Model Information

The "Model Information" table displays the two-level name of the input data set, the name and label of the failure time variable, the name and label of the censoring variable and the values indicating censored times, the model (either the Cox model or the piecewise constant baseline hazard model), the name and label of the OFFSET variable, the name and label of the FREQ variable, the name and label of the WEIGHT variable, and the method of handling ties in the failure time for the Cox model. For ODS purposes, the name of the "Model Information" table is "ModelInfo."

Number of Observations

The "Number of Observations" table displays the number of observations read and used in the analysis. For ODS purposes, the name of the "Number of Observations" is "NObs."

Class Level Information

The "Class Level Information" table is displayed when there are CLASS variables in the model. The table lists the categories of every CLASS variable that is used in the model and the corresponding design variable values. For ODS purposes, the name of the "Class Level Information" table is "ClassLevelInfo."

Class Level Information for Random Effects

The "Class Level Information for Random Effects" table is displayed when the RANDOM statement is specified. The table lists the categories of the classification variable specified in the RANDOM statement. For ODS purposes, the name of the "Class Level Information for Random Effects" table is "ClassLevelInfoR."

Summary of the Number of Event and Censored Values

The "Summary of the Number of Event and Censored Values" table displays, for each stratum, the breakdown of the number of events and censored values. For ODS purposes, the name of the "Summary of the Number of Event and Censored Values" table is "CensoredSummary."

Risk Sets Information

The "Risk Sets Information" table is displayed if you specify the ATRISK option in the PROC PHREG statement. The table displays, for each event time, the number of units at-risk and the number of units that experience the event. For ODS purposes, the name of the "Risk Sets Information" table is "RiskSetInfo."

Descriptive Statistics for Continuous Explanatory Variables

The "Simple Statistics for Continuous Explanatory Variables" table is displayed when you specify the SIMPLE option in the PROC PHREG statement. The table contains, for each stratum, the mean, standard deviation, and minimum and maximum for each continuous explanatory variable in the MODEL statement.

For ODS purposes, the name of the "Descriptive Statistics for Continuous Explanatory Variables" table is "SimpleStatistics."

Frequency Distribution of CLASS Variables

The "Frequency Distribution of CLASS Variables" table is displayed if you specify the SIMPLE option in the PROC PHREG statement and there are CLASS variables in the model. The table lists the frequency of the levels of the CLASS variables. For ODS purposes, the name of the "Frequency Distribution of CLASS Variables" table is "ClassLevelFreq."

Maximum Likelihood Iteration History

The "Maximum Likelihood Iteration History" table is displayed if you specify the ITPRINT option in the MODEL statement. The table contains the iteration number, ridge value or step size, log likelihood, and parameter estimates at each iteration. For ODS purposes, the name of the "Maximum Likelihood Iteration History" table is "IterHistory."

Gradient of Last Iteration

The "Gradient of Last Iteration" table is displayed if you specify the ITPRINT option in the MODEL statement. For ODS purposes, the name of the "Gradient of Last Iteration" table is "LastGradient."

Convergence Status

The "Convergence Status" table displays the convergence status of the Newton-Raphson maximization. For ODS purposes, the name of the "Convergence Status" table is "ConvergenceStatus."

Model Fit Statistics

The "Model Fit Statistics" table displays the values of -2 log likelihood for the null model and the fitted model, the AIC, and SBC. For ODS purposes, the name of the "Model Fit Statistics" table is "FitStatistics."

Covariance Parameter Estimates

The "Covariance Parameter Estimates" table displays the estimate of the variance parameter of the random effect and the standard error estimate of the variance parameter estimator. For ODS purposes, the name of the "Covariance Parameter Estimates" table is "CovParms."

Testing Global Null Hypothesis: BETA=0

The "Testing Global Null Hypothesis: BETA=0" table displays results of the likelihood ratio test, the score test, and the Wald test for testing the hypothesis that all parameters are zero. For the frailty model, the score test is not displayed and an adjusted degrees of freedom is used (see the section "Wald-Type Tests for Penalized Models" on page 5441 for more information.) For ODS purpose, the name of the "Testing Global Null Hypothesis: BETA=0" table is "GlobalTests."

Likelihood Ratio Statistics for Type 1 Analysis

The "Likelihood Ratio Statistics for Type 1 Analysis" table is displayed if the TYPE1 option is specified in the MODEL statement. The table displays the degrees of freedom, the likelihood ratio chi-square statistic, and the *p*-value for each effect in the model. For ODS purposes, the name of "Likelihood Ratio Statistics for Type 1 Analysis" is "Type1."

Type 3 Tests

The "Type 3 Tests" table is displayed if the model contains a CLASS variable or if the TYPE3 option is specified in the MODEL statement. The table displays, for each specified statistic, the Type 3 chi-square, the degrees of freedom, and the *p*-value for each effect in the model. For the frailty model, the table also displays the adjusted Wald-type test results (see the section "Wald-Type Tests for Penalized Models" on page 5441 for details.) For ODS purposes, the name of "Type 3 Tests" is "Type3."

Analysis of Maximum Likelihood Estimates

The "Analysis of Maximum Likelihood Estimates" table displays the maximum likelihood estimate of the parameter; the estimated standard error, computed as the square root of the corresponding diagonal element of the estimated covariance matrix; the ratio of the robust standard error estimate to the model-based standard error estimate if you specify the COVS option in the PROC statement; the Wald Chi-Square statistic, computed as the square of the parameter estimate divided by its standard error estimate; the degrees of freedom of the Wald chi-square statistic, which has a value of 1 unless the corresponding parameter is redundant or infinite, in which case the value is 0; the *p*-value of the Wald chi-square statistic with respect to a chi-square distribution with one degree of freedom; the hazard ratio estimate; and the confidence limits for the hazard ratio if you specified the RISKLIMITS option in the MODEL statement. For ODS purposes, the name of the "Analysis of Maximum Likelihood Estimates" table is "ParameterEstimates."

Solution for Random Effects

The "Solution for Random Effects" table displays the BLUP estimates of the random effects, the estimated standard errors, the confidence intervals for the random effects, the exponentiated values of the BLUP estimates, and confidence intervals for the exponentiated random effects. For ODS purposes, the name of the "Solution for Random Effects" table is "SolutionR."

Regression Models Selected by Score Criterion

The "Regression Models Selected by Score Criterion" table is displayed if you specify SELECTION=SCORE in the MODEL statement. The table contains the number of explanatory variables in each model, the score chi-square statistic, and the names of the variables included in the model. For ODS purposes, the name of the "Regression Models Selected by Score Criterion" table is "BestSubsets."

Analysis of Effects Eligible for Entry

The "Analysis of Effects Eligible for Entry" table is displayed if you use the FORWARD or STEPWISE selection method and you specify the DETAILS option in the MODEL statement. The table contains the

score chi-square statistic for testing the significance of each variable not in the model (after adjusting for the variables already in the model), and the *p*-value of the chi-square statistic with respect to a chi-square distribution with one degree of freedom. This table is produced before a variable is selected for entry in a forward selection step. For ODS purposes, the name of the "Analysis of Effects Eligible for Entry" table is "EffectsToEntry."

Analysis of Effects Eligible for Removal

The "Analysis of Effects Eligible for Removal" table is displayed if you use the BACKWARD or STEPWISE selection method and you specify the DETAILS option in the MODEL statement. The table contains the Wald chi-square statistic for testing the significance of each candidate effect for removal, the degrees of freedom of the Wald chi-square, and the corresponding *p*-value. This table is produced before an effect is selected for removal. For ODS purposes, the name of the "Analysis of Effects Eligible for Removal" table is "EffectsToRemoval."

Summary of Backward Elimination

The "Summary of Backward Elimination" table is displayed if you specify the SELECTION=BACKWARD option in the MODEL statement. The table contains the step number, the effects removed at each step, the corresponding chi-square statistic, the degrees of freedom, and the *p*-value. For ODS purpose, the name of the "Summary of Backward Elimination" table is "ModelBuildingSummary."

Summary of Forward Selection

The "Summary of Forward Selection" table is displayed if you specify the SELECTION=FORWARD option in the MODEL statement. The table contains the step number, the effects entered at each step, the corresponding chi-square statistic, the degrees of freedom, and the *p*-value. For ODS purpose, the name of the "Summary of Forward Selection" table is "ModelBuildingSummary."

Summary of Stepwise Selection

The "Summary of Stepwise Selection" table is displayed if you specify SELECTION=STEPWISE is specified in the MODEL statement. The table contains the step number, the effects entered or removed at each step, the corresponding chi-square statistic, the degrees of freedom, and the corresponding *p*-value. For ODS purpose, the name of the "Summary of Stepwise Selection" table is "ModelBuildingSummary."

Covariance Matrix

The "Covariance Matrix" table is displayed if you specify the COVB option in the MODEL statement. The table contains the estimated covariance matrix for the parameter estimates. For ODS purposes, the name of the "Covariance Matrix" table is "CovB."

Correlation Matrix

The "Correlation Matrix" table is displayed if you specify the COVB option in the MODEL statement. The table contains the estimated correlation matrix for the parameter estimates. For ODS purposes, the name of the "Correlation Matrix" table is "CorrB."

Hazard Ratios for *label*

The "Hazard Ratios for *label*" table is displayed if you specify the HAZARDRATIO statement. The table displays the estimate and confidence limits for each hazard ratio. For ODS purposes, the name of the "Hazard Ratios for *label*" table is "HazardRatios."

Coefficients of Contrast *label*

The "Coefficients of Contrast *label*" table is displayed if you specify the E option in the CONTRAST statement. The table displays the parameter names and the corresponding coefficents of each row of contrast *label*. For ODS purposes, the name of the "Coefficients of Contrast *label*" table is "ContrastCoeff."

Contrast Test Results

The "Contrast Test Results" table is displayed if you specify the CONTRAST statement. The table displays the degrees of freedom, test statistics, and the p-values for testing each contrast. For ODS purposes, the name of the "Contrast Test Results" table is "ContrastTest."

Contrast Estimation and Testing Results by Row

The "Contrast Estimation and Testing Results by Row" table is displayed if you specify the ESTIMATE option in the CONTRAST statement. The table displays, for each row, the estimate of the linear function of the coefficients, its standard error, and the confidence limits for the linear function. For ODS purposes, the name of the "Contrast Estimation and Testing Results by Row" table is "ContrastEstimate."

Linear Coefficients for *label*

The "Linear Coefficients *label*" table is displayed if you specify the E option in the TEST statement with *label* being the TEST statement label. The table contains the coefficients and constants of the linear hypothesis. For ODS purposes, the name of the "Linear Coefficients for *label*" table is "TestCoeff."

L[cov(b)]L' and Lb-c

The "L[cov(b)]L' and Lb-c" table is displayed if you specified the PRINT option in a TEST statement with *label* being the TEST statement label. The table displays the intermediate calculations of the Wald test. For ODS purposes, the name of the "L[cov(b)]L' and Lb-c" table is "TestPrint1."

Ginv(L[cov(b)]L') and Ginv(L[cov(b)]L')(Lb-c)

The "Ginv(L[cov(b)]L') and Ginv(L[cov(b)]L')(Lb-c)" table is displayed if you specified the PRINT option in a TEST statement with *label* being the TEST statement label. The table displays the intermediate calculations of the Wald test. For ODS purposes, the name of the "Ginv(L[cov(b)]L') and Ginv(L[cov(b)]L')(Lb-c)" table is "TestPrint2."

label *Test Results*

The "*label* Test Results" table is displayed if you specify a TEST statement with *label* being the TEST statement label. The table contains the Wald chi-square statistic, the degrees of freedom, and the *p*-value. For ODS purposes, the name of "*label* Test Results" table is "TestStmts."

Average Effect for label

The "Average Effect for *label*" table is displayed if the AVERAGE option is specified in a TEST statement with *label* being the TEST statement label. The table contains the weighted average of the parameter estimates for the variables in the TEST statement, the estimated standard error, the z-score, and the *p*-value. For ODS purposes, the name of the "Average Effect for *label*" is "TestAverage."

Reference Set of Covariates for Plotting

The "Reference Set of Covariates for Plotting" table is displayed if the PLOTS= option is requested without specifying the COVARIATES= data set in the BASELINE statement. The tables contains the values of the covariates for the reference set, where the reference levels are used for the CLASS variables and the sample averages for the continuous variables.

Bayesian Analysis Displayed Output

Model Information

The "Model Information" table displays the two-level name of the input data set, the name and label of the failure time variable, the name and label of the censoring variable and the values indicating censored times, the model (either the Cox model or the piecewise constant baseline hazard model), the name and label of the OFFSET variable, the name and label of the FREQ variable, the name and label of the WEIGHT variable, the method of handling ties in the failure time, the number of burn-in iterations, the number of iterations after the burn-in, and the number of thinning iterations. For ODS purposes, the name of the "Model Information" table is "ModelInfo."

Number of Observations

The "Number of Observations" table displays the number of observations read and used in the analysis. For ODS purposes, the name of the "Number of Observations" is "NObs."

Summary of the Number of Event and Censored Values

The "Summary of the Number of Event and Censored Values" table displays, for each stratum, the breakdown of the number of events and censored values. This table is not produced if the NONSUMMARY option is specified in the PROC PHREG statement. For ODS purposes, the name of the "Summary of the Number of Event and Censored Values" table is "CensoredSummary."

Descriptive Statistics for Continuous Explanatory Variables

The "Simple Statistics for Continuous Explanatory Variables" table is displayed when you specify the SIMPLE option in the PROC PHREG statement. The table contains, for each stratum, the mean, standard deviation, and minimum and maximum for each continuous explanatory variable in the MODEL statement. For ODS purposes, the name of the "Descriptive Statistics for Continuous Explanatory Variables" table is "SimpleStatistics."

Class Level Information

The "Class Level Information" table is displayed if there are CLASS variables in the model. The table lists the categories of every CLASS variable in the model and the corresponding design variable values. For ODS purposes, the name of the "Class Level Information" table is "ClassLevelInfo."

Frequency Distribution of CLASS Variables

The "Frequency Distribution of CLASS Variables" table is displayed if you specify the SIMPLE option in the PROC PHREG statement and there are CLASS variables in the model. The table lists the frequency of the levels of the CLASS variables. For ODS purposes, the name of the "Frequency Distribution of CLASS Variables" table is "ClassLevelFreq."

Regression Parameter Information

The "Regression Parameter Information" table displays the names of the parameters and the corresponding level information of effects containing the CLASS variables. For ODS purposes, the name of the "Regression Parameter Information" table is "ParmInfo."

Constant Baseline Hazard Time Intervals

The "Constant Baseline Hazard Time Intervals" table displays the intervals of constant baseline hazard and the corresponding numbers of failure times and event times. This table is produced only if you specify the PIECEWISE option in the BAYES statement. For ODS purposes, the name of the "Constant Baseline Hazard Time Intervals" table is "Interval."

Maximum Likelihood Estimates

The "Maximum Likelihood Estimates" table displays, for each parameter, the maximum likelihood estimate, the estimated standard error, and the 95% confidence limits. For ODS purposes, the name of the "Maximum Likelihood Estimates" table is "ParameterEstimates."

Hazard Prior

The "Hazard Prior" table is displayed if you specify the PIECEWISE=HAZARD option in the BAYES statement. It describes the prior distribution of the hazard parameters. For ODS purposes, the name of the "Hazard Prior" table is "HazardPrior."

Log-Hazard Prior

The "Log-Hazard Prior" table is displayed if you specify the PIECEWISE=LOGHAZARD option in the BAYES statement. It describes the prior distribution of the log-hazard parameters. For ODS purposes, the name of the "Log-Hazard Prior" table is "HazardPrior."

Coefficient Prior

The "Coefficient Prior" table displays the prior distribution of the regression coefficients. For ODS purposes, the name of the "Coefficient Prior" table is "CoeffPrior."

Initial Values

The "Initial Values" table is displayed if you specify the INITIAL option in the BAYES statement. The table contains the initial values of the parameters for the Gibbs sampling. For ODS purposes, the name of the "Initial Values" table is "InitialValues."

Fit Statistics

The "Fit Statistics" table displays the DIC and pD statistics for each parameter. For ODS purposes, the name of the "Fit Statistics" table is "FitStatistics."

Posterior Summaries

The "Posterior Summaries" table displays the size of the posterior sample, the mean, the standard error, and the percentiles for each model parameter. For ODS purposes, the name of the "Posterior Summaries" table is "PostSummaries."

Posterior Intervals

The "Posterior Intervals" table displays the equal-tail interval and the HPD interval for each model parameter. For ODS purposes, the name of the "Posterior Intervals" table is "PostIntervals."

Posterior Covariance Matrix

The "Posterior Covariance Matrix" table is produced if you include COV in the SUMMARY= option in the BAYES statement. This tables displays the sample covariance of the posterior samples. For ODS purposes, the name of the "Posterior Covariance Matrix" table is "Cov."

Posterior Correlation Matrix

The "Posterior Correlation Matrix" table is displayed if you include CORR in the SUMMARY= option in the BAYES statement. The table contains the sample correlation of the posterior samples. For ODS purposes, the name of the "Posterior Correlation Matrix" table is "Corr."

Posterior Autocorrelations

The "Posterior Autocorrelations" table displays the lag 1, lag 5, lag 10, and lag 50 autocorrelations for each parameter. For ODS purposes, the name of the "Posterior Autocorrelations" table is "AutoCorr."

Gelman-Rubin Diagnostics

The "Gelman-Rubin Diagnostics" table is produced if you include GELMAN in the DIAGNOSTIC= option in the BAYES statement. This table displays the estimate of the potential scale reduction factor and its 97.5% upper confidence limit for each parameter. For ODS purposes, the name of the "Gelman-Rubin Diagnostics" table is "Gelman."

Geweke Diagnostics

The "Geweke Diagnostics" table displays the Geweke statistic and its p-value for each parameter. For ODS purposes, the name of the "Geweke Diagnostics" table is "Geweke."

Raftery-Lewis Diagnostics

The "Raftery-Lewis Diagnostics" tables is produced if you include RAFTERY in the DIAGNOSTIC= option in the BAYES statement. This table displays the Raftery and Lewis diagnostics for each variable. For ODS purposes, the name of the "Raftery-Diagnostics" table is "Raftery."

Heidelberger-Welch Diagnostics

The "Heidelberger-Welch Diagnostics" table is displayed if you include HEIDELBERGER in the DIAGNOSTIC= option in the BAYES statement. This table describes the results of a stationary test and a halfwidth test for each parameter. For ODS purposes, the name of the "Heidelberger-Welch Diagnostics" table is "Heidelberger."

Effective Sample Sizes

The "Effective Sample Sizes" table displays, for each parameter, the effective sample size, the correlation time, and the efficiency. For ODS purposes, the name of the "Effective Sample Sizes" table is "ESS."

Hazard Ratios for label

The "Hazard Ratios for *label*" table is displayed if you specify the HAZARDRATIO statement. The table displays the posterior summary for each hazard ratio. The summary includes the mean, standard error,

quartiles, and equal-tailed and HPD intervals. For ODS purposes, the name of the "Hazard Ratios for *label*" table is "HazardRatios."

Reference Set of Covariates for Plotting

The "Reference Set of Covariates for Plotting" table is displayed if the PLOTS= option is requested without specifying the COVARIATES= data set in the BASELINE statement. The table contains the values of the covariates for the reference set, where the reference levels are used for the CLASS variables and the sample averages for the continuous variables.

ODS Table Names

PROC PHREG assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed separately in Table 66.9 for the maximum likelihood analysis and in Table 66.10 for the Bayesian analysis. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Each of the EFFECT, ESTIMATE, LSMEANS, LSMESTIMATE, and SLICE statements creates ODS tables, which are not listed in Table 66.9 and Table 66.10. For information about these tables, see the corresponding sections of Chapter 19, "Shared Concepts and Topics."

Table 66.9 ODS Tables for a Maximum Likelihood Analysis Produced by PROC PHREG

ODS Table Name	Description	Statement / Option
BestSubsets	Best subset selection	MODEL / SELECTION=SCORE
CensoredSummary	Summary of event and censored observations	Default
ClassLevelFreq	Frequency distribution of CLASS variables	CLASS, PROC / SIMPLE
ClassLevelInfo	CLASS variable levels and design variables	CLASS
ClassLevelInfoR	Class levels for random effects	RANDOM
ContrastCoeff	L matrix for contrasts	CONTRAST / E
ContrastEstimate	Individual contrast estimates	CONTRAST / ESTIMATE=
ContrastTest	Wald test for contrasts	CONTRAST
ConvergenceStatus	Convergence status	Default
CorrB	Estimated correlation matrix of parameter estimators	MODEL / CORRB
CovB	Estimated covariance matrix of parameter estimators	MODEL / COVB
CovParms	Variance estimates of the random effects	RANDOM
EffectsToEnter	Analysis of effects for entry	MODEL / SELECTION=F|S
EffectsToRemove	Analysis of effects for removal	MODEL / SELECTION=B|S
FitStatistics	Model fit statistics	Default
FunctionalFormSupTest	Supremum test for functional form	ASSESS / VAR=

Table 66.9 *continued*

ODS Table Name	Description	Statement / Option
GlobalScore	Global chi-square test	MODEL / NOFIT
GlobalTests	Tests of the global null hypothesis	Default
HazardRatios	Hazard ratios and confidence limits	HAZARDRATIO
IterHistory	Iteration history	MODEL /ITPRINT
LastGradient	Last evaluation of gradient	MODEL / ITPRINT
ModelBuildingSummary	Summary of model building	MODEL / SELECTION=B|F|S
ModelInfo	Model information	Default
NObs	Number of observations	Default
NumberAtRisk	Risk sets information	MODEL / ATRISK
ParameterEstimates	Maximum likelihood estimates of model parameters	Default
ProportionalHazardsSupTest	Supremum test for proportional hazards assumption	ASSESS / PH
ResidualChiSq	Residual chi-square	MODEL / SELECTION=F|B
ReferenceSet	Reference set of covariates for plotting	PROC / PLOTS=
SimpleStatistics	Summary statistics of input continuous explanatory variables	PROC / SIMPLE
SolutionR	Solutions for random effects	RANDOM / SOLUTION
TestAverage	Average effect for test	TEST / AVERAGE
TestCoeff	Coefficients for linear hypotheses	TEST / E
TestPrint1	**L**[cov(**b**)]**L**' and **Lb**-**c**	TEST / PRINT
TestPrint2	Ginv(**L**[cov(**b**)]**L**') and Ginv(**L**[cov(**b**)]**L**')(**Lb**-**c**)	TEST / PRINT
TestStmts	Linear hypotheses testing results	TEST
Type1	Type 1 likelihood ratio tests	MODEL / TYPE1
Type3	Type 3 chi-square tests	MODEL / TYPE3 | CLASS

Table 66.10 ODS Table for a Bayesian Analysis Produced by PROC PHREG

ODS Table Name	Description	Statement / Option
AutoCorr	Autocorrelations of the posterior samples	BAYES
CensoredSummary	Numbers of the event and censored observations	PROC
ClassLevelFreq	Frequency distribution of CLASS variables	CLASS, PROC / SIMPLE
ClassLevelInfo	CLASS variable levels and design variables	CLASS
CoeffPrior	Prior distribution of the regression coefficients	BAYES
Corr	Posterior correlation matrix	BAYES / SUMMARY=CORR
Cov	Posterior covariance Matrix	BAYES / SUMMARY=COV

Table 66.10 *continued*

ODS Table Name	Description	Statement / Option
ESS	Effective sample sizes	BAYES / DIAGNOSTICS=ESS
FitStatistics	Fit statistics	BAYES
Gelman	Gelman-Rubin convergence diagnostics	BAYES / DIAGNOSTICS=GELMAN
Geweke	Geweke convergence diagnostics	BAYES
HazardPrior	Prior distribution of the baseline hazards	BAYES / PIECEWISE
HazardRatios	Posterior summary statistics for hazard ratios	HAZARDRATIO
Heidelberger	Heidelberger-Welch convergence diagnostics	BAYES / DIAGNOSTICS=HEIDELBERGER
InitialValues	Initial values of the Markov chains	BAYES
ModelInfo	Model information	Default
NObs	Number of observations	Default
MCError	Monte Carlo standard errors	BAYES / DIAGNOSTICS=MCERROR
ParameterEstimates	Maximum likelihood estimates of model parameters	Default
ParmInfo	Names of regression coefficients	CLASS,BAYES
Partition	Partition of constant baseline hazard intervals	BAYES / PIECEWISE
PostIntervals	Equal-tail and high probability density intervals of the posterior samples	BAYES
PosteriorSample	Posterior samples	BAYES / (for ODS output data set only)
PostSummaries	Summary statistics of the posterior samples	BAYES
Raftery	Raftery-Lewis convergence diagnostics	BAYES / DIAGNOSTICS=RAFTERY
ReferenceSet	Reference set of covariates for plotting	PROC / PLOTS=
SimpleStatistics	Summary statistics of input continuous explanatory variables	PROC / SIMPLE

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, "Statistical Graphics Using ODS."

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section "Enabling

and Disabling ODS Graphics" on page 612 in Chapter 21, "Statistical Graphics Using ODS."

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section "A Primer on ODS Statistical Graphics" on page 611 in Chapter 21, "Statistical Graphics Using ODS."

You can reference every graph produced through ODS Graphics with a name. The names of the graphs that PROC PHREG generates are listed separately in Table 66.11 for the maximum likelihood analysis and in Table 66.12 for the Bayesian analysis. When the ODS Graphics are in effect in a Bayesian analysis, each of the ESTIMATE, LSMEANS, LSMESTIMATE, and SLICE statements can produce plots associated with their analyses. For information of these plots, see the corresponding sections of Chapter 19, "Shared Concepts and Topics."

Table 66.11 Graphs for a Maximum Likelihood Analysis Produced by PROC PHREG

ODS Graph Name	Plot Description	Statement / Option
CumhazPlot	Cumulative hazard function plot	PROC / PLOTS=CUMHAZ
CumulativeResiduals	Cumulative martingale residual plot	ASSESS / VAR=
CumResidPanel	Panel plot of cumulative martingale residuals	ASSESS / VAR=, CRPANEL
MCFPlot	Mean cumulative function plot	PROC / PLOTS=MCF
ScoreProcess	Standardized score process plot	ASSESS / PH
SurvivalPlot	Survivor function plot	PROC / PLOTS=SURVIVAL

Table 66.12 Graphs for a Bayesian Analysis Produced by PROC PHREG

ODS Graph Name	Plot Description	Statement / Option
ADPanel	Autocorrelation function and density panel	BAYES / PLOTS=(AUTOCORR DENSITY)
AutocorrPanel	Autocorrelation function panel	BAYES / PLOTS= AUTOCORR
AutocorrPlot	Autocorrelation function plot	BAYES / PLOTS(UNPACK)=AUTOCORR
CumhazPlot	Cumulative hazard function plot	PROC / PLOTS=CUMHAZ
DensityPanel	Density panel	BAYES / PLOTS=DENSITY
DensityPlot	Density plot	BAYES / PLOTS(UNPACK)=DENSITY
SurvivalPlot	Survivor function plot	PROC / PLOTS=SURVIVAL
TAPanel	Trace and autocorrelation function panel	BAYES / PLOTS=(TRACE AUTOCORR)
TADPanel	Trace, density, and autocorrelation function panel	BAYES / PLOTS=(TRACE AUTOCORR DENSITY)
TDPanel	Trace and density panel	BAYES / PLOTS=(TRACE DENSITY)

ODS Graph Name	Plot Description	Statement / Option
TracePanel	Trace panel	BAYES / PLOTS=TRACE
TracePlot	Trace plot	BAYES / PLOTS(UNPACK)=TRACE

Examples: PHREG Procedure

This section contains 14 examples of PROC PHREG applications. The first 12 examples use the classical method of maximum likelihood, while the last two examples illustrate the Bayesian methodology.

Example 66.1: Stepwise Regression

Krall, Uthoff, and Harley (1975) analyzed data from a study on multiple myeloma in which researchers treated 65 patients with alkylating agents. Of those patients, 48 died during the study and 17 survived. The following DATA step creates the data set Myeloma. The variable Time represents the survival time in months from diagnosis. The variable VStatus consists of two values, 0 and 1, indicating whether the patient was alive or dead, respectively, at the end of the study. If the value of VStatus is 0, the corresponding value of Time is censored. The variables thought to be related to survival are LogBUN (log(BUN) at diagnosis), HGB (hemoglobin at diagnosis), Platelet (platelets at diagnosis: 0=abnormal, 1=normal), Age (age at diagnosis, in years), LogWBC (log(WBC) at diagnosis), Frac (fractures at diagnosis: 0=none, 1=present), LogPBM (log percentage of plasma cells in bone marrow), Protein (proteinuria at diagnosis), and SCalc (serum calcium at diagnosis). Interest lies in identifying important prognostic factors from these nine explanatory variables.

```
data Myeloma;
   input Time VStatus LogBUN HGB Platelet Age LogWBC Frac
         LogPBM Protein SCalc;

;
```

The stepwise selection process consists of a series of alternating forward selection and backward elimination steps. The former adds variables to the model, while the latter removes variables from the model.

The following statements use PROC PHREG to produce a stepwise regression analyis. Stepwise selection is requested by specifying the SELECTION=STEPWISE option in the MODEL statement. The option SLENTRY=0.25 specifies that a variable has to be significant at the 0.25 level before it can be entered into the model, while the option SLSTAY=0.15 specifies that a variable in the model has to be significant at the 0.15 level for it to remain in the model. The DETAILS option requests detailed results for the variable selection process.

```
proc phreg data=Myeloma;
   model Time*VStatus(0)=LogBUN HGB Platelet Age LogWBC
                         Frac LogPBM Protein SCalc
                         / selection=stepwise slentry=0.25
                           slstay=0.15 details;
run;
```

Results of the stepwise regression analysis are displayed in Output 66.1.1 through Output 66.1.7.

Individual score tests are used to determine which of the nine explanatory variables is first selected into the model. In this case, the score test for each variable is the global score test for the model containing that variable as the only explanatory variable. Output 66.1.1 displays the chi-square statistics and the corresponding *p*-values. The variable LogBUN has the largest chi-square value (8.5164), and it is significant (p=0.0035) at the SLENTRY=0.25 level. The variable LogBUN is thus entered into the model.

Output 66.1.1 Individual Score Test Results for All Variables

The PHREG Procedure

Model Information

Data Set	WORK.MYELOMA	
Dependent Variable	Time	Survival Time
Censoring Variable	VStatus	0=Alive 1=Dead
Censoring Value(s)	0	
Ties Handling	BRESLOW	

Summary of the Number of Event and Censored Values

Total	Event	Censored	Percent Censored
65	48	17	26.15

Output 66.1.1 *continued*

Analysis of Effects Eligible for Entry

Effect	DF	Score Chi-Square	Pr > ChiSq
LogBUN	1	8.5164	0.0035
HGB	1	5.0664	0.0244
Platelet	1	3.1816	0.0745
Age	1	0.0183	0.8924
LogWBC	1	0.5658	0.4519
Frac	1	0.9151	0.3388
LogPBM	1	0.5846	0.4445
Protein	1	0.1466	0.7018
SCalc	1	1.1109	0.2919

Residual Chi-Square Test

Chi-Square	DF	Pr > ChiSq
18.4550	9	0.0302

Output 66.1.2 displays the results of the first model. Since the Wald chi-square statistic is significant ($p = 0.0039$) at the SLSTAY=0.15 level, LogBUN stays in the model.

Output 66.1.2 First Model in the Stepwise Selection Process

Step 1. Effect LogBUN is entered. The model contains the following effects:

LogBUN

Convergence Status

Convergence criterion (GCONV=1E-8) satisfied.

Model Fit Statistics

Criterion	Without Covariates	With Covariates
-2 LOG L	309.716	301.959
AIC	309.716	303.959
SBC	309.716	305.830

Testing Global Null Hypothesis: BETA=0

Test	Chi-Square	DF	Pr > ChiSq
Likelihood Ratio	7.7572	1	0.0053
Score	8.5164	1	0.0035
Wald	8.3392	1	0.0039

Output 66.1.2 *continued*

Analysis of Maximum Likelihood Estimates

Parameter	DF	Parameter Estimate	Standard Error	Chi-Square	Pr > ChiSq	Hazard Ratio
LogBUN	1	1.74595	0.60460	8.3392	0.0039	5.731

The next step consists of selecting another variable to add to the model. Output 66.1.3 displays the chi-square statistics and p-values of individual score tests (adjusted for LogBUN) for the remaining eight variables. The score chi-square for a given variable is the value of the likelihood score test for testing the significance of the variable in the presence of LogBUN. The variable HGB is selected because it has the highest chi-square value (4.3468), and it is significant ($p = 0.0371$) at the SLENTRY=0.25 level.

Output 66.1.3 Score Tests Adjusted for the Variable LogBUN

Analysis of Effects Eligible for Entry

Effect	DF	Score Chi-Square	Pr > ChiSq
HGB	1	4.3468	0.0371
Platelet	1	2.0183	0.1554
Age	1	0.7159	0.3975
LogWBC	1	0.0704	0.7908
Frac	1	1.0354	0.3089
LogPBM	1	1.0334	0.3094
Protein	1	0.5214	0.4703
SCalc	1	1.4150	0.2342

Residual Chi-Square Test

Chi-Square	DF	Pr > ChiSq
9.3164	8	0.3163

Output 66.1.4 displays the fitted model containing both LogBUN and HGB. Based on the Wald statistics, neither LogBUN nor HGB is removed from the model.

Output 66.1.4 Second Model in the Stepwise Selection Process

Step 2. Effect HGB is entered. The model contains the following effects:

LogBUN HGB

Convergence Status

Convergence criterion (GCONV=1E-8) satisfied.

Output 66.1.4 *continued*

Model Fit Statistics

Criterion	Without Covariates	With Covariates
-2 LOG L	309.716	297.767
AIC	309.716	301.767
SBC	309.716	305.509

Testing Global Null Hypothesis: BETA=0

Test	Chi-Square	DF	Pr > ChiSq
Likelihood Ratio	11.9493	2	0.0025
Score	12.7252	2	0.0017
Wald	12.1900	2	0.0023

Analysis of Maximum Likelihood Estimates

Parameter	DF	Parameter Estimate	Standard Error	Chi-Square	Pr > ChiSq	Hazard Ratio
LogBUN	1	1.67440	0.61209	7.4833	0.0062	5.336
HGB	1	-0.11899	0.05751	4.2811	0.0385	0.888

Output 66.1.5 shows Step 3 of the selection process, in which the variable SCalc is added, resulting in the model with LogBUN, HGB, and SCalc as the explanatory variables. Note that SCalc has the smallest Wald chi-square statistic, and it is not significant ($p = 0.1782$) at the SLSTAY=0.15 level.

Output 66.1.5 Third Model in the Stepwise Regression

Step 3. Effect SCalc is entered. The model contains the following effects:

LogBUN HGB SCalc

Convergence Status

Convergence criterion (GCONV=1E-8) satisfied.

Model Fit Statistics

Criterion	Without Covariates	With Covariates
-2 LOG L	309.716	296.078
AIC	309.716	302.078
SBC	309.716	307.692

Output 66.1.5 *continued*

Testing Global Null Hypothesis: BETA=0

Test	Chi-Square	DF	Pr > ChiSq
Likelihood Ratio	13.6377	3	0.0034
Score	15.3053	3	0.0016
Wald	14.4542	3	0.0023

Analysis of Maximum Likelihood Estimates

Parameter	DF	Parameter Estimate	Standard Error	Chi-Square	Pr > ChiSq	Hazard Ratio
LogBUN	1	1.63593	0.62359	6.8822	0.0087	5.134
HGB	1	−0.12643	0.05868	4.6419	0.0312	0.881
SCalc	1	0.13286	0.09868	1.8127	0.1782	1.142

The variable SCalc is then removed from the model in a step-down phase in Step 4 (Output 66.1.6). The removal of SCalc brings the stepwise selection process to a stop in order to avoid repeatedly entering and removing the same variable.

Output 66.1.6 Final Model in the Stepwise Regression

Step 4. Effect SCalc is removed. The model contains the following effects:

LogBUN HGB

Convergence Status

Convergence criterion (GCONV=1E-8) satisfied.

Model Fit Statistics

Criterion	Without Covariates	With Covariates
−2 LOG L	309.716	297.767
AIC	309.716	301.767
SBC	309.716	305.509

Testing Global Null Hypothesis: BETA=0

Test	Chi-Square	DF	Pr > ChiSq
Likelihood Ratio	11.9493	2	0.0025
Score	12.7252	2	0.0017
Wald	12.1900	2	0.0023

Output 66.1.6 *continued*

Analysis of Maximum Likelihood Estimates

Parameter	DF	Parameter Estimate	Standard Error	Chi-Square	Pr > ChiSq	Hazard Ratio
LogBUN	1	1.67440	0.61209	7.4833	0.0062	5.336
HGB	1	-0.11899	0.05751	4.2811	0.0385	0.888

NOTE: Model building terminates because the effect to be entered is the effect that was removed in the last step.

The procedure also displays a summary table of the steps in the stepwise selection process, as shown in Output 66.1.7.

Output 66.1.7 Model Selection Summary

Summary of Stepwise Selection

Step	Effect Entered	Effect Removed	Number DF	Number In	Score Chi-Square	Wald Chi-Square	Pr > ChiSq
1	LogBUN		1	1	8.5164		0.0035
2	HGB		1	2	4.3468		0.0371
3	SCalc		1	3	1.8225		0.1770
4		SCalc	1	2		1.8127	0.1782

The stepwise selection process results in a model with two explanatory variables, LogBUN and HGB.

Example 66.2: Best Subset Selection

An alternative to stepwise selection of variables is best subset selection. This method uses the branch-and-bound algorithm of Furnival and Wilson (1974) to find a specified number of best models containing one, two, or three variables, and so on, up to the single model containing all of the explanatory variables. The criterion used to determine the "best" subset is based on the global score chi-square statistic. For two models A and B, each having the same number of explanatory variables, model A is considered to be better than model B if the global score chi-square statistic for A exceeds that for B.

In the following statements, best subset selection analysis is requested by specifying the SELECTION=SCORE option in the MODEL statement. The BEST=3 option requests the procedure to identify only the three best models for each size. In other words, PROC PHREG will list the three models having the highest score statistics of all the models possible for a given number of covariates.

```
proc phreg data=Myeloma;
   model Time*VStatus(0)=LogBUN HGB Platelet Age LogWBC
                         Frac LogPBM Protein SCalc
                         / selection=score best=3;
run;
```

Output 66.2.1 displays the results of this analysis. The number of explanatory variables in the model is given in the first column, and the names of the variables are listed on the right. The models are listed in descending order of their score chi-square values within each model size. For example, among all models containing two explanatory variables, the model that contains the variables LogBUN and HGB has the largest score value (12.7252), the model that contains the variables LogBUN and Platelet has the second-largest score value (11.1842), and the model that contains the variables LogBUN and SCalc has the third-largest score value (9.9962).

Output 66.2.1 Best Variable Combinations

The PHREG Procedure

Regression Models Selected by Score Criterion

Example 66.3: Modeling with Categorical Predictors

Consider the data for the Veterans Administration lung cancer trial presented in Appendix 1 of Kalbfleisch and Prentice (1980). In this trial, males with advanced inoperable lung cancer were randomized to a standard therapy and a test chemotherapy. The primary endpoint for the therapy comparison was time to death in days, represented by the variable Time. Negative values of Time are censored values. The data include information about a number of explanatory variables: Therapy (type of therapy: standard or test), Cell (type of tumor cell: adeno, large, small, or squamous), Prior (prior therapy: 0=no, 10=yes), Age (age, in years), Duration (months from diagnosis to randomization), and Kps (Karnofsky performance scale). A censoring indicator variable, Censor, is created from the data, with the value 1 indicating a censored time and the value 0 indicating an event time. The following DATA step saves the data in the data set VALung.

```
proc format;
   value yesno 0='no' 10='yes';
   run;

data VALung;
   drop check m;
   retain Therapy Cell;
   infile cards column=column;
   length Check $ 1;
   label Time='time to death in days'
         Kps='Karnofsky performance scale'
         Duration='months from diagnosis to randomization'
         Age='age in years'
         Prior='prior therapy'
         Cell='cell type'
         Therapy='type of treatment';
   format Prior yesno.;
   M=Column;
   input Check $ @@;
   if M>Column then M=1;
   if Check='s'|Check='t' then do;
      input @M Therapy $ Cell $;
      delete;
      end;
   else do;
      input @M Time Kps Duration Age Prior @@;
      Status=(Time>0);
      Time=abs(Time);
      end;
   datalines;

;
```

The following statements use the PHREG procedure to fit the Cox proportional hazards model to these data. The variables Prior, Cell, and Therapy, which are categorical variables, are declared in the CLASS statement. By default, PROC PHREG parameterizes the CLASS variables by using the reference coding with the last category as the reference category. However, you can explicitly specify the reference category of your choice. Here, Prior=no is chosen as the reference category for prior therapy, Cell=large is chosen as the reference category for type of tumor cell, and Therapy=standard is chosen as the reference category for the type of therapy. In the MODEL statement, the term Prior|Therapy is just another way of specifying the main effects Prior, Therapy, and the Prior*Therapy interaction.

```
proc phreg data=VALung;
   class Prior(ref='no') Cell(ref='large') Therapy(ref='standard');
   model Time*Status(0) = Kps Duration Age Cell Prior|Therapy;
   run;
```

Coding of the CLASS variables is displayed in Output 66.3.1. There is one dummy variable for Prior and one for Therapy, since both variables are binary. The dummy variable has a value of 0 for the reference category (Prior=no, Therapy=standard). The variable Cell has four categories and is represented by three dummy variables. Note that the reference category, Cell=large, has a value of 0 for all three dummy variables.

Output 66.3.1 Reference Coding of CLASS Variables

The PHREG Procedure

Class Level Information

Class	Value	Design Variables		
Prior	no	0		
	yes	1		
Cell	adeno	1	0	0
	large	0	0	0
	small	0	1	0
	squamous	0	0	1
Therapy	standard	0		
	test	1		

The test results of individual model effects are shown in Output 66.3.2. There is a strong prognostic effect of Kps on patient's survivivorship ($p < 0.0001$), and the survival times for patients of different Cell types differ significantly ($p = 0.0003$). The Prior*Therapy interaction is marginally significant (p=0.0416)—that is, prior therapy might play a role in whether one treatment is more effective than the other.

Output 66.3.2 Wald Tests of Individual Effects

Type 3 Tests

Effect	DF	Wald Chi-Square	Pr > ChiSq
Kps	1	35.5051	<.0001
Duration	1	0.1159	0.7335
Age	1	1.9772	0.1597
Cell	3	18.5339	0.0003
Prior	1	2.5296	0.1117
Therapy	1	5.2349	0.0221
Prior*Therapy	1	4.1528	0.0416

In the Cox proportional hazards model, the effects of the covariates are to act multiplicatively on the hazard of the survival time, and therefore it is a little easier to interpret the corresponding hazard ratios than the regression parameters. For a parameter that corresponds to a continuous variable, the hazard ratio is the ratio of hazard rates for a increase of one unit of the variable. From Output 66.3.3, the hazard ratio estimate for Kps is 0.968, meaning that an increase of 10 units in Karnofsky performance scale will shrink the hazard rate by $1-(0.968)^{10}$=28%. For a CLASS variable parameter, the hazard ratio presented in the Output 66.3.3 is the ratio of the hazard rates between the given category and the reference category. The hazard rate of

Cell=adeno is 219% that of Cell=large, the hazard rate of Cell=small is 62% that of Cell=large, and the hazard rate of Cell=squamous is only 66% that of Cell=large. Hazard ratios for Prior and Therapy are missing since the model contains the Prior*Therapy interaction. You can use the HAZARDRATIO statement to obtain the hazard ratios for a main effect in the presence of interaction as shown later in this example.

Output 66.3.3 Parameters Estimates with Reference Coding

Analysis of Maximum Likelihood Estimates

Parameter			DF	Parameter Estimate	Standard Error	Chi-Square	Pr > ChiSq

The following PROC PHREG statements illustrate the use of the backward elimination process to identify the effects that affect the survivorship of the lung cancer patients. The option SELECTION=BACKWARD is specified to carry out the backward elimination. The option SLSTAY=0.1 specifies the significant level for retaining the effects in the model.

```
proc phreg data=VALung;
   class Prior(ref='no') Cell(ref='large') Therapy(ref='standard');
   model Time*Status(0) = Kps Duration Age Cell Prior|Therapy
         / selection=backward slstay=0.1;
   run;
```

Results of the backward elimination process are summarized in Output 66.3.4. The effect Duration was eliminated first and was followed by Age.

Output 66.3.4 Effects Eliminated from the Model

The PHREG Procedure

Summary of Backward Elimination

Step	Effect Removed	DF	Number In	Wald Chi-Square	Pr > ChiSq

Finally, the following statements refit the previous model and computes hazard ratios at settings beyond those displayed in the "Analysis of Maximum Likelihood Estimates" table. You can use either the HAZARDRATIO statement or the CONTRAST statement to obtain hazard ratios. Using the CONTRAST statement to compute hazard ratios for CLASS variables can be a daunting task unless you are familiar with the parameterization schemes (see the section "Parameterization of Model Effects" on page 397 of Chapter 19, "Shared Concepts and Topics," for details), but you have control over which specific hazard ratios you want to compute. HAZARDRATIO statements, on the other hand, are designed specifically to provide hazard ratios. They are easy to use and you can also request both the Wald confidence limits and the profile-likelihood confidence limits; the latter is not available for the CONTRAST statements. Three HAZARDRATIO statements are specified; each has the CL=BOTH option to request both the Wald confidence limits and the profile-likelihood limits. The first HAZARDRATIO statement, labeled 'H1', estimates the hazard ratio for an increase of 10 units in the KPS; the UNITS= option specifies the number of units increase. The second HAZARDRATIO statement, labeled 'H2' computes the hazard ratios for comparing any pairs of tumor Cell types. The third HAZARDRATIO statement, labeled 'H3', compares the test therapy with the standard

therapy. The DIFF=REF option specifies that each nonreference category is compared to the reference category. The purpose of using DIFF=REF here is to ensure that the hazard ratio is comparing the test therapy to the standard therapy instead of the other way around. Three CONTRAST statements, labeled 'C1', 'C2', and 'C3', parallel to the HAZARDRATIO statements 'H1', 'H2', and 'H3', respectively, are specified. The ESTIMATE=EXP option specifies that the linear predictors be estimated in the exponential scale, which are precisely the hazard ratios.

```
proc phreg data=VALung;
   class Prior(ref='no') Cell(ref='large') Therapy(ref='standard');
   model Time*Status(0) = Kps Cell Prior|Therapy;
   hazardratio 'H1' Kps / units=10 cl=both;
   hazardratio 'H2' Cell / cl=both;
   hazardratio 'H3' Therapy / diff=ref cl=both;
   contrast 'C1' Kps 10 / estimate=exp;
   contrast 'C2' cell 1  0  0, /* adeno vs large    */
                 cell 1 -1  0, /* adeno vs small    */
                 cell 1  0 -1, /* adeno vs squamous */
                 cell 0 -1  0, /* large vs small    */
                 cell 0  0 -1, /* large vs Squamous */
                 cell 0  1 -1  /* small vs squamous */
                  / estimate=exp;
   contrast 'C3' Prior 0 Therapy 1  Prior*Therapy 0,
                 Prior 0 Therapy 1  Prior*Therapy 1  / estimate=exp;
   run;
```

Output 66.3.6 displays the results of the three HAZARDRATIO statements in separate tables. Results of the three CONTRAST statements are shown in one table in Output 66.3.7. However, point estimates and the Wald confidence limits for the hazard ratio agree in between the two outputs.

Output 66.3.6 Results from HAZARDRATIO Statements

The PHREG Procedure

H1: Hazard Ratios for Kps

Example 66.4: Firth's Correction for Monotone Likelihood

In fitting the Cox regression model by maximizing the partial likelihood, the estimate of an explanatory variable X will be infinite if the value of X at each uncensored failure time is the largest of all the values of X in the risk set at that time (Tsiatis 1981; Bryson and Johnson 1981). You can exploit this information to artificially create a data set that has the condition of monotone likelihood for the Cox regression. The following DATA step modifies the Myeloma data in Example 66.1 to create a new explanatory variable, Contrived, which has the value 1 if the observed time is less than or equal to 65 and has the value 0 otherwise. The phenomenon of monotone likelihood will be demonstrated in the new data set Myeloma2.

```
data Myeloma2;
   set Myeloma;
   Contrived= (Time <= 65);
   run;
```

For illustration purposes, consider a Cox model with three explanatory variables, one of which is the variable Contrived. The following statements invoke PROC PHREG to perform the Cox regression. The IPRINT option is specified in the MODEL statement to print the iteration history of the optimization.

```
proc phreg data=Myeloma2;
   model Time*Vstatus(0)=LOGbun HGB Contrived / itprint;
   run;
```

The symptom of monotonity is demonstrated in Output 66.4.1. The log likelihood converges to the value of –136.56 while the coefficient for Contrived diverges. Although the Newton-Raphson optimization process did not fail, it is obvious that convergence is questionable. A close examination of the standard errors in the "Analyis of Maximum Likelihood Estimates" table reveals a very large value for the coefficient of Contrived. This is very typical of a diverged estimate.

Output 66.4.1 Monotone Likelihood Behavior Displayed

The PHREG Procedure

Example 66.5: Conditional Logistic Regression for m:n Matching

Conditional logistic regression is used to investigate the relationship between an outcome and a set of prognostic factors in matched case-control studies. The outcome is whether the subject is a case or a control. If there is only one case and one control, the matching is 1:1. The *m:n* matching refers to the situation in which there is a varying number of cases and controls in the matched sets. You can perform conditional logistic regression with the PHREG procedure by using the discrete logistic model and forming a stratum for each matched set. In addition, you need to create dummy survival times so that all the cases in a matched set have the same event time value, and the corresponding controls are censored at later times.

Consider the following set of low infant birth-weight data extracted from Appendix 1 of Hosmer and Lemeshow (1989). These data represent 189 women, of whom 59 had low-birth-weight babies and 130 had normal-weight babies. Under investigation are the following risk factors: weight in pounds at the last menstrual period (LWT), presence of hypertension (HT), smoking status during pregnancy (Smoke), and presence of uterine irritability (UI). For HT, Smoke, and UI, a value of 1 indicates a "yes" and a value of 0 indicates a "no." The woman's age (Age) is used as the matching variable. The SAS data set LBW contains

a subset of the data corresponding to women between the ages of 16 and 32.

```
data LBW;
   input id Age Low LWT Smoke HT UI @@;
   Time=2-Low;
   datalines;
 25  16   1   130   0  0  0    143  16   0   110   0  0  0

 ;
```

The variable Low is used to determine whether the subject is a case (Low=1, low-birth-weight baby) or a control (Low=0, normal-weight baby). The dummy time variable Time takes the value 1 for cases and 2 for controls.

The following statements produce a conditional logistic regression analysis of the data. The variable Time is the response, and Low is the censoring variable. Note that the data set is created so that all the cases have the same event time and the controls have later censored times. The matching variable Age is used in the STRATA statement so that each unique age value defines a stratum. The variables LWT, Smoke, HT, and UI are specified as explanatory variables. The TIES=DISCRETE option requests the discrete logistic model.

```
proc phreg data=LBW;
   model Time*Low(0)= LWT Smoke HT UI / ties=discrete;
   strata Age;
run;
```

The procedure displays a summary of the number of event and censored observations for each stratum. These are the number of cases and controls for each matched set shown in Output 66.5.1.

Output 66.5.1 Summary of Number of Case and Controls

The PHREG Procedure

Model Information

Data Set	WORK.LBW
Dependent Variable	Time
Censoring Variable	Low
Censoring Value(s)	0
Ties Handling	DISCRETE

Summary of the Number of Event and Censored Values

Stratum	Age	Total	Event	Censored	Percent Censored
1	16	7	1	6	85.71
2	17	12	5	7	58.33
3	18	10	2	8	80.00
4	19	16	3	13	81.25
5	20	18	8	10	55.56
6	21	12	5	7	58.33
7	22	13	2	11	84.62
8	23	13	5	8	61.54
9	24	13	5	8	61.54
10	25	15	6	9	60.00
11	26	8	4	4	50.00
12	27	3	2	1	33.33
13	28	9	2	7	77.78
14	29	7	1	6	85.71
15	30	7	1	6	85.71
16	31	5	1	4	80.00
17	32	6	1	5	83.33
Total		174	54	120	68.97

Results of the conditional logistic regression analysis are shown in Output 66.5.2. Based on the Wald test for individual variables, the variables LWT, Smoke, and HT are statistically significant while UI is marginal.

The hazard ratios, computed by exponentiating the parameter estimates, are useful in interpreting the results of the analysis. If the hazard ratio of a prognostic factor is larger than 1, an increment in the factor increases the hazard rate. If the hazard ratio is less than 1, an increment in the factor decreases the hazard rate. Results indicate that women were more likely to have low-birth-weight babies if they were underweight in the last menstrual cycle, were hypertensive, smoked during pregnancy, or suffered uterine irritability.

Output 66.5.2 Conditional Logistic Regression Analysis for the Low-Birth-Weight Study

Convergence Status

Convergence criterion (GCONV=1E-8) satisfied.

Output 66.5.2 *continued*

Analysis of Maximum Likelihood Estimates

Parameter	DF	Parameter Estimate	Standard Error	Chi-Square	Pr > ChiSq	Hazard Ratio
LWT	1	-0.01498	0.00706	4.5001	0.0339	0.985
Smoke	1	0.80805	0.36797	4.8221	0.0281	2.244
HT	1	1.75143	0.73932	5.6120	0.0178	5.763
UI	1	0.88341	0.48032	3.3827	0.0659	2.419

For matched case-control studies with one case per matched set (1:n matching), the likelihood function for the conditional logistic regression reduces to that of the Cox model for the continuous time scale. For this situation, you can use the default TIES=BRESLOW.

Example 66.6: Model Using Time-Dependent Explanatory Variables

Time-dependent variables can be used to model the effects of subjects transferring from one treatment group to another. One example of the need for such strategies is the Stanford heart transplant program. Patients are accepted if physicians judge them suitable for heart transplant. Then, when a donor becomes available, physicians choose transplant recipients according to various medical criteria. A patient's status can be changed during the study from waiting for a transplant to being a transplant recipient. Transplant status can be defined by the time-dependent covariate function $z = z(t)$ as

$$z(t) = \begin{cases} 0 & \text{if the patient has not received the transplant at time } t \\ 1 & \text{if the patient has received the transplant at time } t \end{cases}$$

The Stanford heart transplant data that appear in Crowley and Hu (1977) consist of 103 patients, 69 of whom received transplants. The data are saved in a SAS data set called Heart in the following DATA step. For each patient in the program, there is a birth date (Bir_Date), a date of acceptance (Acc_Date), and a date last seen (Ter_Date). The survival time (Time) in days is defined as Time = Ter_Date − Acc_Date. The survival time is said to be uncensored (Status=1) or censored (Status=0), depending on whether Ter_Date

is the date of death or the closing date of the study. The age, in years, at acceptance into the program is Acc_Age = (Acc_Date − Bir_Date) / 365. Previous open-heart surgery for each patient is indicated by the variable PrevSurg. For each transplant recipient, there is a date of transplant (Xpl_Date) and three measures (NMismatch, Antigen, Mismatch) of tissue-type mismatching. The waiting period (WaitTime) in days for a transplant recipient is calculated as WaitTime = Xpl_Date − Acc_Date, and the age (in years) at transplant is Xpl_Age = (Xpl_Date − Bir_Date) / 365. For those who do not receive heart transplants, the WaitTime, Xpl_Age, NMismatch, Antigen, and Mismatch variables contain missing values.

The input data contain dates that have a two-digit year representation. The SAS option YEARCUTOFF=1900 is specified to ensure that a two-digit year xx is year 19xx.

```
options yearcutoff=1900;
data Heart;

Crowley and Hu (1977) have presented a number of analyses to assess the effects of various explanatory variables on the survival of patients. This example fits two of the models that they have considered.

The first model consists of two explanatory variables—the transplant status and the age at acceptance. The transplant status (XStatus) is a time-dependent variable defined by the programming statements between the MODEL statement and the RUN statement. The XStatus variable takes the value 1 or 0 at time t (measured from the date of acceptance), depending on whether or not the patient has received a transplant at that time. Note that the value of XStatus changes for subjects in each risk set (subjects still alive just before each distinct event time); therefore, the variable cannot be created in the DATA step. The variable Acc_Age, which is not time dependent, accounts for the possibility that pretransplant risks vary with age. The following statements fit this model:

```
proc phreg data= Heart;
   model Time*Status(0)= XStatus Acc_Age;
   if (WaitTime = . or Time < WaitTime) then XStatus=0.;
   else  XStatus= 1.0;
run;
```

Results of this analysis are shown in Output 66.6.1. Transplantation appears to be associated with a slight decrease in risk, although the effect is not significant ($p = 0.8261$). The age at acceptance as a pretransplant risk factor adds significantly to the model ($p = 0.0289$). The risk increases significantly with age at acceptance.

Output 66.6.1 Heart Transplant Study Analysis I

The PHREG Procedure

Model Information

Likelihood Ratio	5.3593	2	0.0686
Score	4.8093	2	0.0903
Wald	4.7999	2	0.0907

Output 66.6.1 *continued*

Analysis of Maximum Likelihood Estimates

Parameter	DF	Parameter Estimate	Standard Error	Chi-Square	Pr > ChiSq	Hazard Ratio
XStatus	1	-0.06720	0.30594	0.0482	0.8261	0.935
Acc_Age	1	0.03158	0.01446	4.7711	0.0289	1.032

The second model consists of three explanatory variables—the transplant status, the transplant age, and the mismatch score. Four transplant recipients who were not typed have no Mismatch values; they are excluded from the analysis by the use of a WHERE clause. The transplant age (XAge) and the mismatch score (XScore) are also time dependent and are defined in a fashion similar to that of XStatus. While the patient is waiting for a transplant, XAge and XScore have a value of 0. After the patient has migrated to the recipient population, XAge takes on the value of Xpl_Age (transplant age for the recipient), and XScore takes on the value of Mismatch (a measure of the degree of dissimilarity between donor and recipient). The following statements fit this model:

```
proc phreg data= Heart;
   model Time*Status(0)= XStatus XAge XScore;
   where NotTyped ^= 'y';
   if (WaitTime = . or Time < WaitTime) then do;
      XStatus=0.;
      XAge=0.;
      XScore= 0.;
   end;
   else do;
      XStatus= 1.0;
      XAge= Xpl_Age;
      XScore= Mismatch;
   end;
run;
```

Results of the analysis are shown in Output 66.6.2. Note that only 99 patients are included in this analysis, instead of 103 patients as in the previous analysis, since four transplant recipients who were not typed are excluded. The variable XAge is statistically significant ($p = 0.0143$), with a hazard ratio exceeding 1. Therefore, patients who had a transplant at younger ages lived longer than those who received a transplant later in their lives. The variable XScore has only minimal effect on the survival ($p = 0.1121$).

Example 66.7: Time-Dependent Repeated Measurements of a Covariate

Repeated determinations can be made during the course of a study of variables thought to be related to survival. Consider an experiment to study the dosing effect of a tumor-promoting agent. Forty-five rodents initially exposed to a carcinogen were randomly assigned to three dose groups. After the first death of an animal, the rodents were examined every week for the number of papillomas. Investigators were interested in determining the effects of dose on the carcinoma incidence after adjusting for the number of papillomas.

The input data set TUMOR consists of the following 19 variables:

- ID (subject identification)
- Time (survival time of the subject)
- Dead (censoring status where 1=dead and 0=censored)
- Dose (dose of the tumor-promoting agent)
- P1–P15 (number of papillomas at the 15 times that animals died. These 15 death times are weeks 27, 34, 37, 41, 43, 45, 46, 47, 49, 50, 51, 53, 65, 67, and 71. For instance, subject 1 died at week 47; it had no papilloma at week 27, five papillomas at week 34, six at week 37, eight at week 41, and 10 at weeks 43, 45, 46, and 47. For an animal that died before week 71, the number of papillomas is missing for those times beyond its death.)

The following SAS statements create the data set TUMOR:

```
data Tumor;
   infile datalines missover;
   input ID Time Dead Dose P1-P15;
   label ID='Subject ID';
   datalines;
 1 47 1  1.0  0  5  6  8 10 10 10 10

The number of papillomas (NPap) for each animal in the study was measured repeatedly over time. One way of handling time-dependent repeated measurements in the PHREG procedure is to use programming statements to capture the appropriate covariate values of the subjects in each risk set. In this example, NPap is a time-dependent explanatory variable with values that are calculated by means of the programming statements shown in the following SAS statements:

```
proc phreg data=Tumor;
   model Time*Dead(0)=Dose NPap;
   array pp{*} P1-P14;
   array tt{*} t1-t15;
    t1=27;  t2=34;  t3=37;  t4=41;  t5=43;
    t6=45;  t7=46;  t8=47;  t9=49; t10=50;
   t11=51; t12=53; t13=65; t14=67; t15=71;
   if Time <  tt[1]  then NPap=0;
   else if time >= tt[15] then NPap=P15;
   else do i=1 to dim(pp);
      if tt[i] <= Time < tt[i+1] then NPap= pp[i];
   end;
run;
```

At each death time, the NPap value of each subject in the risk set is recalculated to reflect the actual number of papillomas at the given death time. For instance, subject one in the data set Tumor was in the risk sets at weeks 27 and 34; at week 27, the animal had no papilloma, while at week 34, it had five papillomas. Results of the analysis are shown in Output 66.7.1. After the number of papillomas is adjusted for, the dose effect of the tumor-promoting agent is not statistically significant.

Output 66.7.1 Cox Regression Analysis on the Survival of Rodents

NPap	1	0.11714	0.02998	15.2705	<.0001	1.124

Another way to handle time-dependent repeated measurements in the PHREG procedure is to use the counting process style of input. Multiple records are created for each subject, one record for each distinct pattern of the time-dependent measurements. Each record contains a T1 value and a T2 value representing the time interval (T1,T2] during which the values of the explanatory variables remain unchanged. Each record also contains the censoring status at T2.

One advantage of using the counting process formulation is that you can easily obtain various residuals and influence statistics that are not available when programming statements are used to compute the values of the time-dependent variables. On the other hand, creating multiple records for the counting process formulation requires extra effort in data manipulation.

Consider a counting process style of input data set named Tumor1. It contains multiple observations for each subject in the data set Tumor. In addition to variables ID, Time, Dead, and Dose, four new variables are generated:

- T1 (left endpoint of the risk interval)
- T2 (right endpoint of the risk interval)
- NPap (number of papillomas in the time interval (T1,T2])
- Status (censoring status at T2)

For example, five observations are generated for the rodent that died at week 47 and that had no papilloma at week 27, five papillomas at week 34, six at week 37, eight at week 41, and 10 at weeks 43, 45, 46, and 47. The values of T1, T2, NPap, and Status for these five observations are (0,27,0,0), (27,34,5,0), (34,37,6,0), (37,41,8,0), and (41,47,10,1). Note that the variables ID, Time, and Dead are not needed for the estimation of the regression parameters, but they are useful for plotting the residuals.

The following SAS statements create the data set Tumor1:

```
data Tumor1(keep=ID Time Dead Dose T1 T2 NPap Status);
   array pp{*} P1-P14;
   array qq{*} P2-P15;
   array tt{1:15} _temporary_
      (27 34 37 41 43 45 46 47 49 50 51 53 65 67 71);
   set Tumor;
   T1 = 0;
   T2 = 0;
   Status = 0;
   if ( Time = tt[1] ) then do;
      T2 = tt[1];
      NPap = p1;
      Status = Dead;
      output;
   end;
   else do _i_=1 to dim(pp);
      if ( tt[_i_] = Time ) then do;
         T2= Time;
         NPap = pp[_i_] ;
         Status = Dead;
         output;
      end;
      else if (tt[_i_]  < Time ) then do;
         if (pp[_i_]  ^= qq[_i_] ) then do;
            if qq[_i_]  = . then T2= Time;
            else                 T2= tt[_i_] ;
            NPap= pp[_i_] ;
            Status= 0;
            output;
            T1 = T2;
         end;
      end;
   end;
```

```
      if ( Time >= tt[15] ) then do;
         T2 = Time;
         NPap = P15;
         Status = Dead;
         output;
      end;
      run;
```

In the following SAS statements, the counting process MODEL specification is used. The DFBETA statistics are output to a SAS data set named Out1. Note that Out1 contains multiple observations for each subject—that is, one observation for each risk interval (T1,T2].

```
proc phreg data=Tumor1;
   model (T1,T2)*Status(0)=Dose NPap;
   output out=Out1 resmart=Mart dfbeta=db1-db2;
   id ID Time Dead;
run;
```

The output from PROC PHREG (not shown) is identical to Output 66.7.1 except for the "Summary of the Number of Event and Censored Values" table. The number of event observations remains unchanged between the two specifications of PROC PHREG, but the number of censored observations differs due to the splitting of each subject's data into multiple observations for the counting process style of input.

Next, the MEANS procedure sums up the component statistics for each subject and outputs the results to a SAS data set named Out2:

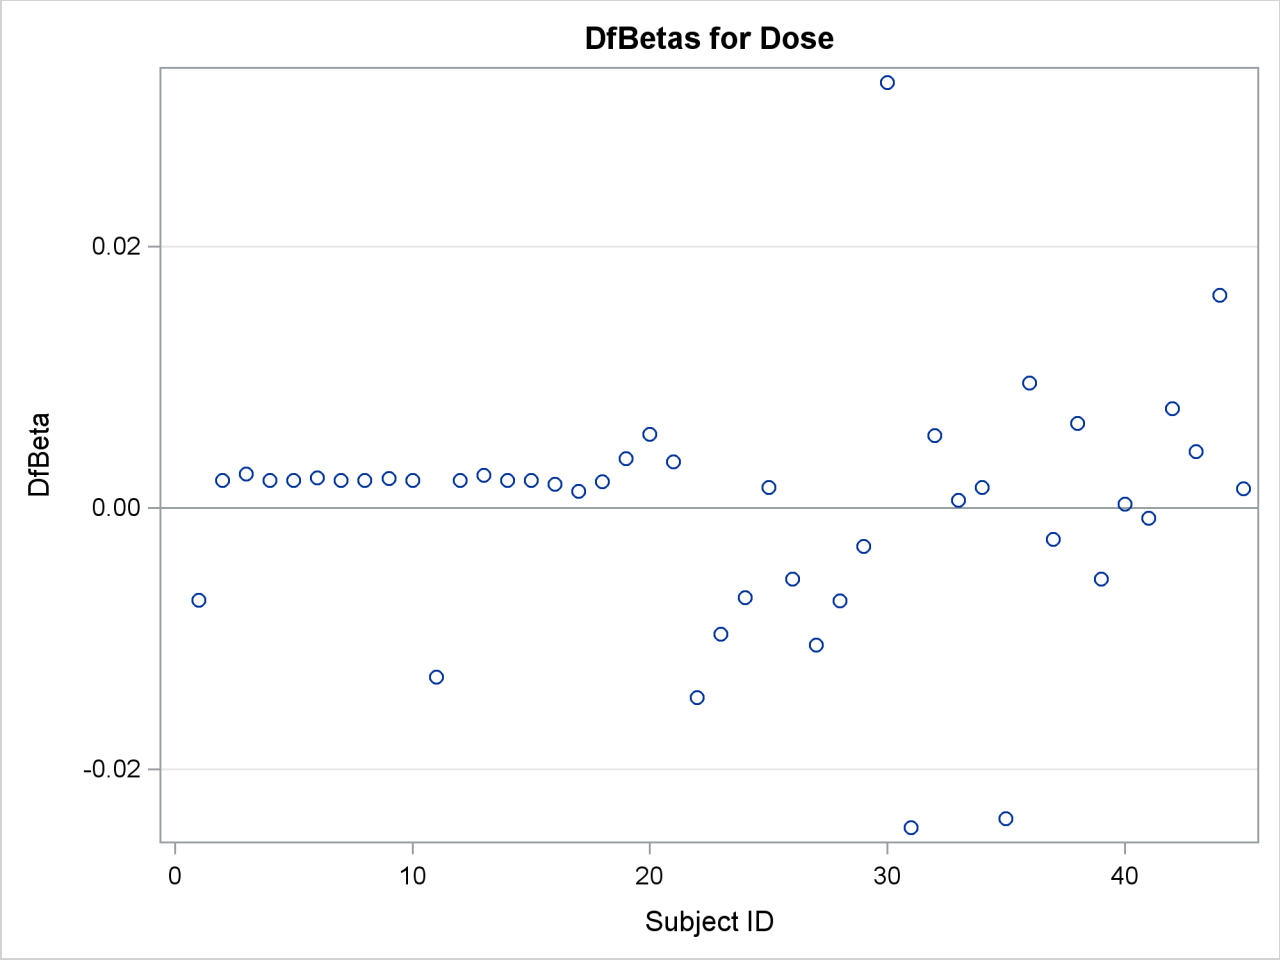
```
proc means data=Out1 noprint;
   by ID Time Dead;
   var Mart db1-db2;
   output out=Out2 sum=Mart db_Dose db_NPap;
run;
```

Finally, DFBETA statistics are plotted against subject ID for easy identification of influential points:

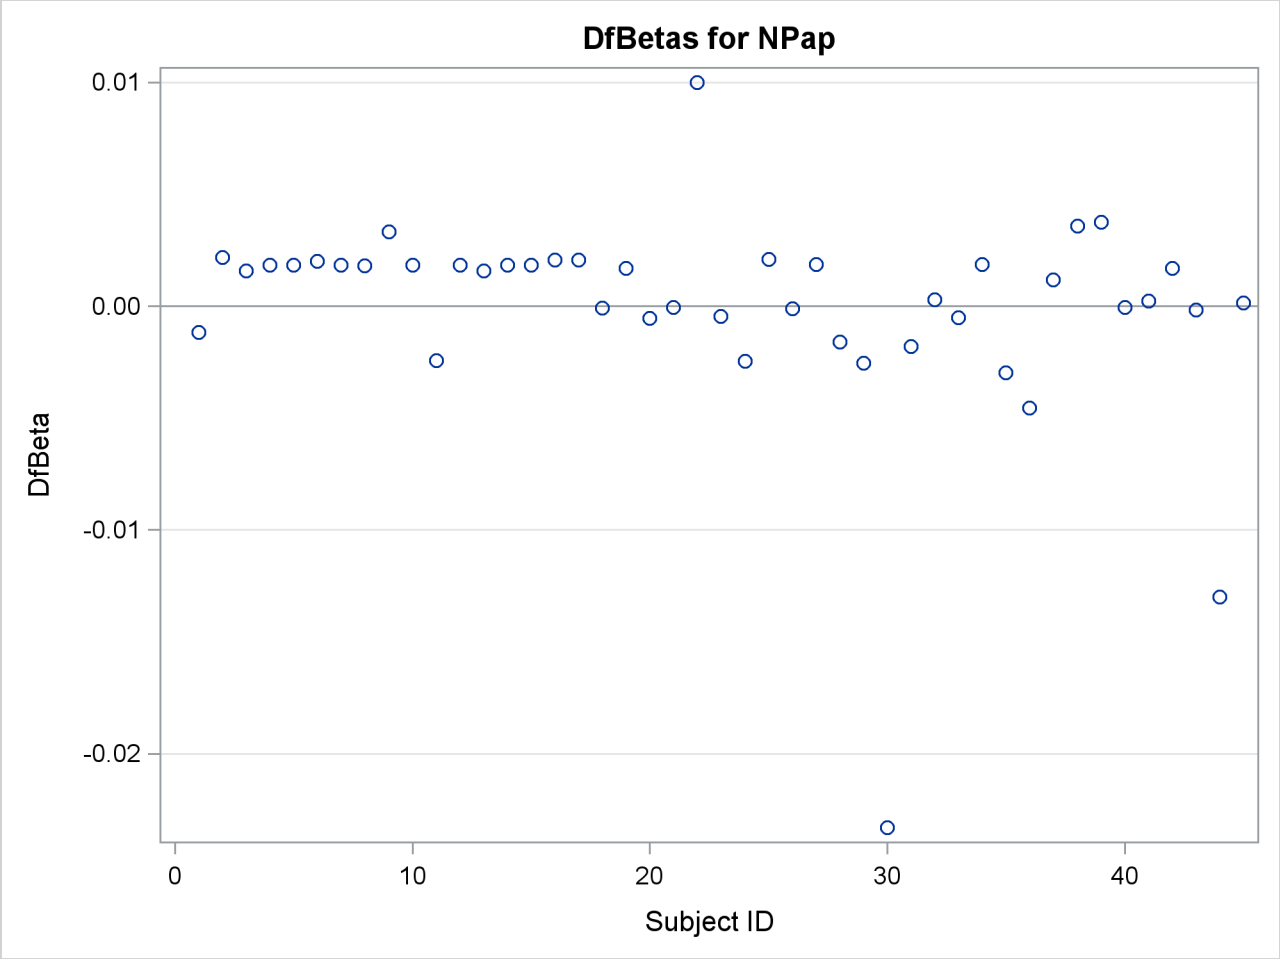
```
title 'DfBetas for Dose';
proc sgplot data=Out2;
   yaxis label="DfBeta" grid;
   refline 0 / axis=y;
   scatter y=db_Dose x=ID;
   run;
title 'DfBetas for NPap';
proc sgplot data=Out2;
   yaxis label="DfBeta" grid;
   refline 0 / axis=y;
   scatter y=db_NPap x=ID;
   run;
```

The plots of the DFBETA statistics are shown in Output 66.7.2 and Output 66.7.3. Subject 30 appears to have a large influence on both the Dose and NPap coefficients. Subjects 31 and 35 have considerable influences on the DOSE coefficient, while subjects 22 and 44 have rather large influences on the NPap coefficient.

Output 66.7.2 Plot of DFBETA Statistic for DOSE versus Subject Number



Output 66.7.3 Plot of DFBETA Statistic for NPAP versus Subject Number



Example 66.8: Survivor Function Estimates for Specific Covariate Values

You might want to use your regression analysis results to generate predicted survival curves for subjects not in the study. The COVARIATES= data set in the BASELINE statement enables you to specify the sets of covariate values for the prediction. By using the PLOTS= option in the PROC PHREG statement, you can display a survival curve for each row of covariates in the COVARIATES= data set. You can elect to output the predicted survival curves in a SAS data set by using just the BASELINE statement. This example illustrates these two tasks by using the Myeloma data in Example 66.1.

In Example 66.1, variables LogBUN and HGB were identified as the most important prognostic factors for the myeloma data. Two sets of covariates for predicting the survivor function are saved in the data set Inrisks in the following DATA step. Also created in this data set is the variable Id, whose values will be used in identifying the covariate sets in the survival plot.

```
data Inrisks;
   length Id $20;
   input LogBUN HGB Id $12-31;
   datalines;
1.00 10.0  logBUN=1.0 HGB=10
1.80 12.0  logBUN=1.8 HGB=12
;
```

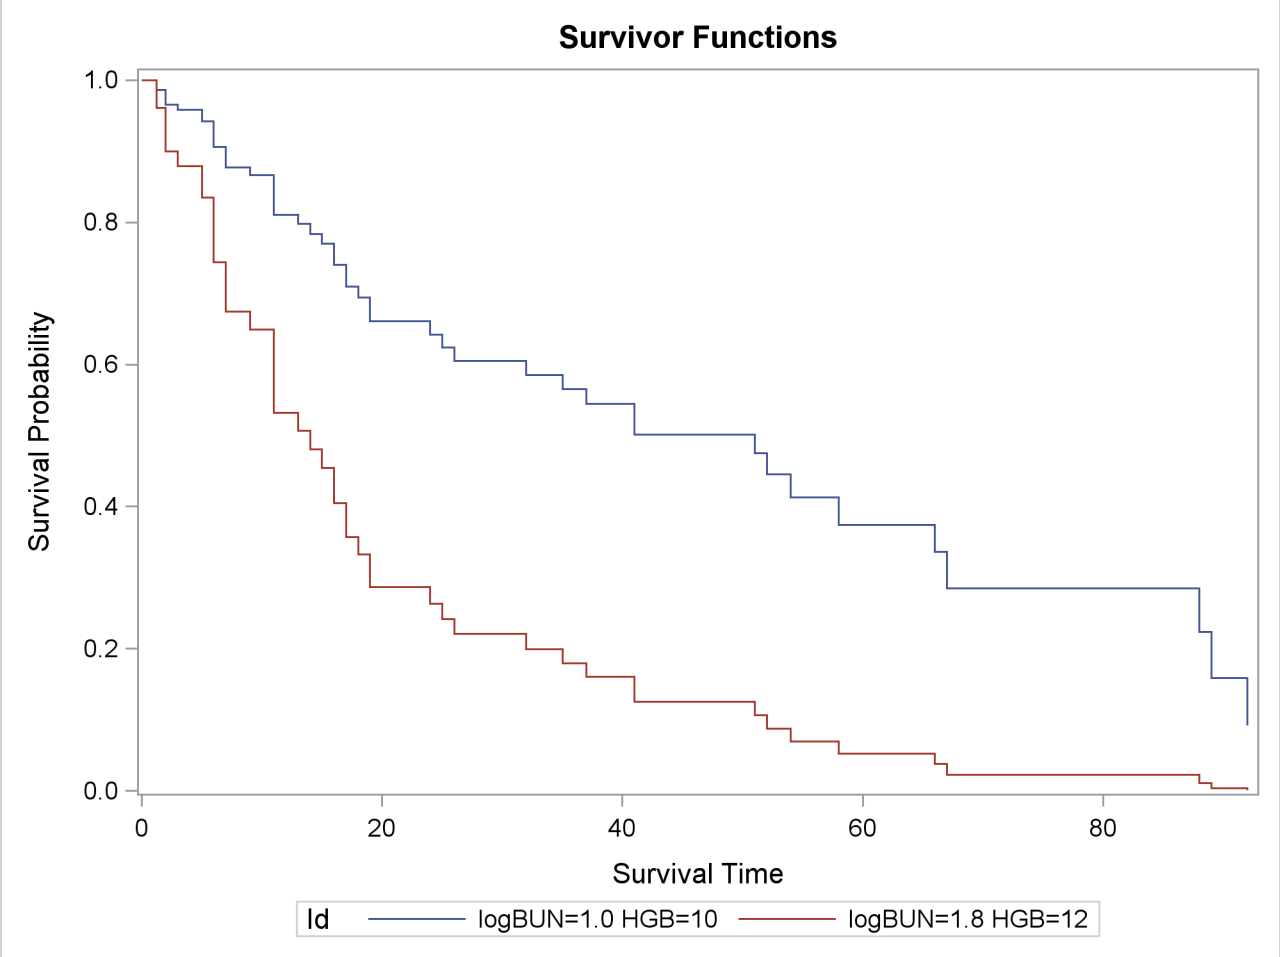
The following statements produce the plot in Output 66.8.1 and create the BASELINE data set Pred1:

```
ods graphics on;
proc phreg data=Myeloma plots(overlay)=survival;
   model Time*VStatus(0)=LogBUN HGB;
   baseline covariates=Inrisks out=Pred1 survival=_all_ / rowid=Id;
run;
ods graphics off;
```

The COVARIATES= option in the BASELINE statement specifies the data set that contains the set of covariates of interest. The PLOTS= option in the PROC PHREG statement creates the survivor plot. The OVERLAY suboption overlays the two curves in the same plot. If the OVERLAY suboption is not specified, each curve is displayed in a separate plot. The ROWID= option in the BASELINE statement specifies that the values of the variable Id in the COVARIATES= data set be used to identify the curves in the plot. The SURVIVAL=_ALL_ option in the BASELINE statement requests that the estimated survivor function, standard error, and lower and upper confidence limits for the survivor function be output into the SAS data set specified in the OUT= option.

The survival Plot (Output 66.8.1) contains two curves, one for each of row of covariates in the data set Inrisks.

Output 66.8.1 Estimated Survivor Function Plot



Finally, PROC PRINT is used to print out the observations in the data set Pred1 for the realization LogBUN=1.00 and HGB=10.0:

```
proc print data=Pred1(where=(logBUN=1 and HGB=10));
run;
```

As shown in Output 66.8.2, there are 32 observations representing the survivor function for the realization LogBUN=1.00 and HGB=10.0. The first observation has survival time 0 and survivor function estimate 1.0. Each of the remaining 31 observations represents a distinct event time in the input data set Myeloma. These observations are presented in ascending order of the event times. Note that all the variables in the COVARIATE=lnRisks data set are included in the OUT=Pred1 data set. Likewise, you can print out the observations that represent the survivor function for the realization LogBUN=1.80 and HGB=12.0.

Output 66.8.2 Survivor Function Estimates for LogBUN=1.0 and HGB=10.0

Example 66.9: Analysis of Residuals

Residuals are used to investigate the lack of fit of a model to a given subject. You can obtain martingale and deviance residuals for the Cox proportional hazards regression analysis by requesting that they be included in the OUTPUT data set. You can plot these statistics and look for outliers.

Consider the stepwise regression analysis performed in Example 66.1. The final model included variables LogBUN and HGB. You can generate residual statistics for this analysis by refitting the model containing those variables and including an OUTPUT statement as in the following invocation of PROC PHREG. The keywords XBETA, RESMART, and RESDEV identify new variables that contain the linear predictor scores $\mathbf{z}'_j\hat{\boldsymbol{\beta}}$, martingale residuals, and deviance residuals. These variables are xb, mart, and dev, respectively.

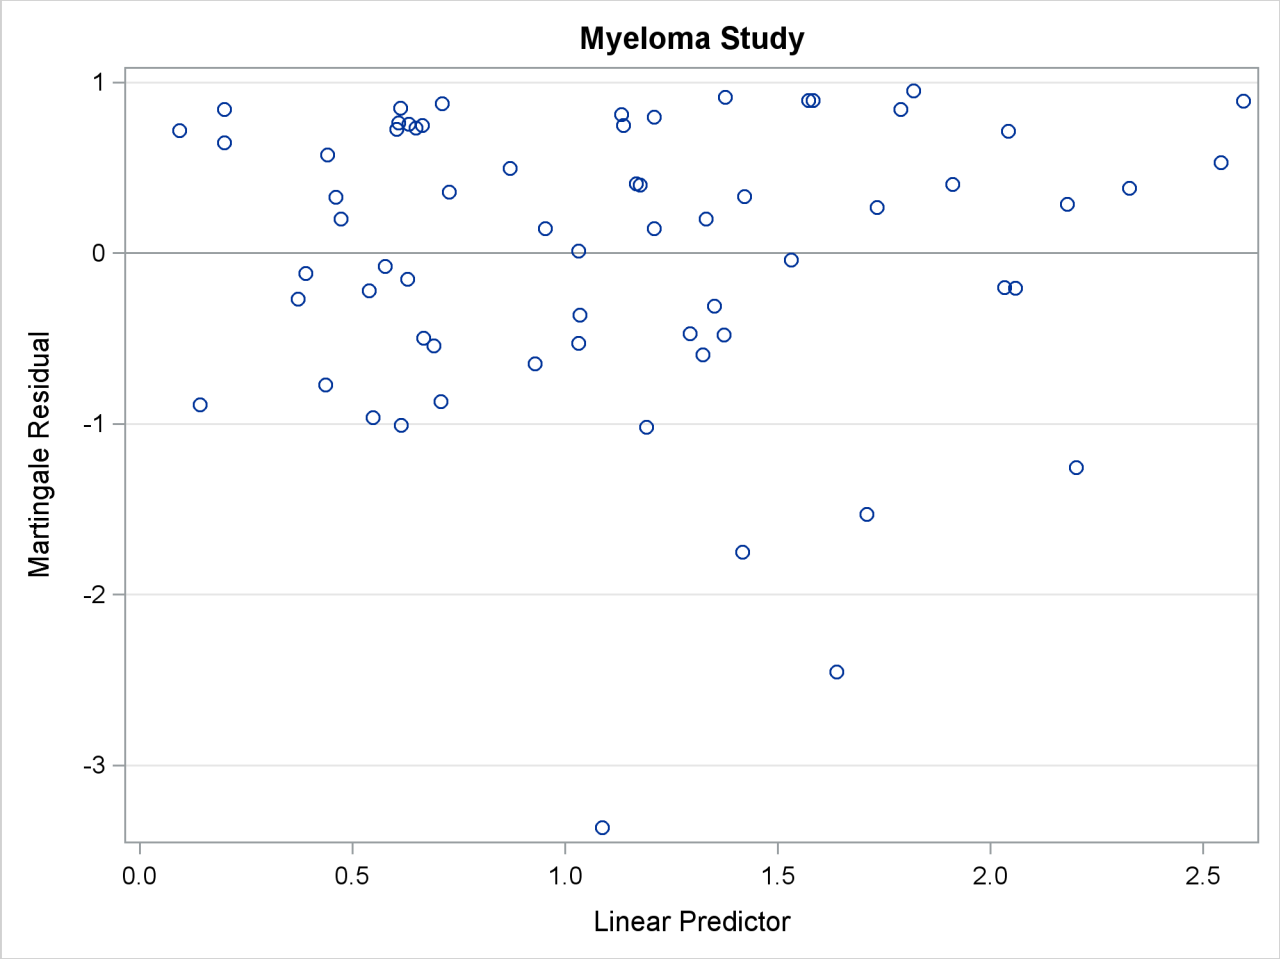
```
proc phreg data=Myeloma noprint;
   model Time*Vstatus(0)=LogBUN HGB;
   output out=Outp xbeta=Xb resmart=Mart resdev=Dev;
run;
```

The following statements plot the residuals against the linear predictor scores:

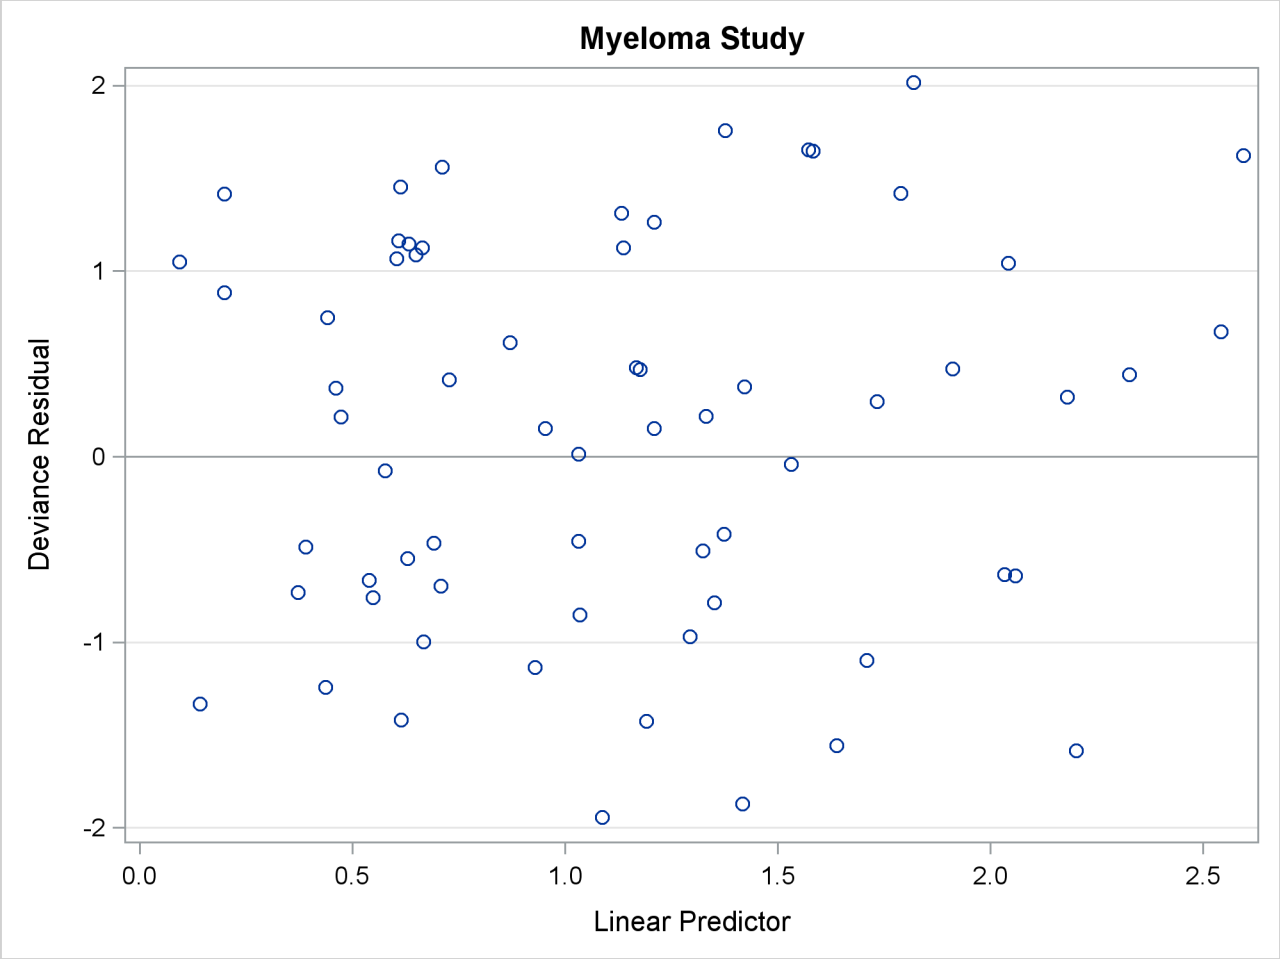
```
title "Myeloma Study";
proc sgplot data=Outp;
   yaxis grid;
   refline 0 / axis=y;
   scatter y=Mart x=Xb;
   run;
proc sgplot data=Outp;
   yaxis grid;
   refline 0 / axis=y;
   scatter y=Dev x=Xb;
   run;
```

The resulting plots are shown in Output 66.9.1 and Output 66.9.2. The martingale residuals are skewed because of the single event setting of the Cox model. The martingale residual plot shows an isolation point (with linear predictor score 1.09 and martingale residual −3.37), but this observation is no longer distinguishable in the deviance residual plot. In conclusion, there is no indication of a lack of fit of the model to individual observations.

Output 66.9.1 Martingale Residual Plot



Output 66.9.2 Deviance Residual Plot



Example 66.10: Analysis of Recurrent Events Data

Recurrent events data consist of times to a number of repeated events for each sample unit—for example, times of recurrent episodes of a disease in patients. Various ways of analyzing recurrent events data are described in the section "Analysis of Multivariate Failure Time Data" on page 5453. The bladder cancer data listed in Wei, Lin, and Weissfeld (1989) are used here to illustrate these methods.

The data consist of 86 patients with superficial bladder tumors, which were removed when the patients entered the study. Of these patients, 48 were randomized into the placebo group, and 38 were randomized into the group receiving thiotepa. Many patients had multiple recurrences of tumors during the study, and new tumors were removed at each visit. The data set contains the first four recurrences of the tumor for each patient, and each recurrence time was measured from the patient's entry time into the study.

The data consist of the following eight variables:

- Trt, treatment group (1=placebo and 2=thiotepa)
- Time, follow-up time
- Number, number of initial tumors
- Size, initial tumor size
- T1, T2, T3, and T4, times of the four potential recurrences of the bladder tumor. A patient with only two recurrences has missing values in T3 and T4.

In the data set Bladder, four observations are created for each patient, one for each of the four potential tumor recurrences. In addition to values of Trt, Number, and Size for the patient, each observation contains the following variables:

- ID, patient's identification (which is the sequence number of the subject)
- Visit, visit number (with value k for the kth potential tumor recurrence)
- TStart, time of the $(k-1)$th recurrence for Visit=k, or the entry time 0 if VISIT=1, or the follow-up time if the $(k-1)$th recurrence does not occur
- TStop, time of the kth recurrence if Visit=k or follow-up time if the kth recurrence does not occur
- Status, event status of TStop (1=recurrence and 0=censored)

For instance, a patient with only one recurrence time at month 6 who was followed until month 10 will have values for Visit, TStart, TStop, and Status of (1,0,6,1), (2,6,10,0), (3,10,10,0), and (4,10,10,0), respectively. The last two observations are redundant for the intensity model and the proportional means model, but they are important for the analysis of the marginal Cox models. If the follow-up time is beyond the time of the fourth tumor recurrence, it is tempting to create a fifth observation with the time of the fourth tumor recurrence as the TStart value, the follow-up time as the TStop value, and a Status value of 0. However, Therneau and Grambsch (2000, Section 8.5) have warned against incorporating such observations into the analysis.

The following SAS statements create the data set Bladder:

```
data Bladder;
   keep ID TStart TStop Status Trt Number Size Visit;
   retain ID TStart 0;
   array tt T1-T4;
   infile datalines missover;
   input Trt Time Number Size T1-T4;
   ID + 1;
   TStart=0;
   do over tt;
      Visit=_i_;
      if tt = . then do;
         TStop=Time;
```

```
         Status=0;
      end;
      else do;
         TStop=tt;
         Status=1;
      end;
      output;
      TStart=TStop;
   end;
   if (TStart < Time) then delete;
   datalines;

First, consider fitting the intensity model (Andersen and Gill 1982) and the proportional means model (Lin et al. 2000). The counting process style of input is used in the PROC PHREG specification. For the proportional means model, inference is based on the robust sandwich covariance estimate, which is requested by the COVB(AGGREGATE) option in the PROC PHREG statement. The COVM option is specified for the analysis of the intensity model to use the model-based covariance estimate. Note that some of the observations in the data set Bladder have a degenerated interval of risk. The presence of these observations does not affect the results of the analysis since none of these observations are included in any of the risk sets. However, the procedure will run more efficiently without these observations; consequently,

in the following SAS statements, the WHERE clause is used to eliminate these redundant observations:

```
title 'Intensity Model and Proportional Means Model';
proc phreg data=Bladder covm covs(aggregate);
   model (TStart, TStop) * Status(0) = Trt Number Size;
   id id;
   where TStart < TStop;
run;
```

Results of fitting the intensity model and the proportional means model are shown in Output 66.10.1 and Output 66.10.2, respectively. The robust sandwich standard error estimate for Trt is larger than its model-based counterpart, rendering the effect of thiotepa less significant in the proportional means model (p=0.0747) than in the intensity model (p=0.0215).

Next, consider the conditional models of Prentice, Williams, and Peterson (1981). In the PWP models, the risk set for the (k+1)th recurrence is restricted to those patients who have experienced the first k recurrences. For example, a patient who experienced only one recurrence is an event observation for the first recurrence; this patient is a censored observation for the second recurrence and should not be included in the risk set for the third or fourth recurrence. The following DATA step eliminates those observations that should not be in the risk sets, forming a new input data set (named Bladder2) for fitting the PWP models. The variable Gaptime, representing the gap times between successive recurrences, is also created.

```
data Bladder2(drop=LastStatus);
    retain LastStatus;
    set Bladder;
    by ID;
    if first.id then LastStatus=1;
    if (Status=0 and LastStatus=0) then delete;
    LastStatus=Status;
    Gaptime=Tstop-Tstart;
run;
```

The following statements fit the PWP total time model. The variables Trt1, Trt2, Trt3, and Trt4 are visit-specific variables for Trt; the variables Number1, Number2, Numvber3, and Number4 are visit-specific variables for Number; and the variables Size1, Size2, Size3, and Size4 are visit-specific variables for Size.

```
title 'PWP Total Time Model with Noncommon Effects';
proc phreg data=Bladder2;
   model (TStart,Tstop) * Status(0) = Trt1-Trt4 Number1-Number4
                                      Size1-Size4;
   Trt1= Trt * (Visit=1);
   Trt2= Trt * (Visit=2);
   Trt3= Trt * (Visit=3);
   Trt4= Trt * (Visit=4);
   Number1= Number * (Visit=1);
   Number2= Number * (Visit=2);
   Number3= Number * (Visit=3);
   Number4= Number * (Visit=4);
   Size1= Size * (Visit=1);
   Size2= Size * (Visit=2);
   Size3= Size * (Visit=3);
   Size4= Size * (Visit=4);
   strata Visit;
run;
```

Results of the analysis of the PWP total time model are shown in Output 66.10.3. There is no significant treatment effect on the total time in any of the four tumor recurrences.

Output 66.10.3 Analysis of the PWP Total Time Model with Noncommon Effects

PWP Total Time Model with Noncommon Effects

You can fit the PWP total time model with common effects by using the following SAS statements. However, the analysis is not shown here.

```
title2 'PWP Total Time Model with Common Effects';
proc phreg data=Bladder2;
   model (tstart,tstop) * status(0) = Trt Number Size;
   strata Visit;
run;
```

You can fit the PWP gap-time model with common effects by using the following statements. Again, the analysis is not shown here.

```
title2 'PWP Gap Time Model with Common Effects';
proc phreg data=Bladder2;
   model Gaptime * Status(0) = Trt Number Size;
   strata Visit;
run;
```

Recurrent events data are a special case of multiple events data in which the recurrence times are regarded as multivariate failure times and the marginal approach of Wei, Lin, and Weissfeld (1989) can be used. WLW fits a Cox model to each of the component times and makes statistical inference of the regression parameters based on a robust sandwich covariance matrix estimate. No specific correlation structure is imposed on the multivariate failure times. For the kth marginal model, let $\boldsymbol{\beta}_k$ denote the row vector of regression parameters, let $\hat{\boldsymbol{\beta}}_k$ denote the maximum likelihood estimate of $\boldsymbol{\beta}_k$, let $\hat{\mathbf{A}}_k$ denote the covariance matrix obtained by inverting the observed information matrix, and let $\mathbf{R}_k$ denote the matrix of score residuals. WLW showed that the joint distribution of $(\hat{\boldsymbol{\beta}}_1, \ldots, \hat{\boldsymbol{\beta}}_4)'$ can be approximated by a multivariate normal distribution with

mean vector $(\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_4)'$ and robust covariance matrix

$$\begin{pmatrix} \mathbf{V}_{11} & \mathbf{V}_{12} & \mathbf{V}_{13} & \mathbf{V}_{14} \\ \mathbf{V}_{21} & \mathbf{V}_{22} & \mathbf{V}_{23} & \mathbf{V}_{24} \\ \mathbf{V}_{31} & \mathbf{V}_{32} & \mathbf{V}_{33} & \mathbf{V}_{34} \\ \mathbf{V}_{41} & \mathbf{V}_{42} & \mathbf{V}_{43} & \mathbf{V}_{44} \end{pmatrix}$$

with the submatrix $\mathbf{V}_{ij}$ given by

$$\mathbf{V}_{ij} = \hat{\mathbf{A}}_i (\mathbf{R}_i' \mathbf{R}_j) \hat{\mathbf{A}}_j$$

In this example, there are four marginal proportional hazards models, one for each potential recurrence time. Instead of fitting one model at a time, you can fit all four marginal models in one analysis by using the STRATA statement and model-specific covariates as in the following statements. Using Visit as the STRATA variable on the input data set Bladder, PROC PHREG simultaneously fits all four marginal models, one for each Visit value. The COVS(AGGREGATE) option is specified to compute the robust sandwich variance estimate by summing up the score residuals for each distinct pattern of ID value. The TEST statement TREATMENT is used to perform the global test of no treatment effect for each tumor recurrence, the AVERAGE option is specified to estimate the parameter for the common treatment effect, and the E option displays the optimal weights for the common treatment effect.

```
title 'Wei-Lin-Weissfeld Model';
proc phreg data=Bladder covs(aggregate);
   model TStop*Status(0)=Trt1-Trt4 Number1-Number4 Size1-Size4;
   Trt1= Trt * (Visit=1);
   Trt2= Trt * (Visit=2);
   Trt3= Trt * (Visit=3);
   Trt4= Trt * (Visit=4);
   Number1= Number * (Visit=1);
   Number2= Number * (Visit=2);
   Number3= Number * (Visit=3);
   Number4= Number * (Visit=4);
   Size1= Size * (Visit=1);
   Size2= Size * (Visit=2);
   Size3= Size * (Visit=3);
   Size4= Size * (Visit=4);
   strata Visit;
   id ID;
   TREATMENT: test trt1,trt2,trt3,trt4/average e;
   run;
```

Out of the 86 patients, 47 patients have only one tumor recurrence, 29 patients have two recurrences, 22 patients have three recurrences, and 14 patients have four recurrences (Output 66.10.5). Parameter estimates for the four marginal models are shown in Output 66.10.6. The 4 DF Wald test (Output 66.10.7) indicates a lack of evidence of a treatment effect in any of the four recurrences (p=0.4105). The optimal weights for estimating the parameter of the common treatment effect are 0.67684, 0.25723, –0.07547, and 0.14140 for Trt1, Trt2, Trt3, and Trt4, respectively, which gives a parameter estimate of –0.5489 with a standard error estimate of 0.2853. A more sensitive test for a treatment effect is the 1 DF test based on this common parameter; however, there is still insufficient evidence for such effect at the 0.05 level (p=0.0543).

Example 66.11: Analysis of Clustered Data

When experimental units are naturally or artificially clustered, failure times of experimental units within a cluster are correlated. Two approaches can be taken to adjust for the intracluster correlation. In the marginal Cox model approach, Lee, Wei, and Amato (1992) estimate the regression parameters in the Cox model by the maximum partial likelihood estimates under an independent working assumption and use a robust sandwich covariance matrix estimate to account for the intracluster dependence. Lin (1994) illustrates this methodology by using a subset of data from the Diabetic Retinopathy Study (DRS). An alternative approach to account for the within-cluster correlation is to use a shared frailty model where cluster effects are incorporated into the model as independent and identically distributed random variables.

The following DATA step creates the data set Blind that represents 197 diabetic patients who have a high risk of experiencing blindness in both eyes as defined by DRS criteria. One eye of each patient is treated with laser photocoagulation. The hypothesis of interest is whether the laser treatment delays the occurrence of blindness. Since juvenile and adult diabetes have very different courses, it is also desirable to examine how the age of onset of diabetes might affect the time of blindness. Since there are no biological differences between the left eye and the right eye, it is natural to assume a common baseline hazard function for the failure times of the left and right eyes.

Each patient is a cluster that contributes two observations to the input data set, one for each eye. The following variables are in the input data set Blind:

- ID, patient's identification
- Time, time to blindness
- Status, blindness indicator (0:censored and 1:blind)
- Treat, treatment received (Laser or Others)
- Type, type of diabetes (Juvenile: onset at age ≤ 20 or Adult: onset at age > 20)

```
proc format;
   value type 0='Juvenile' 1='Adult';
   value Rx  1='Laser' 0='Others';
   run;

data Blind;
   input ID Time Status dty trt @@;
   Type= put(dty, type.);
   Treat= put(trt, Rx.);

1749 41.93 0 1 1 1749 41.93 0 1 0
;
```

As a preliminary analysis, PROC FREQ is used to summarize the number of eyes that developed blindness.

```
proc freq data=Blind;
   table Treat*Status;
   run;
```

By the end of the study, 54 eyes treated with laser photocoagulation and 101 eyes treated by other means have developed blindness (Output 66.11.1).

Output 66.11.1 Distribution of Blindness

The FREQ Procedure

Table of Treat by Status

Treat	Status		
Frequency / Percent / Row Pct / Col Pct	0	1	Total
Laser	143 36.29 72.59 59.83	54 13.71 27.41 34.84	197 50.00
Others	96 24.37 48.73 40.17	101 25.63 51.27 65.16	197 50.00
Total	239 60.66	155 39.34	394 100.00

The following statements use PROC PHREG to carry out the analysis of Lee, Wei, and Amato (1992). The explanatory variables in this Cox model are Treat, Type, and the Treat × Type interaction. The COVS(AGGREGATE) option is specified to compute the robust sandwich covariance matrix estimate. The ID statement identifies the variable that represents the clusters. The HAZARDRATIO statement requests hazard ratios for the treatments be displayed.

```
proc phreg data=Blind covs(aggregate);
   class Treat Type;
   model Time*Status(0)=Treat|Type;
   id ID;
   hazardratio 'Marginal Model Analysis' Treat;
   run;
```

Results of the marginal model analysis are displayed in Output 66.11.2. The robust standard error estimates are smaller than the model-based counterparts, since the ratio of the robust standard error estimate relative to the model-based estimate is less than 1 for each parameter. Laser photocoagulation appears to be effective (p=0.0217) in delaying the occurrence of blindness, although there is also a significant interaction effect between treatment and type of diabetes (p=0.0053).

Output 66.11.2 Inference Based the Marginal Model

The PHREG Procedure

Analysis of Maximum Likelihood Estimates

Parameter			DF	Parameter Estimate	Standard Error	StdErr Ratio	Chi-Square
Treat	Laser		1	-0.42467	0.18497	0.850	5.2713
Type	Adult		1	0.34084	0.19558	0.982	3.0371
Treat*Type	Laser	Adult	1	-0.84566	0.30353	0.865	7.7622

Analysis of Maximum Likelihood Estimates

Parameter			Pr > ChiSq	Hazard Ratio	Label
Treat	Laser		0.0217	.	Treat Laser
Type	Adult		0.0814	.	Type Adult
Treat*Type	Laser	Adult	0.0053	.	Treat Laser * Type Adult

Hazard ratio estimates of the laser treatment relative to nonlaser treatment are displayed in Output 66.11.3. For both types of diabetes, the 95% confidence interval for the hazard ratio lies below 1. This indicates that laser-photocoagulation treatment is more effective in delaying blindless regardless of the type of diabetes. However, the effect is more prominent for adult-onset diabetes than for juvenile-onset diabetes since the hazard ratio estimates for the former are less than those of the latter.

Output 66.11.3 Hazard Ratio Estimates for Marginal Model

Marginal Model Analysis: Hazard Ratios for Treat

Description	Point Estimate	95% Wald Robust Confidence Limits	
Treat Laser vs Others At Type=Adult	0.281	0.175	0.451
Treat Laser vs Others At Type=Juvenile	0.654	0.455	0.940

Next, you analyze the same data by using a shared frailty model. The following statements use PROC PHREG to fit a shared frailty model to the Blind data set. The RANDOM statement identifies the variable ID as the variable that represents the clusters. You must declare the cluster variable as a classification variable in the CLASS statement.

```
proc phreg data=Blind;
   class ID Treat Type;
   model Time*Status(0)=Treat|Type;
   random ID;
   hazardratio 'Frailty Model Analysis' Treat;
   run;
```

Selected results of this analysis are displayed in Output 66.11.4 to Output 66.11.6.

The "Random Class Level Information" table in Output 66.11.4 displays the 197 ID values of the patients. You can suppress the display of this table by using the NOCLPRINT option in the RANDOM statement.

Output 66.11.4 Unique Cluster Identification Values

The PHREG Procedure

Class Level Information for Random Effects

Class	Levels	Values

Type	Adult		.	Type Adult
Treat*Type	Laser	Adult	.	Treat Laser * Type Adult

Estimates of hazard ratios of the laser treatment relative to nonlaser treatment are displayed in Output 66.11.7. These estimates closely resemble those computed in analysis based on the marginal Cox model in Output 66.11.3, which leads to the same conclusion that laser photocoagulation is effective in delaying blindness for both types of diabetes, and more effective for the adult-onset diabetes than for juvenile-onset diabetes.

Output 66.11.7 Hazard Ratio Estimates for Frailty Model

Frailty Model Analysis: Hazard Ratios for Treat

Description	Point Estimate	95% Wald Confidence Limits	
Treat Laser vs Others At Type=Adult	0.231	0.133	0.403
Treat Laser vs Others At Type=Juvenile	0.607	0.391	0.945

Example 66.12: Model Assessment Using Cumulative Sums of Martingale Residuals

The Mayo liver disease example of Lin, Wei, and Ying (1993) is reproduced here to illustrate the checking of the functional form of a covariate and the assessment of the proportional hazards assumption. The data represent 418 patients with primary biliary cirrhosis (PBC), among whom 161 had died as of the date of data listing. A subset of the variables is saved in the SAS data set Liver. The data set contains the following variables:

- Time, follow-up time, in years
- Status, event indicator with value 1 for death time and value 0 for censored time
- Age, age in years from birth to study registration
- Albumin, serum albumin level, in gm/dl
- Bilirubin, serum bilirubin level, in mg/dl
- Edema, edema presence
- Protime, prothrombin time, in seconds

The following statements create the data set Liver:

```
data Liver;
   input Time Status Age Albumin Bilirubin Edema Protime @@;
   label Time="Follow-up Time in Years";
   Time= Time / 365.25;

```

Consider fitting a Cox model for the survival time of the PCB patients with the covariates Bilirubin, log(Protime), log(Albumin), Age, and Edema. The log transform, which is often applied to blood chemistry measurements, is deliberately not employed for Bilirubin. It is of interest to assess the functional form of the variable Bilirubin in the Cox model. The specifications are as follows:

```
ods graphics on;
proc phreg data=Liver;
   model Time*Status(0)=Bilirubin logProtime logAlbumin Age Edema;
   logProtime=log(Protime);
   logAlbumin=log(Albumin);
   assess var=(Bilirubin) /  resample seed=7548;
   run;
ods graphics off;
```

The ASSESS statement creates a plot of the cumulative martingale residuals against the values of the covariate Bilirubin, which is specified in the VAR= option. The RESAMPLE option computes the p-value of a Kolmogorov-type supremum test based on a sample of 1,000 simulated residual patterns.

Parameter estimates of the model fit are shown in Output 66.12.1. The plot in Output 66.12.2 displays the observed cumulative martingale residual process for Bilirubin together with 20 simulated realizations from the null distribution. When ODS Graphics is enabled, this graphical display is requested by specifying the ASSESS statement. It is obvious that the observed process is atypical compared to the simulated realizations. Also, none of the 1,000 simulated realizations has an absolute maximum exceeding that of the observed cumulative martingale residual process. Both the graphical and numerical results indicate that a transform is deemed necessary for Bilirubin in the model.

Output 66.12.1 Cox Model with Bilirubin as a Covariate

The PHREG Procedure

Analysis of Maximum Likelihood Estimates

Parameter	DF	Parameter Estimate	Standard Error	Chi-Square	Pr > ChiSq	Hazard Ratio
Bilirubin	1	0.11733	0.01298	81.7567	<.0001	1.124

Output 66.12.3 Typical Cumulative Residual Plot Patterns

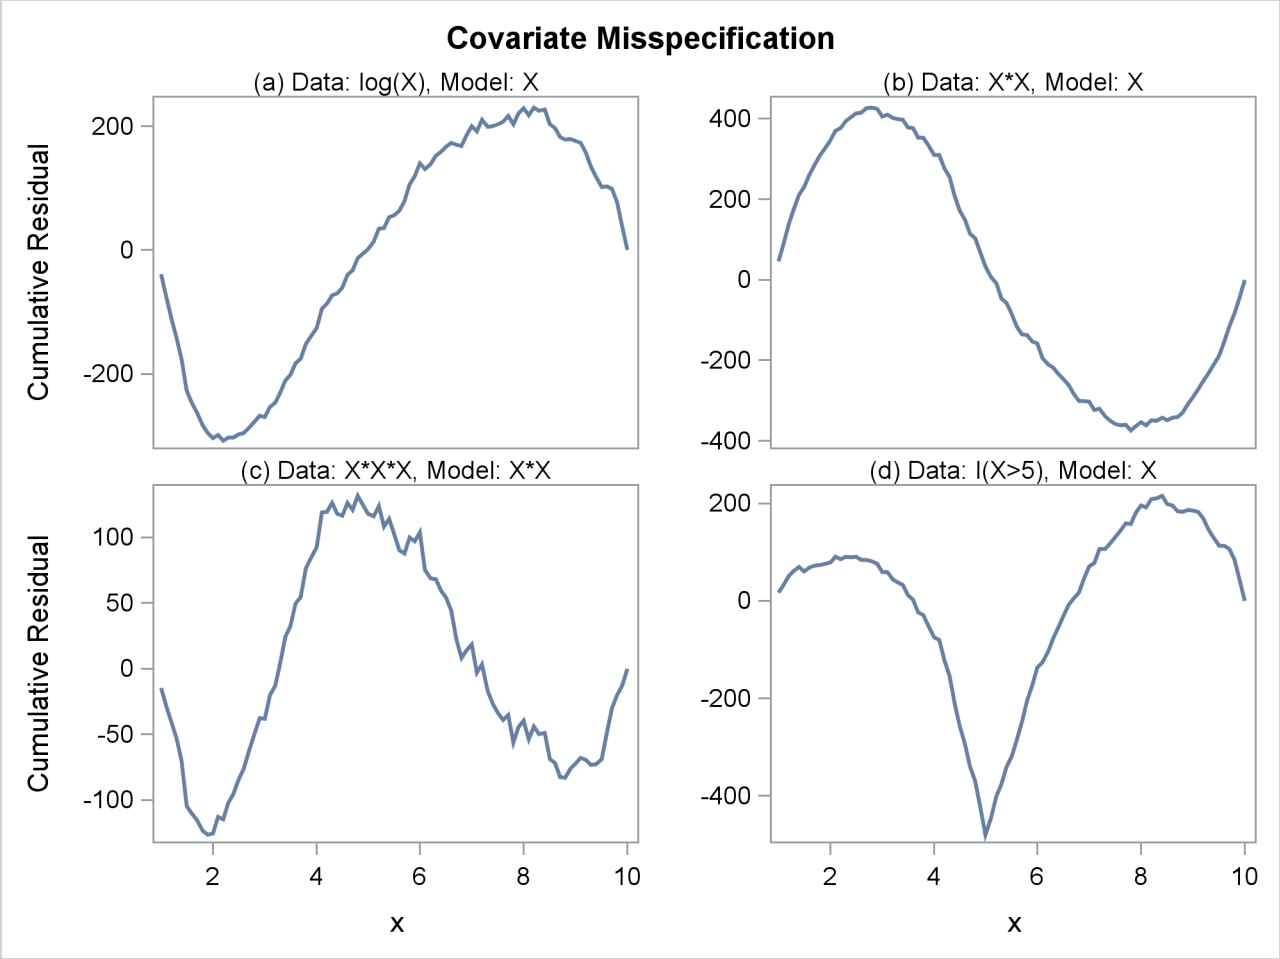

Table 66.13 Model Misspecifications

Plot	Data	Fitted Model
(a)	$\log(X)$	X
(b)	$\{X, X^2\}$	X
(c)	$\{X, X^2, X^3\}$	$\{X, X^2\}$
(d)	$I(X > 5)$	X

The curve of observed cumulative martingale residuals in Output 66.12.2 most resembles the behavior of the curve in plot (a) of Output 66.12.3, indicating that log(Bilirubin) might be a more appropriate term in the model than Bilirubin.

Next, the analysis of the natural history of the PBC is repeated with log(Bilirubin) replacing Bilirubin, and the functional form of log(Bilirubin) is assessed. Also assessed is the proportional hazards assumption for the Cox model. The analysis is carried out by the following statements:

```
ods graphics on;
proc phreg data=Liver;
   model Time*Status(0)=logBilirubin logProtime logAlbumin Age Edema;
   logBilirubin=log(Bilirubin);
   logProtime=log(Protime);
   logAlbumin=log(Albumin);
   assess var=(logBilirubin) ph / crpanel resample seed=19;
   run;
ods html close;
```

The SEED= option specifies a integer seed for generating random numbers. The CRPANEL option in the ASSESS statement requests a panel of four plots. Each plot displays the observed cumulative martingale residual process along with two simulated realizations. The PH option checks the proportional hazards assumption of the model by plotting the observed standardized score process with 20 simulated realizations for each covariate in the model.

Output 66.12.4 displays the parameter estimates of the fitted model. The cumulative martingale residual plots in Output 66.12.5 and Output 66.12.6 show that the observed martingale residual process is more typical of the simulated realizations. The p-value for the Kolmogorov-type supremum test based on 1,000 simulations is 0.052, indicating that the log transform is a much improved functional form for Bilirubin.

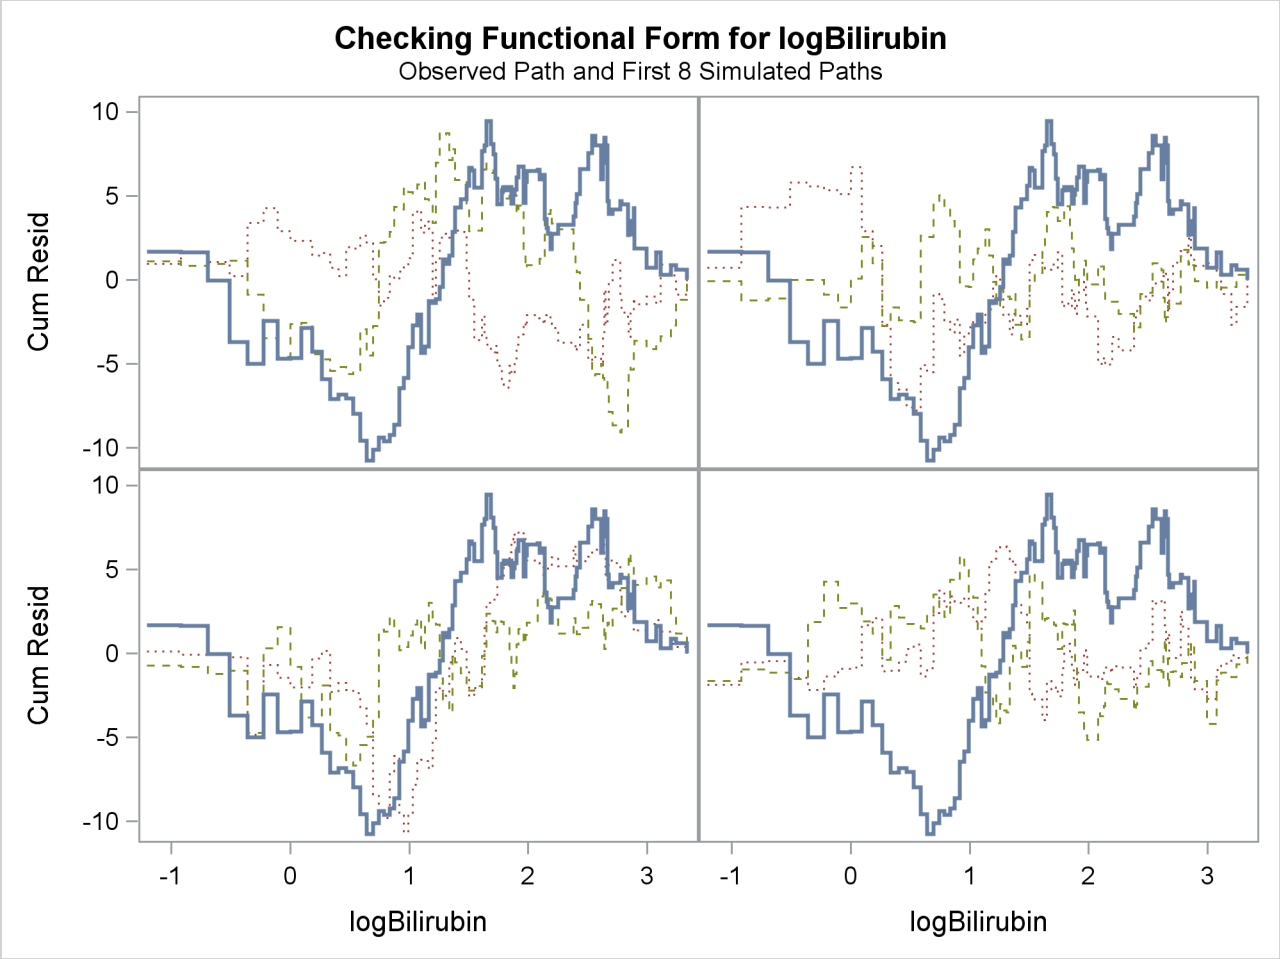
Output 66.12.4 Model with log(Bilirubin) as a Covariate

The PHREG Procedure

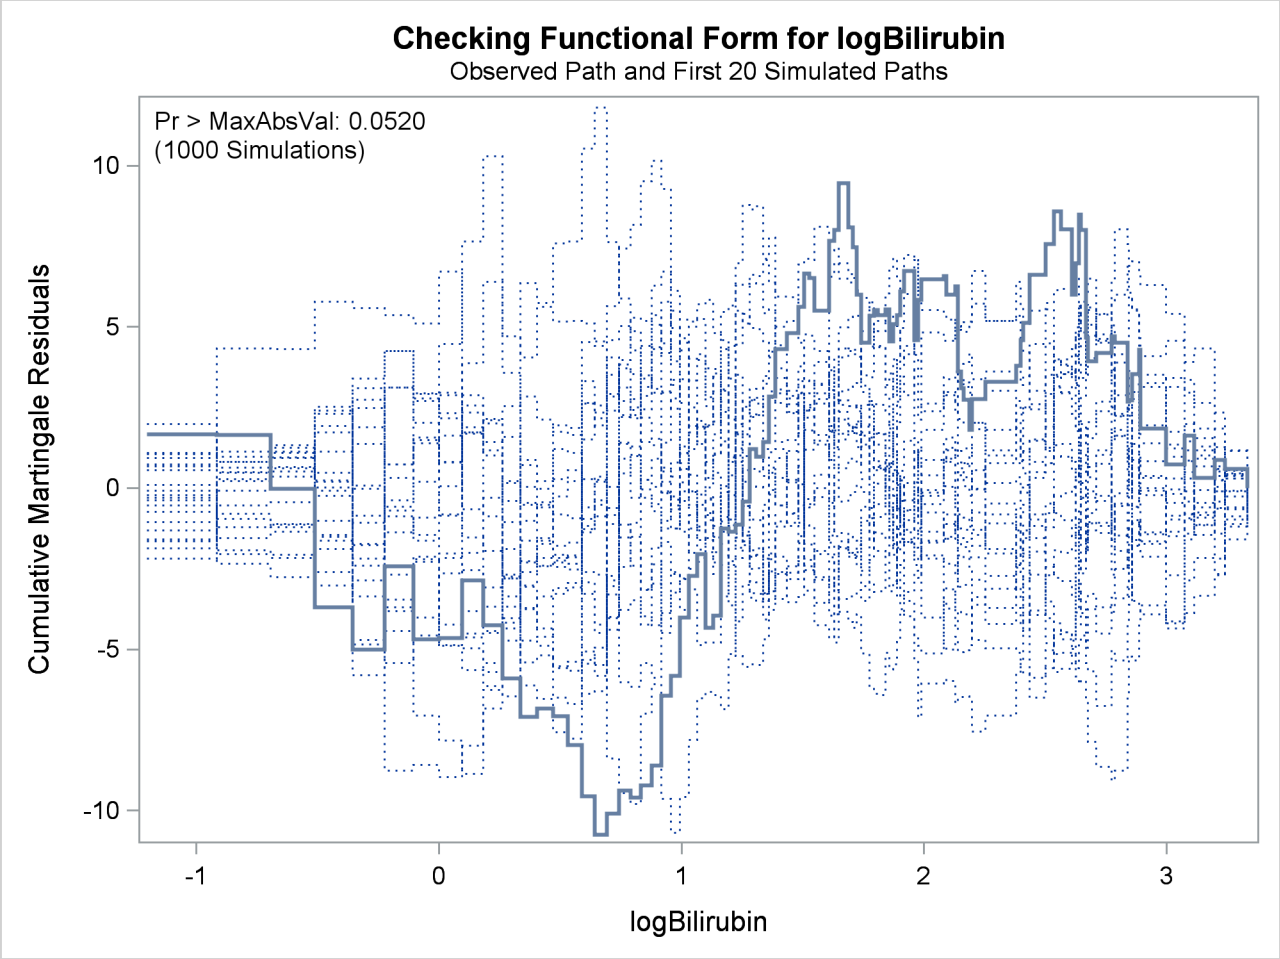
Analysis of Maximum Likelihood Estimates

Parameter	DF	Parameter Estimate	Standard Error	Chi-Square	Pr > ChiSq	Hazard Ratio
logBilirubin	1	0.87072	0.08263	111.0484	<.0001	2.389
logProtime	1	2.37789	0.76674	9.6181	0.0019	10.782
logAlbumin	1	-2.53264	0.64819	15.2664	<.0001	0.079
Age	1	0.03940	0.00765	26.5306	<.0001	1.040
Edema	1	0.85934	0.27114	10.0447	0.0015	2.362

Output 66.12.5 Panel Plot of Cumulative Martingale Residuals versus log(Bilirubin)

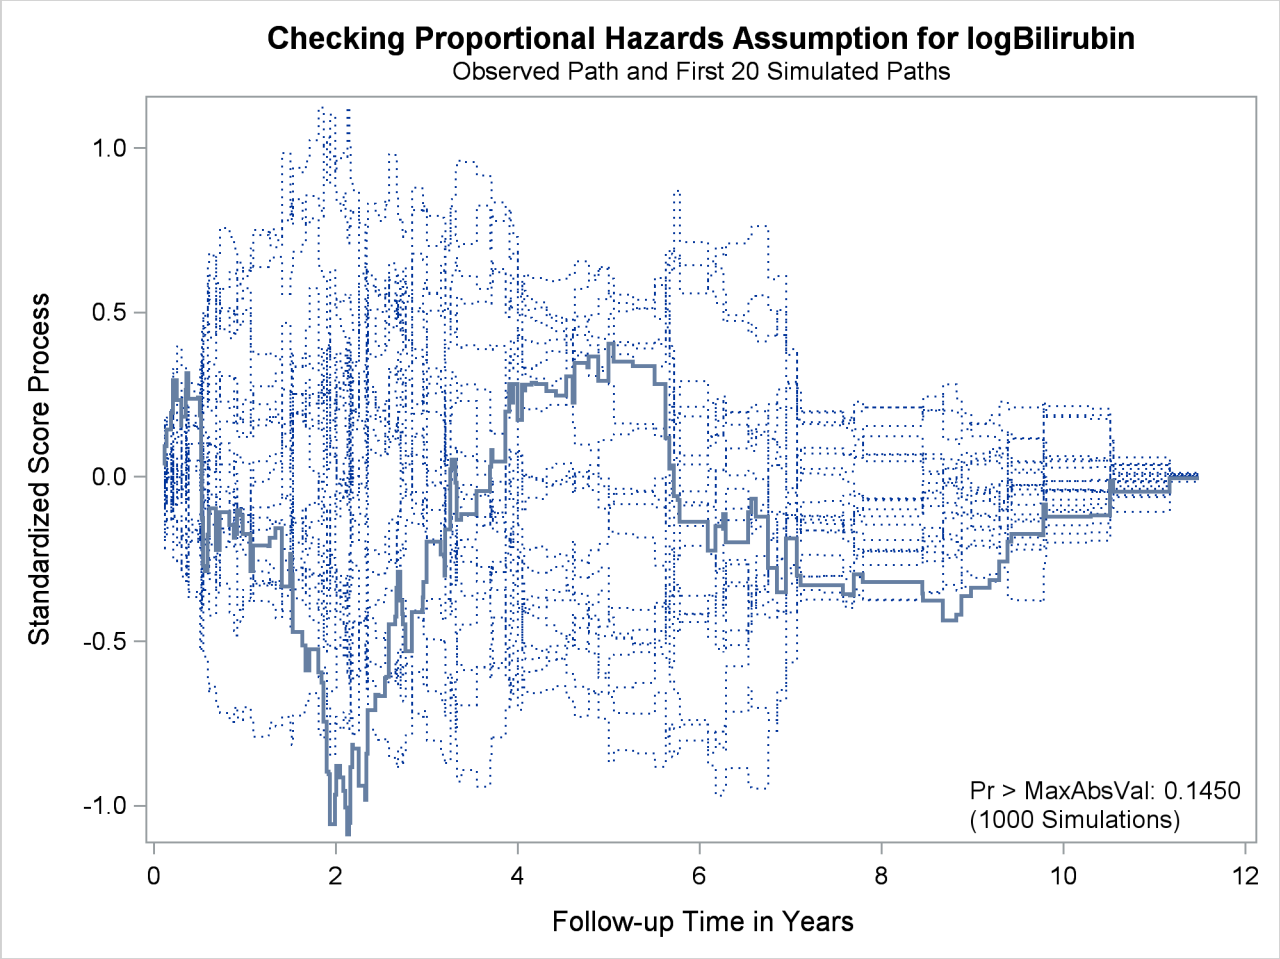


Output 66.12.6 Cumulative Martingale Residuals versus log(Bilirubin)



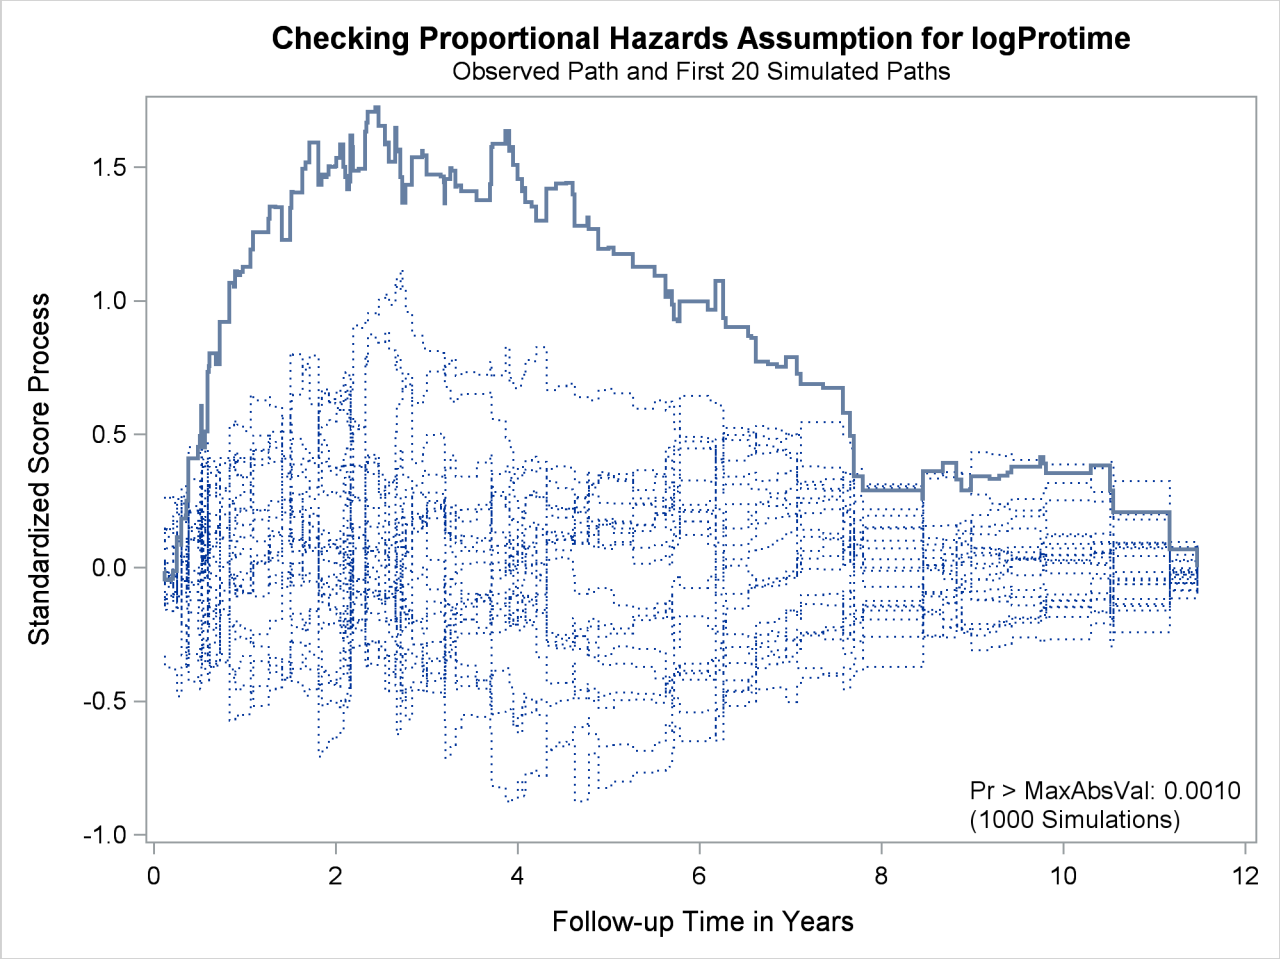
Output 66.12.7 and Output 66.12.8 display the results of proportional hazards assumption assessment for log(Bilirubin) and log(Protime), respectively. The latter plot reveals nonproportional hazards for log(Protime).

Output 66.12.7 Standardized Score Process for log(Bilirubin)



[

Output 66.12.8 Standardized Score Process for log(Protime)



Plots for log(Albumin), Age, and Edema are not shown here. The Kolmogorov-type supremum test results for all the covariates are shown in Output 66.12.9. In addition to log(Protime), the proportional hazards assumption appears to be violated for Edema.

Output 66.12.9 Kolmogorov-Type Supremum Tests for Proportional Hazards Assumption

Supremum Test for Proportionals Hazards Assumption

Variable	Maximum Absolute Value	Replications	Seed	Pr > MaxAbsVal
logBilirubin	1.0880	1000	19	0.1450
logProtime	1.7243	1000	19	0.0010
logAlbumin	0.8443	1000	19	0.4330
Age	0.7387	1000	19	0.4620
Edema	1.4350	1000	19	0.0330

Example 66.13: Bayesian Analysis of the Cox Model

This example illustrates the use of an informative prior. Hazard ratios, which are transformations of the regression parameters, are useful for interpreting survival models. This example also demonstrates the use of the HAZARDRATIO statement to obtain customized hazard ratios.

Consider the VALung data set in Example 66.3. In this example, the Cox model is used for the Bayesian analysis. The parameters are the coefficients of the continuous explanatory variables (Kps, Duration, and Age) and the coefficients of the design variables for the categorical explanatory variables (Prior, Cell, and Therapy). You use the CLASS statement in PROC PHREG to specify the categorical variables and their reference levels. Using the default reference parameterization, the design variables for the categorical variables are Prioryes (for Prior with Prior='no' as reference), Celladeno, Cellsmall, Cellsquamous (for Cell with Cell='large' as reference), and Therapytest (for Therapy='standard' as reference).

Consider the explanatory variable Kps. The Karnofsky performance scale index enables patients to be classified according to their functional impairment. The scale can range from 0 to 100—0 for dead, and 100 for a normal, healthy person with no evidence of disease. Recall that a flat prior was used for the regression coefficient in the example in the section "Bayesian Analysis" on page 5373. A flat prior on the Kps coefficient implies that the coefficient is as likely to be 0.1 as it is to be –100000. A coefficient of –5 means that a decrease of 20 points in the scale increases the hazard by $e^{-20\times-5}$(=2.68×10^{43})-fold, which is a rather unreasonable and unrealistic expectation for the effect of the Karnofsky index, much less than the value of –100000. Suppose you have a more realistic expectation: the effect is somewhat small and is more likely to be negative than positive, and a decrease of 20 points in the Karnofsky index will change the hazard from 0.9-fold (some minor positive effect) to 4-fold (a large negative effect). You can convert this opinion to a more informative prior on the Kps coefficient $\boldsymbol{\beta}_1$. Mathematically,

$$0.9 < e^{-20\boldsymbol{\beta}_1} < 4$$

which is equivalent to

$$-0.0693 < \boldsymbol{\beta}_1 < 0.0053$$

This becomes the plausible range that you believe the Kps coefficient can take. Now you can find a normal distribution that best approximates this belief by placing the majority of the prior distribution mass within this range. Assuming this interval is $\mu \pm 2\sigma$, where μ and σ are the mean and standard deviation of the normal prior, respectively, the hyperparameters μ and σ are computed as follows:

$$\begin{aligned} \mu &= \frac{-0.0693 + 0.0053}{2} = -0.032 \\ \sigma &= \frac{0.0053 - (-0.0693)}{4} = 0.0186 \end{aligned}$$

Note that a normal prior distribution with mean –0.0320 and standard deviation 0.0186 indicates that you believe, before looking at the data, that a decrease of 20 points in the Karnofsky index will probably change the hazard rate by 0.9-fold to 4-fold. This does not rule out the possibility that the Kps coefficient can take a more extreme value such as –5, but the probability of having such extreme values is very small.

Assume the prior distributions are independent for all the parameters. For the coefficient of Kps, you use a normal prior distribution with mean –0.0320 and variance 0.0186^2(=0.00035). For other parameters, you

resort to using a normal prior distribution with mean 0 and variance 1E6, which is fairly noninformative. Means and variances of these independent normal distributions are saved in the data set Prior as follows:

```
proc format;
   value yesno 0='no' 10='yes';

In the following BAYES statement, COEFFPRIOR=NORMAL(INPUT=Prior) specifies the normal prior distribution for the regression coefficients with details contained in the data set Prior. Summary statistics of the posterior distribution are produced by default. Autocorrelations and effective sample size are requested as convergence diagnostics as well as the trace plots for visual analysis. For comparisons of hazards, three HAZARDRATIO statements are specified—one for the variable Therapy, one for the variable Age, and one for the variable Cell.

```
ods graphics on;
proc phreg data=VALung;
   class Prior(ref='no') Cell(ref='large') Therapy(ref='standard');
   model Time*Status(0) = Kps Duration Age Prior Cell Therapy;
   bayes seed=1 coeffprior=normal(input=Prior) diagnostic=(autocorr ess)
         plots=trace;
   hazardratio 'Hazard Ratio Statement 1' Therapy;
   hazardratio 'Hazard Ratio Statement 2' Age / unit=10;
   hazardratio 'Hazard Ratio Statement 3' Cell;
run;
ods graphics off;
```

This analysis generates a posterior chain of 10,000 iterations after 2,000 iterations of burn-in, as depicted in Output 66.13.1.

Output 66.13.1 Model Information

The first HAZARDRATIO statement compares the hazards between the standard therapy and the test therapy. Summaries of the posterior distribution of the corresponding hazard ratio are shown in Output 66.13.11. There is a 95% chance that the hazard ratio of standard therapy versus test therapy lies between 0.5 and 1.1.

Output 66.13.11 Hazard Ratio for Treatment

Hazard Ratio Statement 1: Hazard Ratios for Therapy

Description	N	Mean	Standard Deviation
Therapy standard vs test	10000	0.7645	0.1573

Hazard Ratio Statement 1: Hazard Ratios for Therapy

Quantiles			95% Equal-Tail Interval		95% HPD Interval	
25%	50%	75%				
0.6544	0.7488	0.8583	0.5001	1.1143	0.4788	1.0805

The second HAZARDRATIO statement assesses the change of hazards for an increase in Age of 10 years. Summaries of the posterior distribution of the corresponding hazard ratio are shown in Output 66.13.12.

Output 66.13.12 Hazard Ratio for Age

Hazard Ratio Statement 2: Hazard Ratios for Age

Description	N	Mean	Standard Deviation	Quantiles 25%	50%	75%
Age Unit=10	10000	0.9230	0.0859	0.8635	0.9195	0.9782

Hazard Ratio Statement 2: Hazard Ratios for Age

95% Equal-Tail Interval		95% HPD Interval	
0.7685	1.1011	0.7650	1.0960

The third HAZARDRATIO statement compares the changes of hazards between two types of cells. For four types of cells, there are six different pairs of cell comparisons. The results are shown in Output 66.13.13.

Output 66.13.13 Hazard Ratios for Cell

Hazard Ratio Statement 3: Hazard Ratios for Cell

Description	N	Mean	Standard Deviation

Example 66.14: Bayesian Analysis of Piecewise Exponential Model

This example illustrates using a piecewise exponential model in a Bayesian analysis. Consider the Rats data set in the section "Getting Started: PHREG Procedure" on page 5369. In the following statements, PROC PHREG is used to carry out a Bayesian analysis for the piecewise exponential model. In the BAYES statement, the option PIECEWISE stipulates a piecewise exponential model, and PIECEWISE=HAZARD requests that the constant hazards be modeled in the original scale. By default, eight intervals of constant hazards are used, and the intervals are chosen such that each has roughly the same number of events.

```
data Rats;
   label Days  ='Days from Exposure to Death';
   input Days Status Group @@;
   datalines;
143 1 0   164 1 0   188 1 0   188 1 0
190 1 0   192 1 0   206 1 0   209 1 0
213 1 0   216 1 0   220 1 0   227 1 0
230 1 0   234 1 0   246 1 0   265 1 0
304 1 0   216 0 0   244 0 0   142 1 1
156 1 1   163 1 1   198 1 1   205 1 1
232 1 1   232 1 1   233 1 1   233 1 1
233 1 1   233 1 1   239 1 1   240 1 1
261 1 1   280 1 1   280 1 1   296 1 1
296 1 1   323 1 1   204 0 1   344 0 1
;

proc phreg data=Rats;
   model Days*Status(0)=Group;
   bayes seed=1 piecewise=hazard;
run;
```

The "Model Information" table in Output 66.14.1 shows that the piecewise exponential model is being used.

Output 66.14.1 Model Information

The PHREG Procedure

Bayesian Analysis

Model Information

Data Set	WORK.RATS	
Dependent Variable	Days	Days from Exposure to Death
Censoring Variable	Status	
Censoring Value(s)	0	
Model	Piecewise Exponential	
Sampling Algorithm	ARMS	
Burn-In Size	2000	
MC Sample Size	10000	
Thinning	1	

By default the time axis is partitioned into eight intervals of constant hazard. Output 66.14.2 details the number of events and observations in each interval. Note that the constant hazard parameters are named Lambda1,..., Lambda8. You can supply your own partition by using the INTERVALS= suboption within the PIECEWISE=HAZARD option.

Output 66.14.2 Interval Partition

Constant Hazard Time Intervals

Interval [Lower,	Upper)	N	Event	Hazard Parameter
0	176	5	5	Lambda1
176	201.5	5	5	Lambda2
201.5	218	7	5	Lambda3
218	232.5	5	5	Lambda4
232.5	233.5	4	4	Lambda5
233.5	253.5	5	4	Lambda6
253.5	288	4	4	Lambda7
288	Infty	5	4	Lambda8

The model parameters consist of the eight hazard parameters Lambda1, ..., Lambda8, and the regression coefficient Group. The maximum likelihood estimates are displayed in Output 66.14.3. Again, these estimates are used as the starting values for simulation of the posterior distribution.

Output 66.14.3 Maximum Likelihood Estimates

Maximum Likelihood Estimates

Parameter	DF	Estimate	Standard Error	95% Confidence Limits	
Lambda1	1	0.000953	0.000443	0.000084	0.00182
Lambda2	1	0.00794	0.00371	0.000672	0.0152
Lambda3	1	0.0156	0.00734	0.00120	0.0300
Lambda4	1	0.0236	0.0115	0.00112	0.0461
Lambda5	1	0.3669	0.1959	-0.0172	0.7509
Lambda6	1	0.0276	0.0148	-0.00143	0.0566
Lambda7	1	0.0262	0.0146	-0.00233	0.0548
Lambda8	1	0.0545	0.0310	-0.00626	0.1152
Group	1	-0.6223	0.3468	-1.3020	0.0573

Without using the PRIOR= suboption within the PIECEWISE=HAZARD option to specify the prior of the hazard parameters, the default is to use the noninformative and improper prior displayed in Output 66.14.4.

Output 66.14.4 Hazard Prior

Improper Prior for Hazards

Parameter	Prior
Lambda1	1 / Lambda1
Lambda2	1 / Lambda2
Lambda3	1 / Lambda3
Lambda4	1 / Lambda4
Lambda5	1 / Lambda5
Lambda6	1 / Lambda6
Lambda7	1 / Lambda7
Lambda8	1 / Lambda8

The noninformative uniform prior is used for the regression coefficient Group (Output 66.14.5), as in the section "Bayesian Analysis" on page 5373.

Output 66.14.5 Coefficient Prior

Uniform Prior for Regression Coefficients

Parameter	Prior
Group	Constant

Summary statistics for all model parameters are shown in Output 66.14.6 and Output 66.14.7.

Output 66.14.6 Summary Statistics

Chapter 67

The PLAN Procedure

Contents

Overview: PLAN Procedure

The PLAN procedure constructs designs and randomizes plans for factorial experiments, especially nested and crossed experiments and randomized block designs. PROC PLAN can also be used for generating lists of permutations and combinations of numbers. The PLAN procedure can construct the following types of experimental designs:

- full factorial designs, with and without randomization
- certain balanced and partially balanced incomplete block designs
- generalized cyclic incomplete block designs
- Latin square designs

For other kinds of experimental designs, especially fractional factorial, response surface, and orthogonal array designs, see the FACTEX and OPTEX procedures and the ADX Interface in SAS/QC software.

PROC PLAN generates designs by first generating a selection of the levels for the first factor. Then, for the second factor, PROC PLAN generates a selection of its levels for each level of the first factor. In general, for a given factor, the PLAN procedure generates a selection of its levels for all combinations of levels for the factors that precede it.

The selection can be done in five different ways:

- randomized selection, for which the levels are returned in a random order
- ordered selection, for which the levels are returned in a standard order every time a selection is generated
- cyclic selection, for which the levels returned are computed by cyclically permuting the levels of the previous selection
- permuted selection, for which the levels are a permutation of the integers $1, \ldots, n$
- combination selection, for which the m levels are selected as a combination of the integers $1, \ldots, n$ taken m at a time

The randomized selection method can be used to generate randomized plans. Also, by appropriate use of cyclic selection, any of the designs in the very wide class of generalized cyclic block designs (Jarrett and Hall 1978) can be generated.

There is no limit to the depth to which the different factors can be nested, and any number of randomized plans can be generated.

You can also declare a list of factors to be selected simultaneously with the lowest (that is, the most nested) factor. The levels of the factors in this list can be seen as constituting the treatment to be applied to the cells of the design. For this reason, factors in this list are called *treatments*. With this list, you can generate and randomize plans in one run of PROC PLAN.

Getting Started: PLAN Procedure

Three Replications with Four Factors

Suppose you want to determine if the order in which four drugs are given affects the response of a subject. If you have only three subjects to test, you can use the following statements to design the experiment.

```
proc plan seed=27371;
   factors Replicate=3 ordered Drug=4;
run;
```

These statements produce a design with three replicates of the four levels of the factor Drug arranged in random order. The three levels of Replicate are arranged in order, as shown in Figure 67.1.

Figure 67.1 Three Replications and Four Factors

```
                    The PLAN Procedure

Factor          Select      Levels     Order

Replicate            3           3    Ordered
Drug                 4           4    Random

             Replicate      --Drug-

                     1      3 2 4 1
                     2      1 2 4 3
                     3      4 1 2 3
```

You might also want to apply one of four different treatments to each cell of this plan (for example, applying different amounts of each drug). The following additional statements create the output shown in Figure 67.2:

```
   factors Replicate=3 ordered Drug=4;
   treatments Treatment=4;
run;
```

Figure 67.2 Using the TREATMENTS Statement

                  Treatment           4           4    Random

                   Replicate      --Drug-      --Treatment--

                           1      3 1 2 4      2   1   3   4
                           2      4 3 2 1      4   1   2   3
                           3      3 2 4 1      1   4   2   3
```

Randomly Assigning Subjects to Treatments

You can use the PLAN procedure to design a completely randomized design. Suppose you have 12 experimental units, and you want to assign one of two treatments to each unit. Use a DATA step to store the unrandomized design in a SAS data set, and then call PROC PLAN to randomize it by specifying one factor with the default type of RANDOM, having 12 levels. The following statements produce Figure 67.3 and Figure 67.4:

```
title 'Completely Randomized Design';
/* The unrandomized design */

data Unrandomized;
   do Unit=1 to 12;
      if (Unit <= 6) then Treatment=1;
      else                Treatment=2;
      output;
   end;
run;

/* Randomize the design */

proc plan seed=27371;
   factors Unit=12;
   output data=Unrandomized out=Randomized;
run;

proc sort data=Randomized;
   by Unit;
proc print;
run;
```

Figure 67.3 shows that the 12 levels of the unit factor have been randomly reordered and then lists the new ordering.

Figure 67.3 A Completely Randomized Design for Two Treatments

```
                    Completely Randomized Design

                         The PLAN Procedure

                Factor       Select      Levels      Order

                Unit             12          12     Random

                   ----------------Unit---------------

                    8  5  1  4  6  2 12  7  3  9 10 11
```

After the data set is sorted by the unit variable, the randomized design is displayed (Figure 67.4).

Figure 67.4 A Completely Randomized Design for Two Treatments

```
                    Completely Randomized Design

                      Obs    Unit    Treatment

                       1       1         1
                       2       2         1
                       3       3         2
                       4       4         1
                       5       5         1
                       6       6         1
                       7       7         2
                       8       8         1
                       9       9         2
                      10      10         2
                      11      11         2
                      12      12         2
```

You can also generate the plan by using a TREATMENTS statement instead of a DATA step. The following statements generate the same plan.

```
proc plan seed=27371;
   factors Unit=12;
   treatments Treatment=12 cyclic (1 1 1 1 1 1 2 2 2 2 2 2);
   output out=Randomized;
run;
```

Syntax: PLAN Procedure

The following statements are available in PROC PLAN.

PROC PLAN < *options* > **;**
FACTORS *factor-selections* < / **NOPRINT** > **;**
OUTPUT OUT=*SAS-data-set* < *factor-value-settings* > **;**
TREATMENTS *factor-selections* **;**

To use PROC PLAN, you need to specify the PROC PLAN statement and at least one FACTORS statement before the first RUN statement. The TREATMENTS statement, OUTPUT statement, and additional FACTORS statements can appear either before the first RUN statement or after it.

The rest of this section gives detailed syntax information for each of the statements, beginning with the PROC PLAN statement. The remaining statements are described in alphabetical order.

You can use PROC PLAN interactively by specifying multiple groups of statements, separated by RUN statements. For details, see the section "Using PROC PLAN Interactively" on page 5596.

PROC PLAN Statement

PROC PLAN < *options* > **;**

The PROC PLAN statement starts the PLAN procedure and, optionally, specifies a random number seed or a default method for selecting levels of factors. By default, the procedure uses a random number seed generated from reading the time of day from the computer's clock and randomly selects levels of factors. These defaults can be modified with the SEED= and ORDERED options, respectively. Unlike many SAS/STAT procedures, the PLAN procedure does not have a DATA= option in the PROC statement; in this procedure, both the input and output data sets are specified in the OUTPUT statement.

You can specify the following options in the PROC PLAN statement:

SEED=*number*
specifies an integer used to start the pseudo-random number generator for selecting factor levels randomly. If you do not specify a seed, or if you specify a value less than or equal to zero, the seed is by default generated from reading the time of day from the computer's clock.

ORDERED
selects the levels of the factor as the integers $1, 2, \ldots, m$, in order. For more detail, see "*Selection Types*" on page 5591 and "Specifying Factor Structures" on page 5599.

FACTORS Statement

FACTORS *factor-selections* < / **NOPRINT** > **;**

The FACTORS statement specifies the factors of the plan and generates the plan. Taken together, the *factor-selections* specify the plan to be generated; more than one *factor-selection* request can be used in a FACTORS statement. The form of a *factor-selection* is

name **=** *m* < **OF** *n* > < *selection-type* > **;**

where

name is a valid SAS name. This gives the name of a factor in the design.

m is a positive integer that gives the number of values to be selected. If *n* is specified, the value of *m* must be less than or equal to *n*.

n is a positive integer that gives the number of values to be selected from.

selection-type specifies one of five methods for selecting *m* values. Possible values are COMB, CYCLIC, ORDERED, PERM, and RANDOM. The CYCLIC *selection-type* has additional optional specifications that enable you to specify an initial block of numbers to be cyclically permuted and an increment used to permute the numbers. By default, the *selection-type* is RANDOM, unless you use the ORDERED option in the PROC PLAN statement. In this case, the default *selection-type* is ORDERED. For details, see the following section, "*Selection-Types*"; for examples, see the section "Syntax Examples" on page 5592.

The following option can appear in the FACTORS statement after the slash:

NOPRINT
suppresses the display of the plan. This is particularly useful when you require only an output data set. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 20, "Using the Output Delivery System," for more information.

Selection-Types

PROC PLAN interprets *selection-type* as follows:

RANDOM selects the m levels of the factor randomly without replacement from the integers $1, 2, \ldots, n$. Or, if n is not specified, RANDOM selects levels by randomly ordering the integers $1, 2, \ldots, m$.

ORDERED selects the levels of the factor as the integers $1, 2, \ldots, m$, in that order.

PERM selects the m levels of the factor as a permutation of the integers $1, \ldots m$ according to an algorithm that cycles through all $m!$ permutations. The permutations are produced in a sorted standard order; see Example 67.6.

COMB selects the m levels of the factor as a combination of the integers $1, \ldots, n$ taken m at a time, according to an algorithm that cycles through all $n!/(m!(n-m)!)$ combinations. The combinations are produced in a sorted standard order; see Example 67.6.

CYCLIC < (*initial-block*) > < *increment* > selects the levels of the factor by cyclically permuting the integers $1, 2, \ldots, n$. Wrapping occurs at m if n is not specified, and at n if n is specified. Additional optional specifications are as follows.

With the *selection-type* CYCLIC, you can optionally specify an *initial-block* and an *increment*. The *initial-block* must be specified within parentheses, and it specifies the block of

numbers to permute. The first permutation is the block you specify, the second is the block permuted by 1 (or by the *increment* you specify), and so on. By default, the *initial-block* is the integers $1, 2, \ldots, m$. If you specify an *initial-block*, it must have m values. Values specified in the *initial-block* do not have to be given in increasing order.

The *increment* specifies the increment by which to permute the block of numbers. By default, the *increment* is 1.

Syntax Examples

This section gives some simple syntax examples. For more complex examples and details on how to generate various designs, see "Specifying Factor Structures" on page 5599. The examples in this section assume that you use the default random selection method and do not use the ORDERED option in the PROC PLAN statement.

The following specification generates a random permutation of the numbers 1, 2, 3, 4, and 5.

```
factors A=5;
```

The following specification generates a random permutation of five of the integers from 1 to 8, selected without replacement.

```
factors A=5 of 8;
```

Adding the ORDERED *selection-type* to the two previous specifications generates an ordered list of the integers 1 to 5. The following specification cyclically permutes the integers 1, 2, 3, and 4.

```
factors A=4 cyclic;
```

Since this simple request generates only one permutation of the numbers, the procedure generates an ordered list of the integers 1 to 4. The following specification cyclically permutes the integers 5 to 8.

```
factors A=4 of 8 cyclic (5 6 7 8);
```

In this case, since only one permutation is performed, the procedure generates an ordered list of the integers 5 to 8. The following specification produces an ordered list for A, with values 1 and 2.

```
factors A=2 ordered B=4 of 8 cyclic (5 6 7 8) 2;
```

The associated factor levels for B are 5, 6, 7, 8 for level 1 of A, and 7, 8, 1, 2 for level 2 of A.

Handling More Than One *Factor-Selection*

For cases with more than one *factor-selection* in the same FACTORS statement, PROC PLAN constructs the design as follows:

1. PROC PLAN first generates levels for the first *factor-selection*. These levels are permutations of integers (1, 2, and so on) appropriate for the selection type chosen. If you do not specify a selection type, PROC PLAN uses the default (RANDOM); if you specify the ORDERED option in the PROC PLAN statement, the procedure uses ORDERED as the default selection type.

2. For every integer generated for the first *factor-selection*, levels are generated for the second *factor-selection*. These levels are generated according to the specifications following the second equal sign.

3. This process is repeated until levels for all *factor-selections* have been generated.

The following statements give an example of generating a design with two random factors:

```
proc plan;
   factors One=4 Two=3;
run;
```

The procedure first generates a random permutation of the integers 1 to 4 and then, for each of these, generates a random permutation of the integers 1 to 3. You can think of factor Two as being nested within factor One, where the levels of factor One are to be randomly assigned to 4 units.

As another example, six random permutations of the numbers 1, 2, 3 can be generated by specifying the following statements:

```
proc plan;
   factors a=6 ordered b=3;
run;
```

OUTPUT Statement

OUTPUT OUT=*SAS-data-set* < **DATA=***SAS-data-set* > < *factor-value-settings* > **;**

The OUTPUT statement applies only to the last plan generated. If you use PROC PLAN interactively, the OUTPUT statement for a given plan must be immediately preceded by the FACTORS statement (and the TREATMENTS statement, if appropriate) for the plan.

See "Output Data Sets" on page 5597 for more information about how output data sets are constructed.

You can specify the following options in the OUTPUT statement:

OUT=*SAS-data-set*

DATA=*SAS-data-set*

You can use the OUTPUT statement both to output the last plan generated and to use the last plan generated to randomize another SAS data set.

When you specify only the OUT= option in the OUTPUT statement, PROC PLAN saves the last plan generated to the specified data set. The output data set contains one variable for each factor in the plan and one observation for each cell in the plan. The value of a variable in a given observation is the level of the corresponding factor for that cell. The OUT= option is required.

When you specify both the DATA= and OUT= options in the OUTPUT statement, then PROC PLAN uses the last plan generated to randomize the input data set (DATA=), saving the results to the output data set (OUT=). The output data set has the same form as the input data set but has modified values for the variables that correspond to factors (see the section "Output Data Sets" on page 5597 for details). Values for variables not corresponding to factors are transferred without change.

factor-value-settings
specify the values input or output for the factors in the design. The form for *factor-value-settings* is different when only an OUT= data set is specified and when both OUT= and DATA= data sets are specified.

Both forms are discussed in the following section.

Factor-Value-Settings with Only an OUT= Data Set

When you specify only an OUT= data set, the form for each *factor-value-setting* specification is one of the following:

factor-name < **NVALS=***list-of-n-numbers* > < **ORDERED** | **RANDOM** > **;**

or

factor-name < **CVALS=***list-of-n-strings* > < **ORDERED** | **RANDOM** > **;**

where

factor-name is a factor in the last FACTORS statement preceding the OUTPUT statement.

NVALS= lists n numeric values for the factor. By default, the procedure uses NVALS=$(1\ 2\ 3 \cdots n)$.

CVALS= lists n character strings for the factor. Each string can have up to 40 characters, and each string must be enclosed in quotes. **WARNING:** When you use the CVALS= option, the variable created in the output data set has a length equal to the length of the longest string given as a value; shorter strings are padded with trailing blanks. For example, the values output for the first level of a two-level factor with the following two different specifications are not the same.

```
CVALS='String 1' "String 2")

CVALS='String 1' "A longer string")
```

The value output with the second specification is 'String 1' followed by seven blanks. In order to match two such values (for example, when merging two plans), you must use the TRIM function in the DATA step (see *SAS Language Reference: Dictionary*).

ORDERED | RANDOM specifies how values (those given with the NVALS= or CVALS= option, or the default values) are associated with the levels of a factor (the integers $1, 2, \ldots, n$). The default association type is ORDERED, for which the first value specified is output for a factor level setting of 1, the second value specified is output for a level of 2, and so on. You can also specify an association type of RANDOM, for which the levels are associated with the values in a random order. Specifying RANDOM is useful for randomizing crossed experiments (see the section "Randomizing Designs" on page 5601).

The following statements give an example of using the OUTPUT statement with only an OUT= data set and with both the NVALS= and CVALS= specifications.

```
proc plan;
   factors a=6 ordered b=3;
```

```
   output out=design a nvals=(10 to 60 by 10)
                     b cvals=('HSX' 'SB2' 'DNY');
run;
```

The DESIGN data set contains two variables, a and b. The values of the variable a are 10 when factor a equals 1, 20 when factor a equals 2, and so on. Values of the variable b are 'HSX' when factor b equals 1, 'SB2' when factor b equals 2, and 'DNY' when factor b equals 3.

Factor-Value-Settings with OUT= and DATA= Data Sets

If you specify an input data set with DATA=, then PROC PLAN assumes that each factor in the last plan generated corresponds to a variable in the input set. If the variable name is different from the name of the factor to which it corresponds, the two can be associated in the values specification by

input-variable-name = *factor-name* **;**

Then, the NVALS= or CVALS= specification can be used. The values given by NVALS= or CVALS= specify the input values as well as the output values for the corresponding variable.

Since the procedure assumes that the collection of input factor values constitutes a plan position description (see the section "Output Data Sets" on page 5597), the values must correspond to integers less than or equal to m, the number of values selected for the associated factor. If any input values do not correspond, then the collection does not define a plan position, and the corresponding observation is output without changing the values of any of the factor variables.

The following statements demonstrate the use of *factor-value-settings*. The input SAS data set a contains variables Block and Plot, which are renamed Day and Hour, respectively.

```
proc plan;
   factors Day=7 Hour=6;
   output data=a out=b
      Block = Day  cvals=('Mon' 'Tue' 'Wed' 'Thu'
                          'Fri' 'Sat' 'Sun'      )
      Plot  = Hour;
run;
```

For another example of using both a DATA= and OUT= data set, see the section "Randomly Assigning Subjects to Treatments" on page 5588.

TREATMENTS Statement

TREATMENTS *factor-selections* **;**

The TREATMENTS statement specifies the *treatments* of the plan to generate, but it does not generate a plan. If you supply several FACTORS and TREATMENTS statements before the first RUN statement, the procedure uses only the last TREATMENTS specification and applies it to the plans generated by each of the FACTORS statements. The TREATMENTS statement has the same form as the FACTORS statement. The individual *factor-selections* also have the same form as in the FACTORS statement:

name **=** *m* < **OF** *n* > < *selection-type* > **;**

The procedure generates each *treatment* simultaneously with the lowest (that is, the most nested) factor in the last FACTORS statement. The *m* value for each *treatment* must be at least as large as the *m* for the most nested factor.

The following statements give an example of using both a FACTORS and a TREATMENTS statement. First the FACTORS statement sets up the rows and columns of a 3×3 square (factors r and c). Then, the TREATMENTS statement augments the square with two cyclic treatments. The resulting design is a 3×3 Graeco-Latin square, a type of design useful in main-effects factorial experiments.

```
proc plan;
   factors r=3 ordered c=3 ordered;
   treatments a=3 cyclic
              b=3 cyclic 2;
run;
```

The resulting Graeco-Latin square design is shown in Figure 67.5. Notice how the values of r and c are ordered (1, 2, 3) as requested.

Figure 67.5 A 3×3 Graeco-Latin Square

```
                    The PLAN Procedure

r       --c--       --a--       --b--

1       1 2 3       1 2 3       1 2 3
2       1 2 3       2 3 1       3 1 2
3       1 2 3       3 1 2       2 3 1
```

Details: PLAN Procedure

Using PROC PLAN Interactively

After specifying a design with a FACTORS statement and running PROC PLAN with a RUN statement, you can generate additional plans and output data sets without invoking PROC PLAN again.

In PROC PLAN, all statements can be used interactively. You can execute statements singly or in groups by following the single statement or group of statements with a RUN statement.

If you use PROC PLAN interactively, you can end the procedure with a DATA step, another PROC step, an ENDSAS statement, or a QUIT statement. The syntax of the QUIT statement is

```
quit;
```

When you use PROC PLAN interactively, additional RUN statements do not end the procedure but tell PROC PLAN to execute additional statements.

Output Data Sets

To understand how PROC PLAN creates output data sets, you need to look at how the procedure represents a plan. A plan is a list of values for all the factors, the values being chosen according to the *factor-selection* requests you specify. For example, consider the plan produced by the following statements:

```
proc plan seed=12345;
   factors a=3 b=2;
run;
```

The plan as displayed by PROC PLAN is shown in Figure 67.6.

Figure 67.6 A Simple Plan

The PLAN Procedure

Factor	Select	Levels	Order
a	3	3	Random
b	2	2	Random

a	-b-
2	2 1
1	1 2
3	2 1

The first cell of the plan has a=2 and b=2, the second has a=2 and b=1, the third has a=1 and b=1, and so on. If you output the plan to a data set with the OUTPUT statement, by default the output data set contains a numeric variable with that factor's name; the values of this numeric variable are the numbers of the successive levels selected for the factor in the plan. For example, the following statements produce Figure 67.7.

```
proc plan seed=12345;
   factors a=3 b=2;
   output out=out;
proc print data=out;
run;
```

Figure 67.7 Output Data Set from Simple Plan

Obs	a	b
1	2	2
2	2	1
3	1	1
4	1	2
5	3	2
6	3	1

Alternatively, you can specify the values that are output for a factor with the CVALS= or NVALS= option. Also, you can specify that the internal values be associated with the output values in random order with the RANDOM option. See the section "OUTPUT Statement" on page 5593.

If you also specify an input data set (DATA=), each factor is associated with a variable in the DATA= data set. This occurs either implicitly by the factor and variable having the same name or explicitly as described in the specifications for the OUTPUT statement. In this case, the values of the variables corresponding to the factors are first read and then interpreted as describing the position of a cell in the plan. Then the respective values taken by the factors at that position are assigned to the variables in the OUT= data set. For example, consider the data set defined by the following statements.

```
data in;
   input a b;
   datalines;
1 1
2 1
3 1
;
```

Suppose you specify this data set as an input data set for the OUTPUT statement.

```
proc plan seed=12345;
   factors a=3 b=2;
   output out=out data=in;
proc print data=out;
run;
```

PROC PLAN interprets the first observation as referring to the cell in the first row and column of the plan, since a=1 and b=1; likewise, the second observation is interpreted as the cell in the second row and first column, and the third observation as the cell in the third row and first column. In the output data set, a and b have the values they have in the plan at these positions, as shown in Figure 67.8.

Figure 67.8 Output Form of Input Data Set from Simple Plan

Obs	a	b
1	2	2
2	1	1
3	3	2

When the factors are random, this has the effect of randomizing the input data set in the same manner as the plan produced (see the sections "Randomizing Designs" on page 5601 and "Randomly Assigning Subjects to Treatments" on page 5588).

Specifying Factor Structures

By appropriately combining features of the PLAN procedure, you can construct an extensive set of designs. The basic tools are the *factor-selections*, which are used in the FACTORS and TREATMENTS statements. Table 67.1 summarizes how the procedure interprets various *factor-selections* (assuming that the ORDERED option is not specified in the PROC PLAN statement).

Table 67.1 *Factor-Selection* Interpretation

Form of Request	Interpretation	Example	Results
name=*m*	produce a random permutation of the integers $1, 2, \ldots, m$	`t=15`	lists a random ordering of the numbers $1, 2, \ldots, 15$
name=*m* cyclic	cyclically permute the integers $1, 2, \ldots, m$	`t=5 cyclic`	selects the integers 1 to 5. On the next iteration, selects 2,3,4,5,1; then 3,4,5,1,2; and so on.
name=*m* of *n*	choose a random sample of m integers (without replacement) from the set of integers $1, 2, \ldots, n$	`t=5 of 15`	lists a random selection of 5 numbers from 1 to 15. First, the procedure selects 5 numbers and then arranges them in random order.
name=*m* of *n* ordered	has the same effect as *name*=*m* ordered	`t=5 of 15 ordered`	lists the integers 1 to 5 in increasing order (same as t=5 ordered)
name=*m* of *n* cyclic	permute m of the n integers	`t=5 of 30 cyclic`	selects the integers 1 to 5. On the next iteration, selects 2,3,4,5,6; then 3,4,5,6,7; and so on. The 30th iteration produces 30,1,2,3,4; the 31st iteration produces 1,2,3,4,5; and so on.

Table 67.1 *continued*

Form of Request	Interpretation	Example	Results
name=*m* perm	produce a list of all permutations of *m* integers	`t=5 perm`	lists the integers 1,2,3,4,5 on the first iteration; on the second lists 1,2,3,5,4; on the 119th iteration lists 5,4,3,1,2; and on the last (120th) lists 5,4,3,2,1.
name=*m* of *n* comb	choose combinations of *m* integers from *n* integers	`t=3 of 5 comb`	lists all combinations of 5 choose 3 integers. The first iteration is 1,2,3; the second is 1,2,4; the third is 1,2,5; and so on until the last iteration 3,4,5.
name=*m* of *n* cyclic (*initial-block*)	permute *m* of the *n* integers, starting with the values specified in the *initial-block*	`t=4 of 30 cyclic (2 10 15 18)`	selects the integers 2,10,15,18. On the next iteration, selects 3,11,16,19; then 4,12,17,20; and so on. The thirteenth iteration is 14,22,27,30; the fourteenth iteration is 15,23,28,1; and so on.
name=*m* of *n* cyclic (*initial-block*) *increment*	permute *m* of the *n* integers. Start with the values specified in the *initial-block*, then add the *increment* to each value.	`t=4 of 30 cyclic (2 10 15 18) 2`	selects the integers 2,10,15,18. On the next iteration, selects 4,12,17,20; then 6,14,19,22; and so on. The wrap occurs at the eighth iteration. The eighth iteration is 16,24,29,2; and so on.

In Table 67.1, in order for more than one iteration to appear in the plan, another *name*=*j* factor selection (with $j > 1$) must precede the example factor selection. For example, the following statements produce six of the iterations described in the last entry of Table 67.1.

```
proc plan;
   factors c=6 ordered t=4 of 30 cyclic (2 10 15 18) 2;
run;
```

The following statements create a randomized complete block design and output the design to a data set.

```
proc plan ordered;
   factors blocks=3 cell=5;
   treatments t=5 random;
   output out=rcdb;
run;
```

Randomizing Designs

In many situations, proper randomization is crucial for the validity of any conclusions to be drawn from an experiment. Randomization is used both to neutralize the effect of any unknown systematic biases that might be involved in the design and to provide a basis for the assumptions underlying the analysis.

You can use PROC PLAN to randomize an already existing design: one produced by a previous call to PROC PLAN, perhaps, or a more specialized design taken from a standard reference such as Cochran and Cox (1957). The method is to specify the appropriate block structure in the FACTORS statement and then to specify the data set where the design is stored with the DATA= option in the OUTPUT statement. For an illustration of this method, see the section "Randomly Assigning Subjects to Treatments" on page 5588).

Two sorts of randomization are provided for, corresponding to the RANDOM factor selection and association types in the FACTORS and OUTPUT statements, respectively. Designs in which factors are completely nested (for example, block designs) should be randomized by specifying that the selection type of each factor is RANDOM in the FACTORS statement, which is the default (see Example 67.3). On the other hand, if the factors are crossed (for example, row-and-column designs), they should be randomized by one random reassignment of their values for the whole design. To do this, specify that the association type of each factor is RANDOM in the OUTPUT statement (see Example 67.4).

Displayed Output

The PLAN procedure displays the following output:

- the *m* value for each factor, which is the number of values to be selected
- the *n* value for each factor, which is the number of values to be selected from
- the selection type for each factor, as specified in the FACTORS statement
- the initial block and increment number for cyclic factors
- the *factor-value-selections* making up each plan

In addition, notes are written to the log that give the starting and ending values of the random number seed for each call to PROC PLAN.

ODS Table Names

PROC PLAN assigns a name to each table it creates. You can use these names to reference the table in the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 67.2 ODS Tables Produced by PROC PLAN

ODS Table Name	Description	Statements
FInfo	General factor information	FACTORS and no TREATMENTS
PFInfo	Plot factor information	FACTORS and TREATMENTS
Plan	Computed plan	default
TFInfo	Treatment factor information	FACTORS and TREATMENTS

Examples: PLAN Procedure

Example 67.1: A Split-Plot Design

This plan is appropriate for a split-plot design with main plots forming a randomized complete block design. In this example, there are three blocks, four main plots per block, and two subplots per main plot. First, three random permutations (one for each of the blocks) of the integers 1, 2, 3, and 4 are produced. The four integers correspond to the four levels of the main plot factor a; the permutation determines how the levels of a are assigned to the main plots within a block. For each of these 12 numbers (four numbers per block for three blocks), a random permutation of the integers 1 and 2 is produced. Each two-integer permutation determines the assignment of the two levels of the subplot factor b within a main plot. The following statements produce Output 67.1.1:

```
title 'Split Plot Design';
proc plan seed=37277;
   factors Block=3 ordered a=4 b=2;
run;
```

Output 67.1.1 A Split-Plot Design

Split Plot Design

The PLAN Procedure

Factor	Select	Levels	Order
Block	3	3	Ordered
a	4	4	Random
b	2	2	Random

Block	a	-b-
1	4	2 1
	3	2 1
	1	2 1
	2	2 1
2	4	1 2
	3	1 2
	1	2 1
	2	1 2
3	4	2 1
	2	2 1
	3	2 1
	1	2 1

Example 67.2: A Hierarchical Design

In this example, three plants are nested within four pots, which are nested within three houses. The FACTORS statement requests a random permutation of the numbers 1, 2, and 3 to choose Houses randomly. The second step requests a random permutation of the numbers 1, 2, 3, and 4 for each of those first three numbers to randomly assign Pots to Houses. Finally, the FACTORS statement requests a random permutation of 1, 2, and 3 for each of the 12 integers in the second set of permutations. This last step randomly assigns Plants to Pots. The following statements produce Output 67.2.1:

```
title 'Hierarchical Design';
proc plan seed=17431;
   factors Houses=3 Pots=4 Plants=3 / noprint;
   output out=nested;
run;

proc print data=nested;
run;
```

Output 67.2.1 A Hierarchical Design

Hierarchical Design

Obs	Houses	Pots	Plants
1	1	3	2
2	1	3	3
3	1	3	1

34	3	3	3
35	3	3	2
36	3	3	1

Example 67.3: An Incomplete Block Design

Jarrett and Hall (1978) give an example of a generalized cyclic design with good efficiency characteristics. The design consists of two replicates of 52 treatments in 13 blocks of size 8. The following statements use the PLAN procedure to generate this design in an appropriately randomized form and store it in a SAS data set GCBD. Then the design is sorted and transposed to display in randomized order. The following statements produce Output 67.3.1 and Output 67.3.2:

```
title 'Generalized Cyclic Block Design';
proc plan seed=33373;
   treatments Treatment=8 of 52 cyclic (1 2 3 4 32 43 46 49) 4;
   factors Block=13 Plot=8;
   output out=GCBD;
quit;
proc sort data=GCBD out=GCBD;
   by Block Plot;
proc transpose data= GCBD(rename=(Plot=_NAME_))
               out =tGCBD(drop=_NAME_);
   by Block;
   var Treatment;
proc print data=tGCBD noobs;
run;
```

Output 67.3.1 A Generalized Cyclic Block Design

Generalized Cyclic Block Design

The PLAN Procedure

Plot Factors

13	47	35	45	24	46	38	41	48

Example 67.4: A Latin Square Design

All of the preceding examples involve designs with completely nested block structures, for which PROC PLAN was especially designed. However, by appropriate coordination of its facilities, a much wider class of designs can be accommodated. A Latin square design is based on experimental units that have a row-and-column block structure. The following example uses the CYCLIC option for a treatment factor tmts to generate a simple 4×4 Latin square. Randomizing a Latin square design involves randomly permuting the row, column, and treatment values independently. In order to do this, use the RANDOM option in the OUTPUT statement of PROC PLAN. The example also uses *factor-value-settings* in the OUTPUT statement. The following statements produce Output 67.4.1:

```
title 'Latin Square Design';
proc plan seed=37430;
   factors Row=4 ordered Col=4 ordered / noprint;
   treatments Tmt=4 cyclic;
   output out=LatinSquare
          Row cvals=('Day 1' 'Day 2' 'Day 3' 'Day 4') random
          Col cvals=('Lab 1' 'Lab 2' 'Lab 3' 'Lab 4') random
          Tmt nvals=(      0     100     250     450) random;
quit;
proc sort data=LatinSquare out=LatinSquare;
   by Row Col;
proc transpose data= LatinSquare(rename=(Col=_NAME_))
                out =tLatinSquare(drop=_NAME_);
   by Row;
   var Tmt;
proc print data=tLatinSquare noobs;
run;
```

Output 67.4.1 A Randomized Latin Square Design

Latin Square Design

Row	Lab_1	Lab_2	Lab_3	Lab_4
Day 1	0	250	100	450
Day 2	250	450	0	100
Day 3	100	0	450	250
Day 4	450	100	250	0

Example 67.5: A Generalized Cyclic Incomplete Block Design

The following statements depict how to create an appropriately randomized generalized cyclic incomplete block design for v treatments (given by the value of t) in b blocks (given by the value of b) of size k (with values of p indexing the cells within a block) with initial block $(e_1\ e_2\ \cdots\ e_k)$ and increment number i.

```
factors b=b p=k ;
treatments t=k of v cyclic (e1 e2 ... ek ) i ;
```

For example, the specification

```
proc plan seed=37430;
   factors b=10 p=4;
   treatments t=4 of 30 cyclic (1 3 4 26) 2;
run;
```

generates the generalized cyclic incomplete block design given in Example 1 of Jarrett and Hall (1978), which is given by the rows and columns of the plan associated with the treatment factor t in Output 67.5.1.

Output 67.5.1 A Generalized Cyclic Incomplete Block Design

The PLAN Procedure

Plot Factors

Factor	Select	Levels	Order
b	10	10	Random
p	4	4	Random

Treatment Factors

Factor	Select	Levels	Order	Initial Block / Increment
t	4	30	Cyclic	(1 3 4 26) / 2

Output 67.5.1 *continued*

b	---p---	-----t-----
2	2 3 1 4	1 3 4 26
1	3 2 4 1	3 5 6 28
3	2 3 4 1	5 7 8 30
10	4 2 3 1	7 9 10 2
9	4 1 2 3	9 11 12 4
4	1 3 2 4	11 13 14 6
5	1 2 4 3	13 15 16 8
8	3 2 4 1	15 17 18 10
7	2 4 1 3	17 19 20 12
6	2 1 4 3	19 21 22 14

Example 67.6: Permutations and Combinations

Occasionally, you might need to generate all possible permutations of n things, or all possible combinations of n things taken m at a time.

For example, suppose you are planning an experiment in cognitive psychology where you want to present four successive stimuli to each subject. You want to observe each permutation of the four stimuli. The following statements use PROC PLAN to create a data set containing all possible permutations of four numbers in random order.

```
title 'All Permutations of 1,2,3,4';
proc plan seed=60359;
   factors    Subject  = 24
              Order    = 4  ordered;
   treatments Stimulus = 4  perm;
   output out=Psych;
run;
proc sort data=Psych out=Psych;
   by Subject Order;
proc transpose data= Psych(rename=(Order=_NAME_))
                out =tPsych(drop=_NAME_);
   by Subject;
   var Stimulus;
proc print data=tPsych noobs;
run;
```

The variable Subject is set at 24 levels because there are $4! = 24$ total permutations to be listed. If Subject $>$ 24, the list repeats. Output 67.6.1 displays the PROC PLAN output. Note that the variable Subject is listed in random order.

Output 67.6.1 List of Permutations

All Permutations of 1,2,3,4

The PLAN Procedure

Plot Factors

Factor	Select	Levels	Order
Subject	24	24	Random
Order	4	4	Ordered

Treatment Factors

Factor	Select	Levels	Order
Stimulus	4	4	Perm

Subject	-Order-	-Stimulus-
4	1 2 3 4	1 2 3 4
15	1 2 3 4	1 2 4 3
24	1 2 3 4	1 3 2 4
1	1 2 3 4	1 3 4 2
5	1 2 3 4	1 4 2 3
17	1 2 3 4	1 4 3 2
19	1 2 3 4	2 1 3 4
14	1 2 3 4	2 1 4 3
6	1 2 3 4	2 3 1 4
23	1 2 3 4	2 3 4 1
8	1 2 3 4	2 4 1 3
2	1 2 3 4	2 4 3 1
13	1 2 3 4	3 1 2 4
16	1 2 3 4	3 1 4 2
12	1 2 3 4	3 2 1 4
18	1 2 3 4	3 2 4 1
21	1 2 3 4	3 4 1 2
9	1 2 3 4	3 4 2 1
22	1 2 3 4	4 1 2 3
10	1 2 3 4	4 1 3 2
7	1 2 3 4	4 2 1 3
11	1 2 3 4	4 2 3 1
3	1 2 3 4	4 3 1 2
20	1 2 3 4	4 3 2 1

The output data set Psych contains 96 observations of the 3 variables (Subject, Order, and Stimulus). Sorting the output data set by Subject and by Order within Subject results in all possible permutations of Stimulus in random order. PROC TABULATE displays these permutations in Output 67.6.2.

Output 67.6.2 Randomized Permutations

All Permutations of 1,2,3,4

Subject	_1	_2	_3	_4
1	1	3	4	2
2	2	4	3	1
3	4	3	1	2
4	1	2	3	4
5	1	4	2	3
6	2	3	1	4
7	4	2	1	3
8	2	4	1	3
9	3	4	2	1
10	4	1	3	2
11	4	2	3	1
12	3	2	1	4
13	3	1	2	4
14	2	1	4	3
15	1	2	4	3
16	3	1	4	2
17	1	4	3	2
18	3	2	4	1
19	2	1	3	4
20	4	3	2	1
21	3	4	1	2
22	4	1	2	3
23	2	3	4	1
24	1	3	2	4

As another example, suppose you have six alternative treatments, any four of which can occur together in a block (in no particular order). The following statements use PROC PLAN to create a data set containing all possible combinations of six numbers taken four at a time. In this case, you use ODS to create the data set.

```
title 'All Combinations of (6 Choose 4) Integers';
proc plan;
   factors Block=15 ordered
           Treat= 4 of 6 comb;
   ods output Plan=Combinations;
run;
proc print data=Combinations noobs;
run;
```

The variable Block has 15 levels since there are a total of $6!/(4!2!) = 15$ combinations of four integers chosen from six integers. The data set formed by ODS from the displayed plan has one row for each block, with the four values of Treat corresponding to four different variables, as shown in Output 67.6.3 and Output 67.6.4.

Output 67.6.3 List of Combinations

All Combinations of (6 Choose 4) Integers

The PLAN Procedure

Factor	Select	Levels	Order
Block	15	15	Ordered
Treat	4	6	Comb

Block	-Treat-
1	1 2 3 4

12	2	3	4	6
13	2	3	5	6
14	2	4	5	6
15	3	4	5	6

Example 67.7: Crossover Designs

In *crossover* experiments, the same experimental units or subjects are given multiple treatments in sequence, and the model for the response at any one period includes an effect for the treatment applied in the previous period. A good design for a crossover experiment is therefore one that balances how often each treatment is preceded by each other treatment. Cox (1992) gives the following example of a balanced crossover experiment for paper production. In this experiment, the subjects are production runs of the mill, with the treatments being six different concentrations of pulp used in sequence. The following statements construct this design in a standard form:

```
proc plan;
   factors Run=6 ordered Period=6 ordered;
   treatments Treatment=6 cyclic (1 2 6 3 5 4);
run;
```

Output 67.7.1 shows the results of the preceding statements.

Output 67.7.1 Crossover Design for Six Treatments

```
                          The PLAN Procedure

                            Plot Factors

                Factor      Select      Levels     Order

                Run              6           6    Ordered
                Period           6           6    Ordered

                          Treatment Factors

                                                  Initial Block
Factor          Select      Levels     Order      / Increment

Treatment            6           6    Cyclic     (1 2 6 3 5 4) / 1

                   Run      ---Period--      -Treatment-

                     1      1 2 3 4 5 6      1 2 6 3 5 4
                     2      1 2 3 4 5 6      2 3 1 4 6 5
                     3      1 2 3 4 5 6      3 4 2 5 1 6
                     4      1 2 3 4 5 6      4 5 3 6 2 1
                     5      1 2 3 4 5 6      5 6 4 1 3 2
                     6      1 2 3 4 5 6      6 1 5 2 4 3
```

The construction method for this example is due to Williams (1949). The initial block for the treatment variable Treatment is defined as follows for $n = 6$:

$$(1 \quad 2\ n \quad 3\ n-1 \quad \ldots \quad n/2\ n/2+2 \quad n/2)$$

This general form serves to generate a balanced crossover design for n treatments and n subjects in n periods when n is even. When n is odd, $2n$ subjects are required, with the following initial blocks, respectively for odd and even n:

$$(1 \quad 2 \;\; n \quad 3 \;\; n-1 \quad \ldots \quad n/2+1 \;\; n/2)$$
$$(n/2 \;\; n/2+1 \quad \ldots \quad n-1 \;\; 3 \quad n \;\; 2 \quad 1)$$

In order to randomize Williams' crossover designs, the following statements randomly permute the subjects and treatments:

```
proc plan seed=136149876;
   factors Run=6 ordered Period=6 ordered / noprint;
   treatments Treatment=6 cyclic (1 2 6 3 5 4);
   output out=RandomizedDesign
      Run       random
      Treatment random
      ;

/*
/ Relabel Period to obtain the same design as in Cox (1992).
/-------------------------------------------------------------------*/
data RandomizedDesign; set RandomizedDesign;
   Period = mod(Period+2,6)+1;
run;
proc sort data=RandomizedDesign;
   by Run Period;
proc transpose data=RandomizedDesign out=tDesign(drop=_name_);
   by notsorted Run;
   var Treatment;
data tDesign; set tDesign;
   rename COL1-COL6 = Period_1-Period_6;
proc print data=tDesign noobs;
run;
```

In the preceding statements, Run and Treatment are randomized by using the RANDOM option in the OUTPUT statement, and new labels for Period are obtained in a subsequent DATA step. This Period relabeling is not necessary and might not be valid for Williams' designs in general; it is used in this example only to match results with those of Cox (1992). The SORT and TRANSPOSE steps then prepare the design to be printed in a standard form, shown in Output 67.7.2.

Output 67.7.2 Randomized Crossover Design

Run	Period_1	Period_2	Period_3	Period_4	Period_5	Period_6
1	3	6	2	5	4	1
2	5	3	4	6	1	2
3	1	4	5	2	6	3
4	2	1	6	4	3	5
5	6	5	1	3	2	4
6	4	2	3	1	5	6

The analysis of a crossover experiment requires for each observation a *carryover* variable whose values are the treatment in the preceding period. The following statements add such a variable to the randomized design constructed previously:

```
proc sort data=RandomizedDesign;
   by Run Period;
data RandomizedDesign; set RandomizedDesign;
   by Run period;
   LagTreatment = lag(Treatment);
   if (first.Run) then LagTreatment = .;
run;

proc transpose data=RandomizedDesign out=tDesign(drop=_name_);
   by notsorted Run;
   var LagTreatment;
data tDesign; set tDesign;
   rename COL1-COL6 = Period_1-Period_6;
proc print data=tDesign noobs;
run;
```

Output 67.7.3 displays the values of the carryover variable for each run and period.

Output 67.7.3 Lag Treatment Effect in Crossover Design

Run	Period_1	Period_2	Period_3	Period_4	Period_5	Period_6
1	.	3	6	2	5	4
2	.	5	3	4	6	1
3	.	1	4	5	2	6
4	.	2	1	6	4	3
5	.	6	5	1	3	2
6	.	4	2	3	1	5

Of course, the carryover variable has no effect in the first period, which is why it is coded with a missing value in this case.

The experimental LAG effect in the EFFECT statement in PROC ORTHOREG provides a convenient mechanism for incorporating the carryover effect into the analysis. The following statements first add the observed data to the design to create the Mills data set. Then PROC ORTHOREG is invoked, and the carryover effect is defined as a lag effect with the relevant period and subject information specified. ODS is used to trim down the results to show only the parts that are usually of interest in crossover analysis. For more information about the EFFECTS statement in PROC ORTHOREG, see the section "EFFECT Statement" on page 5344.

```

The Type I analysis of variance indicates that all effects are significant—in particular, both the direct and the carryover effects of the treatment. In the presence of carryover effects, the LS-means need to be defined with some care. The LS-means for treatments computed using balanced margins for the carryover effect are inestimable; so the OBSMARGINS option is specified in the LSMEANS statement in order to use the observed margins instead. The observed margins take the absence of a carryover effect in the first period into account. Note that the LS-means themselves of the carryover effect are inestimable, but their differences are estimable. The LS-means of the direct effect of the treatment and the ANOM differences for the LS-means of their carryover effect match the "adjusted direct effects" and "adjusted residual effects," respectively, of Cox (1992).

Chapter 68

The PLM Procedure

Contents

Overview: PLM Procedure

The PLM procedure performs postfitting statistical analyses for the contents of a SAS item store that was previously created with the STORE statement in some other SAS/STAT procedure. An item store is a special SAS-defined binary file format used to store and restore information with a hierarchical structure.

The statements available in the PLM procedure are designed to reveal the contents of the source item store via the Output Delivery System (ODS) and to perform postfitting tasks such as the following:

- testing hypotheses
- computing confidence intervals
- producing prediction plots
- scoring a new data set

The use of item stores and PROC PLM enables you to separate common postprocessing tasks, such as testing for treatment differences and predicting new observations under a fitted model, from the process of model building and fitting. A numerically expensive model fitting technique can be applied once to produce a source item store. The PLM procedure can then be called multiple times and the results of the fitted model analyzed without incurring the model fitting expenditure again.

The PLM procedure offers the most advanced postprocessing techniques available in SAS/STAT software. These techniques include step-down multiplicity adjustments for p-values, F tests with order restrictions, analysis of means (ANOM), and sampling-based linear inference based on Bayes posterior estimates.

The following procedures support the STORE statement for the generation of item stores that can be processed with the PLM procedure: GENMOD, GLIMMIX, GLM, LOGISTIC, MIXED, ORTHOREG, PHREG, SURVEYLOGISTIC, SURVEYPHREG, and SURVEYREG. For details about the STORE statement, see the section "STORE Statement" on page 516 of Chapter 19, "Shared Concepts and Topics."

Basic Features

The PLM procedure, unlike most SAS/STAT procedures, does not operate primarily on an input data set. Instead, the procedure requires you to specify an item store with the SOURCE= option in the PROC PLM statement. The item store contains the necessary information and context about the statistical model that was fit when the store was created. SAS data sets are used only to provide input information in some circumstances. For example, when scoring a data set or when computing least squares means with specially defined population margins. In other words, instead of reading raw data and fitting a model, the PLM procedure reads the results of a model having been fit.

In order to interact with the item store and to reveal its contents, the PLM procedure supports the SHOW statement which converts item store information into standard ODS tables for viewing and further processing.

The PLM procedure is sensitive to the contents of the item store. For example, if a BAYES statement was in effect when the item store was created, the posterior parameter estimates are saved to the item store so that the PLM procedure can perform postprocessing tasks by taking the posterior distribution of estimable functions into account. As another example, for item stores that are generated by a mixed model procedure using the Satterthwaite or Kenward-Roger (Kenward and Roger 1997) degrees-of-freedom method, these methods continue to be available when the item store contents are processed with the PLM procedure.

Because the PLM procedure does not read data and does not fit a model, the processing time of this procedure is usually considerably less than the processing time of the procedure that generates the item store.

PROC PLM Contrasted with Other SAS Procedures

In contrast to other analytic procedures in SAS/STAT software, the PLM procedure does not use an input data set. Instead, it retrieves information from an item store.

Some of the statements in the PLM procedure are also available as postprocessing statements in other procedures. Table 68.1 lists SAS/STAT procedures that support the same postprocessing statements as PROC PLM does.

Table 68.1 SAS/STAT Procedures with Postprocessing Statements Similar to PROC PLM

	EFFECTPLOT	ESTIMATE	LSMEANS	LSMESTIMATE	SLICE	TEST
GENMOD	√	√*	√	√	√	
GLIMMIX		√*	√*	√*	√	
GLM		√*	√*			√*
LOGISTIC	√	√	√	√	√	√*
MIXED		√*	√*	√	√	
ORTHOREG	√	√	√	√	√	√
PHREG		√	√	√	√	√*
SURVEYLOGISTIC		√	√	√	√	√*
SURVEYPHREG		√	√	√	√	√
SURVEYREG		√	√	√	√	√

Table entries marked with √ indicate procedures that support statements with the same functionality as in PROC PLM. Those entries marked with √* indicate procedures that support statements with same names but different syntaxes from PROC PLM. You can find the most comprehensive set of features for these statements in the PLM procedure. For example, the LSMEANS statement is available in all of the listed procedures. For example, the ESTIMATE statement available in the GENMOD, GLIMMIX, GLM and MIXED procedures does not support all options that PROC PLM supports, such as multiple rows and multiplicity adjustments.

The WHERE statement in other procedures enables you to conditionally select a subset of the observations from the input data set so that the procedure processes only the observations that meet the specified conditions. Since the PLM procedure does not use an input data set, the WHERE statement in the PLM procedure has different functionality. If the item store contains information about By groups—that is, a BY statement was in effect when the item store was created—you can use the WHERE statement to select specific BY groups for the analysis. You can also use the FILTER statement in the PLM procedure to filter results from the ODS output and output data sets.

Getting Started: PLM Procedure

The following DATA step creates a data set from a randomized block experiment with a factorial treatment structure of factors A and B:

```
data BlockDesign;
   input block a b y @@;
   datalines;
   1 1 1  56  1 1 2  41
   1 2 1  50  1 2 2  36
   1 3 1  39  1 3 2  35
   2 1 1  30  2 1 2  25
   2 2 1  36  2 2 2  28
   2 3 1  33  2 3 2  30
   3 1 1  32  3 1 2  24
   3 2 1  31  3 2 2  27
   3 3 1  15  3 3 2  19
   4 1 1  30  4 1 2  25
   4 2 1  35  4 2 2  30
   4 3 1  17  4 3 2  18
;
```

The GLM procedure is used in the following statements to fit the model and to create a source item store for the PLM procedure:

```
proc glm data=BlockDesign;
   class block a b;
   model y = block a b a*b / solution;
   store sasuser.BlockAnalysis / label='PLM: Getting Started';
run;
```

The CLASS statement identifies the variables Block, A, and B as classification variables. The MODEL statement specifies the response variable and the model effects. The block effect models the design effect, and the a, b, and a*b effects model the factorial treatment structure. The STORE statement requests that the context and results of this analysis be saved to an item store named sasuser.BlockAnalysis. Because the SASUSER library is specified as the library name of the item store, the store will be available after the SAS session completes. The optional label in the STORE statement identifies the store in subsequent analyses with the PLM procedure.

Note that having BlockDesign as the name of the output store would not create a conflict with the input data set name, because data sets and item stores are saved as files of different types.

Figure 68.1 displays the results from the GLM procedure. The "Class Level Information" table shows the number of levels and their values for the three classification variables. The "Parameter Estimates" table shows the estimates and their standard errors along with t tests.

Figure 68.1 Class Variable Information, Fit Statistics, and Parameter Estimates

The GLM Procedure

Class Level Information

Class	Levels	Values
block	4	1 2 3 4
a	3	1 2 3
b	2	1 2

R-Square	Coeff Var	Root MSE	y Mean
0.848966	15.05578	4.654747	30.91667

Parameter		Estimate		Standard Error	t Value	Pr > |t|
Intercept		20.41666667	B	2.85043856	7.16	<.0001
block	1	17.00000000	B	2.68741925	6.33	<.0001
block	2	4.50000000	B	2.68741925	1.67	0.1148
block	3	-1.16666667	B	2.68741925	-0.43	0.6704
block	4	0.00000000	B	.	.	.
a	1	3.25000000	B	3.29140294	0.99	0.3391
a	2	4.75000000	B	3.29140294	1.44	0.1695
a	3	0.00000000	B	.	.	.
b	1	0.50000000	B	3.29140294	0.15	0.8813
b	2	0.00000000	B	.	.	.
a*b	1 1	7.75000000	B	4.65474668	1.66	0.1167
a*b	1 2	0.00000000	B	.	.	.
a*b	2 1	7.25000000	B	4.65474668	1.56	0.1402
a*b	2 2	0.00000000	B	.	.	.
a*b	3 1	0.00000000	B	.	.	.
a*b	3 2	0.00000000	B	.	.	.

The following statements invoke the PLM procedure and use sasuser.BlockAnalysis as the source item store:

```
proc plm source=sasuser.BlockAnalysis;
run;
```

These statements produce Figure 68.2. The "Store Information" table displays information that is gleaned from the source item store. For example, the store was created by the GLM procedure at the indicated time and date, and the input data set for the analysis was WORK.BLOCKDESIGN. The label used earlier in the STORE statement of the GLM procedure also appears as a descriptor in Figure 68.2.

Figure 68.2 Default Information

The PLM Procedure

Store Information

Item Store	SASUSER.BLOCKANALYSIS
Label	PLM: Getting Started
Data Set Created From	WORK.BLOCKDESIGN
Created By	PROC GLM
Date Created	18FEB11:10:45:13
Response Variable	y
Class Variables	block a b
Model Effects	Intercept block a b a*b

Class Level Information

Class	Levels	Values
block	4	1 2 3 4
a	3	1 2 3
b	2	1 2

The "Store Information" table also echoes partial information about the variables and model effects that are used in the analysis. The "Class Level Information" table is produced by the PLM procedure by default whenever the model contains effects that depend on CLASS variables.

The following statements request a display of the fit statistics and the parameter estimates from the source item store and a test of the treatment main effects and their interactions:

```
proc plm source=sasuser.BlockAnalysis;
   show fit parms;
   test a b a*b;
run;
```

The statements produce Figure 68.3. Notice that the estimates and standard errors in the "Parameter Estimates" table agree with the results displayed earlier by the GLM procedure, except for small differences in formatting.

Figure 68.3 Fit Statistics, Parameter Estimates, and Tests of Effects

The PLM Procedure

Fit Statistics

MSE	21.66667
Error df	15

Parameter Estimates

Effect	block	a	b	Estimate	Standard Error
Intercept				20.4167	2.8504
block	1			17.0000	2.6874
block	2			4.5000	2.6874
block	3			-1.1667	2.6874
block	4			0	.
a		1		3.2500	3.2914
a		2		4.7500	3.2914
a		3		0	.
b			1	0.5000	3.2914
b			2	0	.
a*b		1	1	7.7500	4.6547
a*b		1	2	0	.
a*b		2	1	7.2500	4.6547
a*b		2	2	0	.
a*b		3	1	0	.
a*b		3	2	0	.

Type III Tests of Model Effects

Effect	Num DF	Den DF	F Value	Pr > F
a	2	15	7.54	0.0054
b	1	15	8.38	0.0111
a*b	2	15	1.74	0.2097

Since the main effects, but not the interaction are significant in this experiment, the subsequent analysis focuses on the main effects, in particular on the effect of variable A.

The following statements request the least squares means of the A effect along with their pairwise differences:

```
proc plm source=sasuser.BlockAnalysis seed=3;
   lsmeans     a          / diff;
   lsmestimate a -1 1,
                  1  1 -2 / uppertailed ftest;
run;
```

The LSMESTIMATE statement tests two linear combinations of the A least squares means: equality of the first two levels and whether the sum of the first two level effects equals twice the effect of the third level. The FTEST option in the LSMESTIMATE statement requests a joint F tests for this two-row contrast. The UPPERTAILED option requests that the F test also be carried out under one-sided order restrictions. Since F tests under order restrictions (chi-bar-square statistic) require a simulation-based approach for the calculation of p-values, the random number stream is initialized with a known seed value through the SEED= option in the PROC PLM statement.

The results of the LSMEANS and the LSMESTIMATE statement are shown in Figure 68.4.

Figure 68.4 LS-Means Related Inference for A Effect

The PLM Procedure

a Least Squares Means

a	Estimate	Standard Error	DF	t Value	Pr > |t|
1	32.8750	1.6457	15	19.98	<.0001
2	34.1250	1.6457	15	20.74	<.0001
3	25.7500	1.6457	15	15.65	<.0001

Differences of a Least Squares Means

a	_a	Estimate	Standard Error	DF	t Value	Pr > |t|
1	2	-1.2500	2.3274	15	-0.54	0.5991
1	3	7.1250	2.3274	15	3.06	0.0079
2	3	8.3750	2.3274	15	3.60	0.0026

Least Squares Means Estimates

Effect	Label	Estimate	Standard Error	DF	t Value	Tails	Pr > t
a	Row 1	1.2500	2.3274	15	0.54	Upper	0.2995
a	Row 2	15.5000	4.0311	15	3.85	Upper	0.0008

F Test for Least Squares Means Estimates

Effect	Num DF	Den DF	F Value	Pr > F	ChiBar Sq Value	Pr > ChiBarSq
a	2	15	7.54	0.0054	15.07	0.0001

The least squares means for the three levels of variable A are 32.875, 34.125, and 25.75. The differences between the third level and the first and second levels are statistically significant at the 5% level (p-values of 0.0079 and 0.0026, respectively). There is no significant difference between the first two levels. The first row of the "Least Squares Means Estimates" table also displays the difference between the first two

levels of factor A. Although the (absolute value of the) estimate and its standard error are identical to those in the "Differences of a Least Squares Means" table, the *p*-values do not agree because one-sided tests were requested in the LSMESTIMATE statement.

The "F Test" table in Figure 68.4 shows the two degree-of-freedom test for the linear combinations of the LS-means. The *F* value of 7.54 with *p*-value of 0.0054 represents the usual (two-sided) *F* test. Under the one-sided right-tailed order restriction imposed by the UPPERTAILED option, the ChiBarSq value of 15.07 represents the observed value of the chi-bar-square statistic of Silvapulle and Sen (2004). The associated *p*-value of 0.0001 was obtained by simulation.

Now suppose that you are interested in analyzing the relationship of the interaction cell means. (Typically this would not be the case in this example since the a*b interaction is not significant; see Figure 68.3.) The SLICE statement in the following PROC PLM run produces an *F* test of equality and all pair-wise differences of the interaction means for the subset (partition) where variable B is at level '1'. With ODS Graphics enabled, the pairwise differences are displayed in a diffogram by default.

```
ods graphics on;
proc plm source=sasuser.BlockAnalysis;
   slice a*b / sliceby(b='1') diff;
run;
ods graphics off;
```

The results are shown in Figure 68.5. Since variable A has three levels, the test of equality of the A means at level '1' of B is a two-degree comparison. This comparison is statistically significant (*p*-value equals 0.0040). You can conclude that the three levels of A are not the same for the first level of B.

Figure 68.5 Results from Analyzing an Interaction Partition

The PLM Procedure

F Test for a*b Least Squares Means Slice

Slice	Num DF	Den DF	F Value	Pr > F
b 1	2	15	8.18	0.0040

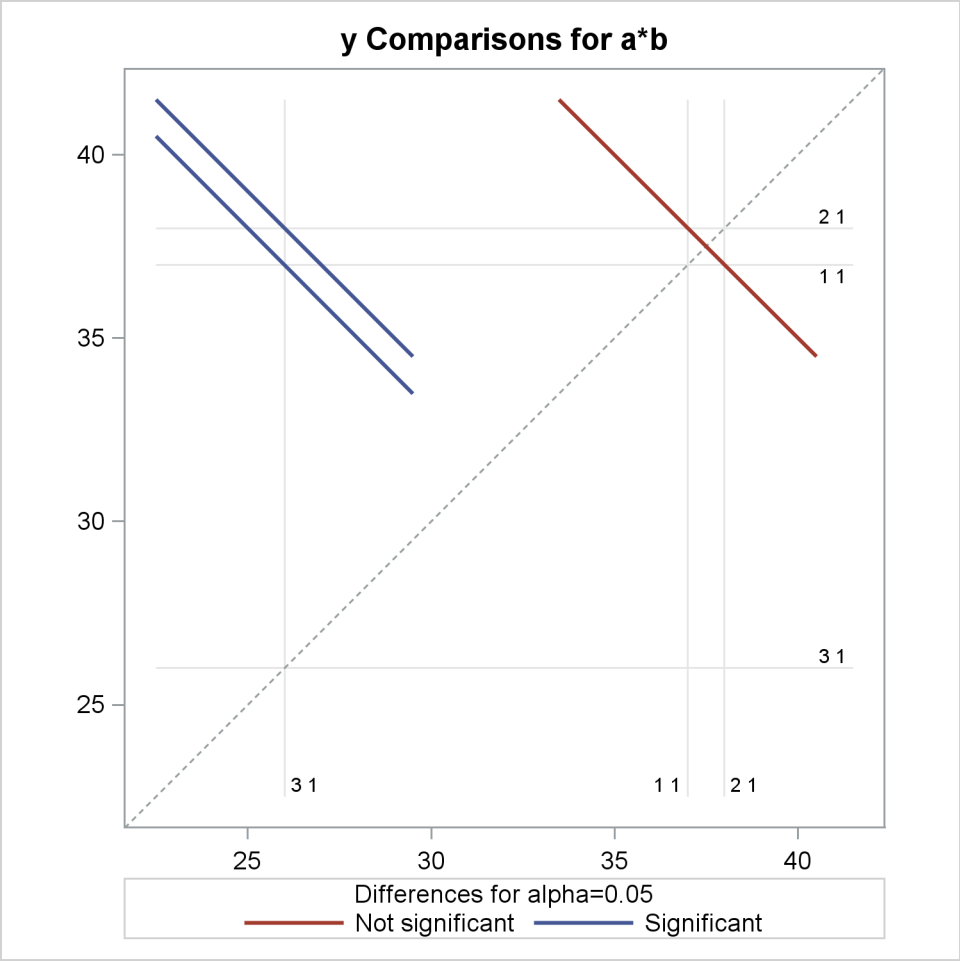
Simple Differences of a*b Least Squares Means

Slice	a	_a	Estimate	Standard Error	DF	t Value	Pr > |t|
b 1	1	2	-1.0000	3.2914	15	-0.30	0.7654
b 1	1	3	11.0000	3.2914	15	3.34	0.0045
b 1	2	3	12.0000	3.2914	15	3.65	0.0024

The table of "Simple Differences" was produced by the DIFF option in the SLICE statement. As is the case with the marginal comparisons in Figure 68.4, there are significant differences against the third level of A if variable B is held fixed at '1'.

Figure 68.6 shows the diffogram that displays the three pairwise least squares mean differences and their significance. Each line segment corresponds to a comparison. It centers at the least squares means in the pair with its length corresponding to the projected width of a confidence interval for the difference. If the variable B is held fixed at '1', both the first two levels are significantly different from the third level, but the difference between the first and the second level is not significant.

Figure 68.6 LS-Means Difference Diffogram



Syntax: PLM Procedure

You can specify the following statements in the PLM procedure:

PROC PLM SOURCE=*item-store-specification* < *options* > ;
EFFECTPLOT < *plot-type* < *(plot-definition-options)* > > < / *options* > ;
ESTIMATE < *'label'* > *estimate-specification* < **(***divisor***=***n***)** >
< , . . . < *'label'* > *estimate-specification* < **(***divisor***=***n***)** > > < / *options* > ;
FILTER *expression* ;
LSMEANS < *model-effects* > < / *options* > ;
LSMESTIMATE *model-effect* < *'label'* > *values* < *divisor***=***n* >
< , . . . < *'label'* > *values* < *divisor***=***n* > > < / *options* > ;
SCORE DATA=*SAS-data-set* < **OUT=***SAS-data-set* >
< *keyword* < **=***name* > >. . .
< *keyword* < **=***name* > > < / *options* > ;
SHOW *options* ;
SLICE *model-effect* < / *options* > ;
TEST < *model-effects* > < / *options* > ;
WHERE *expression* ;

With the exception of the PROC PLM statement and the FILTER statement, any statement can appear multiple times and in any order. The default order in which the statements are processed by the PLM procedure depends on the specification in the item store and can be modified with the STMTORDER= option in the PROC PLM statement.

In contrast to many other SAS/STAT modeling procedures, the PLM procedure does not have common modeling statements such as the CLASS and MODEL statements. This is because the information about classification variables and model effects is contained in the source item store that is passed to the procedure in the PROC PLM statement. All subsequent statements are checked for consistency with the stored model. For example, the statement

```
lsmeans c / diff;
```

is detected as not valid unless one of the following conditions was true at the time when the source store was created:

- The effect C was used in the model.
- C was specified in the CLASS statement.
- The CLASS variables in the model had a GLM parameterization.

The FILTER, SCORE, SHOW, and WHERE statements are described in full after the PROC PLM statement in alphabetical order. The EFFECTPLOT, ESTIMATE, LSMEANS, LSMESTIMATE, SLICE, and TEST statements are also used by many other procedures. Summary descriptions of functionality and syntax for these statements are also given after the PROC PLM statement in alphabetical order, but full documentation about them is available in Chapter 19, "Shared Concepts and Topics."

PROC PLM Statement

PROC PLM SOURCE=*item-store-specification* < *options* > **;**

The PROC PLM statement invokes the procedure. The SOURCE= option with *item-store-specification* is required.

You can specify the following *options*:

ALPHA=α

specifies the nominal significance level for multiplicity corrections and for the construction of confidence intervals. The value of α must be between 0 and 1. The default is the value specified in the source item store, or 0.05 if the item store does not provide a value. The confidence level based on α is $1 - \alpha$.

DDFMETHOD=RESIDUAL | RES | ERROR

DDFMETHOD=NONE

DDFMETHOD=KENROG | KR | KENWARDROGER

DDFMETHOD=SATTERTH | SAT | SATTERTHWAITE

specifies the method for determining denominator degrees of freedom for tests and confidence intervals. The default degree-of-freedom method is determined by the contents of the item store. You can override the default to some extent with the DDFMETHOD= option.

If you choose DDFMETHOD=NONE, then infinite denominator degrees of freedom are assumed for tests and confidence intervals. This essentially produces z tests and intervals instead of t tests and intervals and chi-square tests instead of F tests.

The KENWARDROGER and SATTERTHWAITE methods require that the source item store contain information about these methods. This information is currently available for item stores that were created with the MIXED or GLIMMIX procedures when the appropriate DDFM= option was in effect.

ESTEPS=ϵ

specifies the tolerance value used in determining the estimability of linear functions. The default value is determined by the contents of the source item store; it is usually 1E−4.

FORMAT=NOLOAD | RELOAD

specifies how the PLM procedure handles user-defined formats, which are not permanent. When the item store is created, user-defined formats are stored. When the PLM procedure opens an item store, these formats are loaded by default. If the format already exists in your SAS session, this operation amounts to a reloading of the format (FORMAT=RELOAD) that replaces the existing format.

With FORMAT=NOLOAD, you prevent the PLM procedure from reloading the format from the item store. As a consequence, PLM statements might fail if a format was present at the item store creation and is not available in your SAS session. Also, if you modify the format that was used in the item store creation and use FORMAT=NOLOAD, you might obtain unexpected results because levels of classification variables are remapped.

The "Class Level Information" table always displays the formatted values of classification variables that were used in fitting the model, regardless of the FORMAT= option. For more details about using formats with the PLM procedure, see "User-Defined Formats and the PLM Procedure" on page 5646.

MAXLEN=*n*

determines the maximum length of informational strings in the "Store Information" table. This table displays, for example, lists of classification or BY variables and lists of model effects. The value of *n* determines the truncation length for these strings. The minimum and maximum values for *n* are 20 and 256, respectively. The default is $n = 100$.

NOCLPRINT< =*number* **>**

suppresses the display of the "Class Level Information" table if you do not specify *number*. If you specify *number*, only levels with totals that are less than *number* are listed in the table. The PLM procedure produces the "Class Level Information" table by default when the model contains effects that depend on classification variables.

NOINFO

suppresses the display of the "Store Information" table.

NOPRINT

suppresses the generation of tabular and graphical output. When the NOPRINT option is in effect, ODS tables are also not produced.

PERCENTILES=*value-list*

PERCENTILE=*value-list*

supplies a list of percentiles for the construction of highest posterior density (HPD) intervals when the PLM procedure performs a sampling-based analysis (for example, when processing an item store that contains posterior parameter estimates from a Bayesian analysis). The default set of percentiles depends on the contents of the source item store; it is typically PERCENTILES=25, 50, 75. The entries in *value-list* must be strictly between 0 and 100.

PLOTS < (*global-plot-option***) > < =***specific-plot-options* **>**

controls the plots produced through ODS Graphics. ODS Graphics must be enabled before requesting plots. For example:

```
ods graphics on;

proc plm plots=all;
   lsmeans a/diff;
run;

ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section "Enabling and Disabling ODS Graphics" on page 612 in Chapter 21, "Statistical Graphics Using ODS."

Global Plot Option

The following *global-plot-option* applies to all plots produced by PROC PLM.

UNPACKPANEL
UNPACK
breaks a graphic that is otherwise paneled into individual component plots.

Specific Plot Options

You can specify the following *specific-plot-options*:

ALL
requests that all the appropriate plots be produced.

NONE
suppresses all plots.

SEED=*number*
specifies the random number seed for analyses that depend on a random number stream. You can also specify the random number seed through some PLM statements (for example, through the SEED= options in the ESTIMATE, LSMEANS, and LSMESTIMATE statements). However, note that there is only a single random number stream per procedure run. Specifying the SEED= option in the PROC PLM statement initializes the stream for all subsequent statements. If you do not specify a random number seed, the source item store might supply one for you. If a seed is in effect when the PLM procedure opens the source store, the "Store Information" table displays its value.

If the random number seed is less than or equal to zero, the seed is generated from reading the time of day from the computer clock and a log message indicates the chosen seed value.

SINGCHOL=*number*
tunes the singularity criterion in Cholesky decompositions. The default value depends on the contents of the source item store. The default value is typically 1E4 times the machine epsilon; this product is approximately 1E−12 on most computers.

SINGRES=*number*
sets the tolerance for which the residual variance or scale parameter is considered to be zero. The default value depends on the contents of the source item store. The default value is typically 1E4 times the machine epsilon; this product is approximately 1E−12 on most computers.

SINGULAR=*number*
tunes the general singularity criterion applied by the PLM procedure in divisions and inversions. The default value used by the PLM procedure depends on the contents of the item store. The default value is typically 1E4 times the machine epsilon; this product is approximately 1E−12 on most computers.

SOURCE=*item-store-specification*

RESTORE=*item-store-specification*

specifies the source item store for processing. This option is required because, in contrast to SAS data sets, there is no default item store. An *item-store-specification* consists of a one- or two-level name as with SAS data sets. As with data sets, the default library association of an item store is with the WORK library, and any stores created in this library are deleted when the SAS session concludes.

STMTORDER=SYNTAX | GROUP

STMT=SYNTAX | GROUP

affects the order in which statements are grouped during processing. The default behavior depends on the contents of the source item store and can be modified with the STMTORDER= option. If STMTORDER=SYNTAX is in effect, the statements are processed in the order in which they appear. Note that this precludes the hierarchical grouping of ODS objects. If STMTORDER=GROUP is in effect, the statements are processed in groups and in the following order: SHOW, TEST, LSMEANS, SLICE, LSMESTIMATE, ESTIMATE, and SCORE.

WHEREFORMAT

specifies that the constants (literals) specified in WHERE expressions for group selection are in terms of the formatted values of the BY variables. By default, WHERE expressions are specified in terms of the unformatted (raw) values of the BY variables, as in the SAS DATA step.

ZETA=*number*

tunes the sensitivity in forming Type III functions. Any element in the estimable function basis with an absolute value less than *number* is set to 0. The default depends on the contents of the source item store; it usually is 1E−8.

EFFECTPLOT Statement

EFFECTPLOT < *plot-type* < *(plot-definition-options)* > > < / *options* > **;**

The EFFECTPLOT statement produces a display of the fitted model and provides options for changing and enhancing the displays. Table 68.2 describes the available *plot-types* and their *plot-definition-options*.

Table 68.2 *Plot-Types* and *Plot-Definition-Options*

Plot-Type and Description	Plot-Definition-Options
CONTOUR Displays a contour plot of predicted values against two continuous covariates.	PLOTBY= variable or CLASS effect X= continuous variable Y= continuous variable
FIT Displays a curve of predicted values versus a continuous variable.	PLOTBY= variable or CLASS effect X= continuous variable

Table 68.2 *continued*

Plot-Type and Description	Plot-Definition-Options
INTERACTION Displays a plot of predicted values (possibly with error bars) versus the levels of a CLASS effect. The predicted values are connected with lines and can be grouped by the levels of another CLASS effect.	PLOTBY= variable or CLASS effect SLICEBY= variable or CLASS effect X= CLASS variable or effect
SLICEFIT Displays a curve of predicted values versus a continuous variable grouped by the levels of a CLASS effect.	PLOTBY= variable or CLASS effect SLICEBY= variable or CLASS effect X= continuous variable

For full details about the syntax and options of the EFFECTPLOT statement, see the section "EFFECTPLOT Statement" on page 425 of Chapter 19, "Shared Concepts and Topics."

ESTIMATE Statement

ESTIMATE < *'label'* > *estimate-specification* < **(***divisor***=***n***)** >
< **,** . . . < *'label'* > *estimate-specification* < **(***divisor***=***n***)** > >
< **/** *options* > **;**

The ESTIMATE statement provides a mechanism for obtaining custom hypothesis tests. Estimates are formed as linear estimable functions of the form $\mathbf{L}\boldsymbol{\beta}$. You can perform hypothesis tests for the estimable functions, construct confidence limits, and obtain specific nonlinear transformations.

Table 68.3 summarizes important *options* in the ESTIMATE statement.

Table 68.3 Important ESTIMATE Statement Options

Option	Description
Construction and Computation of Estimable Functions	
DIVISOR=	Specifies a list of values to divide the coefficients
NOFILL	Suppresses the automatic fill-in of coefficients for higher-order effects
SINGULAR=	Tunes the estimability checking difference

Table 68.3 *continued*

Option	Description
Degrees of Freedom and *p*-values	
ADJUST=	Determines the method for multiple comparison adjustment of estimates
ALPHA=α	Determines the confidence level $(1-\alpha)$
LOWER	Performs one-sided, lower-tailed inference
STEPDOWN	Adjusts multiplicity-corrected *p*-values further in a step-down fashion
TESTVALUE=	Specifies values under the null hypothesis for tests
UPPER	Performs one-sided, upper-tailed inference
Statistical Output	
CL	Constructs confidence limits
CORR	Displays the correlation matrix of estimates
COV	Displays the covariance matrix of estimates
E	Prints the **L** matrix
JOINT	Produces a joint F or chi-square test for the estimable functions
PLOTS=	Requests ODS statistical graphics if the analysis is sampling-based
SEED=	Specifies the seed for computations that depend on random numbers
Generalized Linear Modeling	
CATEGORY=	Specifies how to construct estimable functions with multinomial data
EXP	Exponentiates and displays estimates
ILINK	Computes and displays estimates and standard errors on the inverse linked scale

For details about the syntax of the ESTIMATE statement, see the section "ESTIMATE Statement" on page 451 of Chapter 19, "Shared Concepts and Topics."

FILTER Statement

FILTER *expression* **;**

The FILTER statement enables you to filter the results of the PLM procedure, specifically the contents of ODS tables and the output data sets. There can be at most one FILTER statement per PROC PLM run, and the filter is applied to all BY groups and to all queries generated through WHERE expressions.

A filter *expression* follows the same pattern as a *where-expression* in the WHERE statement. The expressions consist of operands and operators. For more information about specifying *where-expressions*, see the WHERE statement for the PLM procedure and *SAS Language Reference: Concepts*.

Valid keywords for the formation of operands in the FILTER statement are shown in Table 68.4.

Table 68.4 Keywords for Filtering Results

Keyword	Description
Prob	Regular (unadjusted) *p*-values from *t*, *F*, or chi-square tests
ProbChi	Regular (unadjusted) *p*-values from chi-square tests
ProbF	Regular (unadjusted) *p*-values from *F* tests
ProbT	Regular (unadjusted) *p*-values from *t* tests
AdjP	Adjusted *p*-values
Estimate	Results displayed in "Estimates" column of ODS tables
Pred	Predicted values in SCORE output data sets
Resid	Residuals in SCORE output data sets.
Std	Standard errors in ODS tables and in SCORE results
Mu	Results displayed in the "Mean" column of ODS tables (this column is typically produced by the ILINK option)
tValue	The value of the usual *t* statistic
FValue	The value of the usual *F* statistic
Chisq	The value of the chi-square statistic
testStat	The value of the test statistic (a generic keyword for the 'tValue', 'FValue', and 'Chisq' tokens)
Lower	The lower confidence limit displayed in ODS tables
Upper	The upper confidence limit displayed in ODS tables
AdjLower	The adjusted lower confidence limit displayed in ODS tables
AdjUpper	The adjusted upper confidence limit displayed in ODS tables
LowerMu	The lower confidence limit for the mean displayed in ODS tables
UpperMu	The upper confidence limit for the mean displayed in ODS tables
AdjLowerMu	The adjusted lower confidence limit for the mean displayed in ODS tables
AdjUpperMu	The adjusted upper confidence limit for the mean displayed in ODS tables

When you write filtering expressions, be advised that filtering variables that are not used in the results are typically set to missing values. For example, the following statements select all results (filter nothing) because no adjusted *p*-values are computed:

```
proc plm source=MyStore;
  lsmeans a / diff;
  filter adjp < 0.05;
run;
```

If the adjusted *p*-values are set to missing values, the condition < 0.05 is true in each case (missing values always compare smaller than the smallest nonmissing value).

See "Example 68.6: Comparing Multiple B-Splines" on page 5664 for an example of using the FILTER statement.

Filtering results has no affect on the item store contents that are displayed with the SHOW statement. However, BY-group selection with the WHERE statement can limit the amount of information that is displayed by the SHOW statements.

LSMEANS Statement

LSMEANS < *model-effects* > < / *options* > **;**

The LSMEANS statement computes and compares least squares means (LS-means) of fixed effects. LS-means are *predicted population margins*—that is, they estimate the marginal means over a balanced population. In a sense, LS-means are to unbalanced designs as class and subclass arithmetic means are to balanced designs.

Table 68.5 summarizes important options in the LSMEANS statement.

Table 68.5 Important LSMEANS Statement Options

Option	Description
Construction and Computation of LS-Means	
AT	Modifies the covariate value in computing LS-means
BYLEVEL	Computes separate margins
DIFF	Requests differences of LS-means
OM=	Specifies the weighting scheme for LS-means computation as determined by the input data set
SINGULAR=	Tunes estimability checking
Degrees of Freedom and *p*-values	
ADJUST=	Determines the method for multiple comparison adjustment of LS-means differences
ALPHA=α	Determines the confidence level $(1-\alpha)$
STEPDOWN	Adjusts multiple comparison *p*-values further in a step-down fashion
Statistical Output	
CL	Constructs confidence limits for means and mean differences
CORR	Displays the correlation matrix of LS-means
COV	Displays the covariance matrix of LS-means
E	Prints the **L** matrix
LINES	Produces a "Lines" display for pairwise LS-means differences
MEANS	Prints the LS-means
PLOTS=	Requests ODS statistical graphics of means and mean comparisons
SEED=	Specifies the seed for computations that depend on random numbers
Generalized Linear Modeling	
EXP	Exponentiates and displays estimates of LS-means or LS-means differences
ILINK	Computes and displays estimates and standard errors of LS-means (but not differences) on the inverse linked scale
ODDSRATIO	Reports (simple) differences of least squares means in terms of odds ratios if permitted by the link function

For details about the syntax of the LSMEANS statement, see the section "LSMEANS Statement" on page 467 of Chapter 19, "Shared Concepts and Topics."

LSMESTIMATE Statement

LSMESTIMATE *model-effect* < *'label'* > *values* < *divisor*=*n* >
< , . . . < *'label'* > *values* < *divisor*=*n* > >
< / *options* > ;

The LSMESTIMATE statement provides a mechanism for obtaining custom hypothesis tests among least squares means.

Table 68.6 summarizes important options in the LSMESTIMATE statement.

Table 68.6 Important LSMESTIMATE Statement Options

Option	Description
Construction and Computation of LS-Means	
AT	Modifies covariate values in computing LS-means
BYLEVEL	Computes separate margins
DIVISOR=	Specifies a list of values to divide the coefficients
OM=	Specifies the weighting scheme for LS-means computation as determined by a data set
SINGULAR=	Tunes estimability checking
Degrees of Freedom and *p*-values	
ADJUST=	Determines the method for multiple comparison adjustment of LS-means differences
ALPHA=α	Determines the confidence level $(1-\alpha)$
LOWER	Performs one-sided, lower-tailed inference
STEPDOWN	Adjusts multiple comparison *p*-values further in a step-down fashion
TESTVALUE=	Specifies values under the null hypothesis for tests
UPPER	Performs one-sided, upper-tailed inference
Statistical Output	
CL	Constructs confidence limits for means and mean differences
CORR	Displays the correlation matrix of LS-means
COV	Displays the covariance matrix of LS-means
E	Prints the **L** matrix
ELSM	Prints the **K** matrix
JOINT	Produces a joint F or chi-square test for the LS-means and LS-means differences
PLOTS=	Requests ODS statistical graphics of means and mean comparisons
SEED=	Specifies the seed for computations that depend on random numbers

Table 68.6 *continued*

Option	Description
Generalized Linear Modeling	
CATEGORY=	Specifies how to construct estimable functions with multinomial data
EXP	Exponentiates and displays LS-means estimates
ILINK	Computes and displays estimates and standard errors of LS-means (but not differences) on the inverse linked scale

For details about the syntax of the LSMESTIMATE statement, see the section "LSMESTIMATE Statement" on page 483 of Chapter 19, "Shared Concepts and Topics."

SCORE Statement

SCORE DATA=*SAS-data-set* < **OUT=***SAS-data-set* >
< *keyword*< **=***name* > >. . .
< *keyword*< **=***name* > > < / *options* > **;**

The SCORE statement applies the contents of the source item store to compute predicted values and other observation-wise statistics for a SAS data set.

You can specify the following syntax elements in the SCORE statement before the option slash (/):

DATA=*SAS-data-set*

specifies the input data set for scoring. This option is required, and the data set is examined for congruity with the previously fitted (and stored) model. For example, all necessary variables to form a row of the **X** matrix must be present in the input data set and must be of the correct type and format. The following variables do not have to be present in the input data set:

- the response variable
- the *events* and *trials* variables used in the *events/trials* syntax for binomial data
- variables used in WEIGHT or FREQ statements

OUT=*SAS-data-set*

specifies the name of the output data set. If you do not specify an output data set with the OUT= option, the PLM procedure uses the DATA*n* convention to name the output data set.

keyword< =*name* **>**

specifies a statistic to be included in the OUT= data set and optionally assigns the statistic the variable name *name*. Table 68.7 lists the keywords and the default names assigned by the PLM procedure if you do not specify a *name*.

Table 68.7 Keywords for Output Statistics

Keyword	Description	Expression	Name
PREDICTED	Linear predictor	$\widehat{\eta} = \mathbf{x}\widehat{\boldsymbol{\beta}}$	Predicted
STDERR	Standard deviation of linear predictor	$\sqrt{\mathrm{Var}(\widehat{\eta})}$	StdErr
RESIDUAL	Residual	$y - g^{-1}(\widehat{\eta})$	Resid
LCLM	Lower confidence limit for the linear predictor		LCLM
UCLM	Upper confidence limit for the linear predictor		UCLM
LCL	Lower prediction limit for the linear predictor		LCL
UCL	Upper prediction limit for the linear predictor		UCL

Prediction limits (LCL, UCL) are available only for statistical models that allow such limits, typically regression-type models for normally distributed data with an identity link function.

You can specify the following options in the SCORE statement after a slash (/):

ALPHA=*number*
determines the coverage probability for two-sided confidence and prediction intervals. The coverage probability is computed as $1 - number$. The value of *number* must be between 0 and 1; the default is 0.05.

DF=*number*
specifies the degrees of freedom to use in the construction of prediction and confidence limits.

ILINK
requests that predicted values be inversely linked to produce predictions on the data scale. By default, predictions are produced on the linear scale where covariate effects are additive.

NOUNIQUE
requests that names not be made unique in the case of naming conflicts. By default, the PLM procedure avoids naming conflicts by assigning a unique name to each output variable. If you specify the NOUNIQUE option, variables with conflicting names are not renamed. In that case, the first variable added to the output data set takes precedence.

NOVAR
requests that variables from the input data set not be added to the output data set.

OBSCAT
requests that statistics in models for multinomial data be written to the output data set only for the response level that corresponds to the observed level of the observation.

SAMPLE

requests that the sample of parameter estimates in the item store be used to form scoring statistics. This option is useful when the item store contains the results of a Bayesian analysis and a posterior sample of parameter estimates. The predicted value is then computed as the average predicted value across the posterior estimates, and the standard error measures the standard deviation of these estimates. For example, let $\widehat{\boldsymbol{\beta}}_1, \ldots, \widehat{\boldsymbol{\beta}}_k$ denote the k posterior sample estimates of $\boldsymbol{\beta}$, and let $\mathbf{x}_i$ denote the x-vector for the ith observation in the scoring data set. If the SAMPLE option is in effect, the output statistics for the predicted value, the standard error, and the residual of the ith observation are computed as

$$\begin{aligned}
\eta_{ij} &= \mathbf{x}_i \widehat{\boldsymbol{\beta}}_j \\
\text{PRED}_i &= \overline{\eta}_i = \frac{1}{k} \sum_{j=1}^{k} \eta_{ij} \\
\text{STDERR}_i &= \left(\frac{1}{k-1} \sum_{j=1}^{k} \left(\eta_{ij} - \overline{\eta}_i \right)^2 \right)^{1/2} \\
\text{RESIDUAL}_i &= y_i - g^{-1}\left(\overline{\eta}_i \right)
\end{aligned}$$

where $g^{-1}(\cdot)$ denotes the inverse link function.

If, in addition, the ILINK option is in effect, the calculations are as follows:

$$\begin{aligned}
\eta_{ij} &= \mathbf{x}_i \widehat{\boldsymbol{\beta}}_j \\
\text{PRED}_i &= \frac{1}{k} \sum_{j=1}^{k} g^{-1}\left(\eta_{ij} \right) \\
\text{STDERR}_i &= \left(\frac{1}{k-1} \sum_{j=1}^{k} \left(g^{-1}(\eta_{ij}) - \text{PRED}_i \right)^2 \right)^{1/2} \\
\text{RESIDUAL}_i &= y_i - \text{PRED}_i
\end{aligned}$$

The LCL and UCL statistics are not available with the SAMPLE option. When the LCLM and UCLM statistics are requested, the SAMPLE option yields the lower $100 \times \alpha/2\%$ and upper $100 \times (1 - \alpha/2)\%$ percentiles of the predicted values under the sample (posterior) distribution. When you request residuals with the SAMPLE option, the calculation depends on whether the ILINK option is specified.

SHOW Statement

SHOW *options* **;**

The SHOW statement uses the Output Delivery System to display contents of the item store. This statement is useful for verifying that the contents of the item store apply to the analysis and for generating ODS tables. You can specify the following options after the SHOW statement:

ALL | _ALL_
displays all applicable contents.

BYVAR | BY
displays information about the BY variables in the source item store. If a BY statement was present when the item store was created, the PLM procedure performs the analysis separately for each BY group.

CLASSLEVELS | CLASS
displays the "Class Level Information" table. This table is produced by the PLM procedure by default if the model contains effects that depend on classification variables.

CORRELATION | CORR | CORRB
produces the correlation matrix of the parameter estimates. If the source item store contains a posterior sample of parameter estimates, the computed matrix is the correlation matrix of the sample covariance matrix.

COVARIANCE | COV | COVB
produces the covariance matrix of the parameter estimates. If the source item store contains a posterior sample of parameter estimates, the PLM procedure computes the empirical sample covariance matrix from the posterior estimates. You can convert this matrix into a sample correlation matrix with the CORRELATION option in the SHOW statement.

EFFECTS
displays information about the constructed effects in the model. Constructed effects are those that were created with the EFFECT statement in the procedure run that generated the source item store.

FITSTATS | FIT
displays the fit statistics from the item store.

HESSIAN | HESS
displays the Hessian matrix.

HERMITE | HERM

generates the Hermite matrix $\mathbf{H} = (\mathbf{X}'\mathbf{X})^{-}(\mathbf{X}'\mathbf{X})$. The PLM procedure chooses a reflexive, g_2-inverse for the generalized inverse of the crossproduct matrix $\mathbf{X}'\mathbf{X}$. See "Important Linear Algebra Concepts" on page 44 of Chapter 3, "Introduction to Statistical Modeling with SAS/STAT Software," for information about generalized inverses and the sweep operator.

PARAMETERS< =*n* >

PARMS< =*n* >

displays the parameter estimates. The structure of the display depends on whether a posterior sample of parameter estimates is available in the source item store. If such a sample is present, up to the first 20 parameter vectors are shown in wide format. You can modify this number with the *n* argument.

If no posterior sample is present, the single vector of parameter estimates is shown in narrow format. If the store contains information about the covariance matrix of the parameter estimates, then standard errors are added.

PROGRAM< (WIDTH=*n*) >

PROG< (WIDTH=*n*) >

displays the SAS program that generated the item store, provided that this was stored at store generation time. The program does not include comments, titles, or some other global statements. The optional width parameter *n* determines the display width of the source code.

XPX | CROSSPRODUCT

displays the crossproduct matrix $\mathbf{X}'\mathbf{X}$.

XPXI

displays the generalized inverse of the crossproduct matrix $\mathbf{X}'\mathbf{X}$. The PLM procedure obtains a reflexive g_2-inverse by sweeping. See "Important Linear Algebra Concepts" on page 44 of Chapter 3, "Introduction to Statistical Modeling with SAS/STAT Software," for information about generalized inverses and the sweep operator.

SLICE Statement

SLICE *model-effect* < / *options* > **;**

The SLICE statement provides a general mechanism for performing a partitioned analysis of the LS-means for an interaction. This analysis is also known as an analysis of simple effects.

The SLICE statement uses the same options as the LSMEANS statement, which are summarized in Table 19.19. For details about the syntax of the SLICE statement, see the section "SLICE Statement" on page 513 of Chapter 19, "Shared Concepts and Topics."

TEST Statement

TEST < *model-effects* > < / *options* > **;**

The TEST statement enables you to perform *F* tests for model effects that test Type I, II, or Type III hypotheses. See Chapter 15, "The Four Types of Estimable Functions," for details about the construction of Type I, II, and III estimable functions.

Table 68.8 summarizes options in the TEST statement.

Table 68.8 TEST Statement Options

Option	Description
CHISQ	Requests chi-square tests
DDF=	Specifies denominator degrees of freedom for fixed effects
E	Requests Type I, Type II, and Type III coefficients
E1	Requests Type I coefficients
E2	Requests Type II coefficients
E3	Requests Type III coefficients
HTYPE=	Indicates the type of hypothesis test to perform
INTERCEPT	Adds a row that corresponds to the overall intercept

For details about the syntax of the TEST statement, see the section "TEST Statement" on page 517 of Chapter 19, "Shared Concepts and Topics."

WHERE Statement

WHERE *expression* **;**

The WHERE statement in the PLM procedure is helpful when the item store contains BY-variable information and you want to apply the PROC PLM statements to only a subset of the BY groups.

A WHERE expression is a type of SAS expression that defines a condition. In the DATA step and in procedures that use SAS data sets as input source, the WHERE expression is used to select observations for inclusion in the DATA step or in the analysis. In the PLM procedure, which does not accept a SAS data set but rather takes an item store that was created by a qualifying SAS/STAT procedure, the WHERE statement is also used to specify conditions. The conditional selection does not apply to observations in PROC PLM, however. Instead, you use the WHERE statement in the PLM procedure to select a subset of BY groups from the item store to which to apply the PROC PLM statements.

The general syntax of the WHERE statement is

WHERE *operand* < *operator* > < *operand* > **;**

where

operand is something to be operated on. The operand can be the name of a BY variable in the item store, a SAS function, a constant, or a predefined name to identify columns in result tables.

operator is a symbol that requests a comparison, logical operation, or arithmetic calculation. All SAS expression operators are valid for a WHERE expression.

For more details about how to specify general WHERE expressions, see *SAS Language Reference: Concepts*. Notice that the FILTER statement accepts similar expressions that are specified in terms of predefined keywords. Expressions in the WHERE statement of the PLM procedure are written in terms of BY variables.

There is no limit to the number of WHERE statements in the PLM procedure. When you specify multiple WHERE statements, the statements are *not* cumulative. Each WHERE statement is executed separately. You can think of each selection WHERE statement as one analytic query to the item store: the WHERE statement defines the query, and the PLM procedure is the querying engine. For example, suppose that the item store contains results for the numeric BY variables A and B. The following statements define two separate queries of the item store:

```
WHERE a = 4;
WHERE (b < 3) and (a > 4);
```

The PLM procedure first applies the requested analysis to all BY groups where a equals 4 (irrespective of the value of variable b). The analysis is then repeated for all BY groups where b is less than 3 and a is greater than 4.

Group selection with WHERE statements is possible only if the item store contains BY variables. You can use the BYVAR option in the SHOW statement to display the BY variables in the item store.

Note that WHERE expressions in the SAS DATA step and in many procedures are specified in terms of the unformatted values of data set variables, even if a format was applied to the variable. If you specify the WHEREFORMAT option in the PROC PLM statement, the PLM procedure evaluates WHERE expressions for BY variables in terms of the formatted values. For example, assume that the following format was applied to the variable tx when the item store was created:

```
proc format;
  value bf 1 = 'Control'
           2 = 'Treated';
run;
```

Then the following two PROC PLM runs are equivalent:

```
proc plm source=MyStore;
  show parms;
  where b = 2;
run;

proc plm source=MyStore whereformat;
  show parms;
  where b = 'Treated';
run;
```

Details: PLM Procedure

BY Processing and the PLM Procedure

When a BY statement is in effect for the anlaysis that creates an item store, the information about BY variables and BY-group-specific modeling results are transferred to the item store. In this case, the PLM procedure automatically assumes a processing mode for the item store that is akin to BY processing, with the PLM statements being applied in turn for each of the BY groups. Also, you can then obtain a table of BY groups with the BYVAR option in the SHOW statement. The "Source Information" table also displays the variable names of the BY variables if BY groups are present. The WHERE statement can be used to restrict the analysis to specific BY groups that meet the conditions of the WHERE expression.

See Example 68.4 for an example that uses BY-group-specific information in the source item store.

As with procedures that operate on input data sets, the BY variable information is added automatically to any output data sets and ODS tables produced by the PLM procedure.

When you score a data set with the SCORE statement and the item store contains BY variables, three situations can arise:

- None of the BY variables are present in the scoring data set. In this situation the results of the BY groups in the item store are applied in turn to the entire scoring data set. For example, if the scoring data set contains 50 observations and no BY-variable information, the number of observations in the output data set of the SCORE statement equals 50 times the number of BY groups.
- The scoring data set contains only a part of the BY variables, or the variables have different type or format. The PLM procedure does not process such an incompatible scoring data set.
- All BY variables are in the scoring data set in the same type and format as when the item store was created. The BY-group-specific results are applied to each observation in the scoring data set. The scoring data set does not have to be sorted or grouped by the BY variables. However, it is computationally more efficient if the scoring data set is arranged by groups of the BY variables.

Analysis Based on Posterior Estimates

If an item store that are saved from a Bayesian analysis (by PROC GENMOD or PROC PHREG), then PROC PLM can perform sampling-based inference based on Bayes posterior estimates that are saved in the item store. For example, the following statements request that a Bayesian analysis and results be saved to an item store named sasuser.gmd. For the Bayesian analysis, the random number generator seed is set to 1. By default, a noninformative distribution is set as the prior distribution for the regression coefficients and the posterior sample size is 10,000.

```
proc genmod data=gs;
   class a b;
   model y = a b;
   bayes seed=1;
   store sasuser.gmd / label='Bayesian Analysis';
run;
```

When the PLM procedure opens the item store sasuser.gmd, it detects that the results were saved from a Bayesian analysis. The posterior sample of regression coefficient estimates are then loaded to perform statistical inference tasks.

The majority of postprocessing tasks involve inference based on an estimable linear function $\mathbf{L}\widehat{\boldsymbol{\beta}}$, which often requires its mean and variance. When the standard frequentist analyses are performed, the mean and variance have explicit forms because the parameter estimate $\widehat{\boldsymbol{\beta}}$ is analytically tractable. However, explicit forms are not usually available when Bayesian models are fitted. Instead, empirical means and variance-covariance matrices for the estimable function are constructed from the posterior sample.

Let $\widehat{\boldsymbol{\beta}}_i, i = 1, \ldots, N_p$ denote the N_p vectors of posterior sample estimates of $\boldsymbol{\beta}$ saved in sasuser.gmd. Use these vectors to construct the posterior sample of estimable functions $\mathbf{L}\boldsymbol{\beta}_i$. The posterior mean of the estimable function is thus

$$\overline{\mathbf{L}\widehat{\boldsymbol{\beta}}} = \frac{1}{N_p}\sum_{i=1}^{N_p}\mathbf{L}\widehat{\boldsymbol{\beta}}_i$$

and the posterior variance of the estimable function is

$$\mathbf{V}\left(\mathbf{L}\widehat{\boldsymbol{\beta}}\right) = \frac{1}{N_p-1}\sum_{i=1}^{N_p}\left(\mathbf{L}\widehat{\boldsymbol{\beta}}_i - \overline{\mathbf{L}\widehat{\boldsymbol{\beta}}}\right)^2$$

Sometimes statistical inference on a transformation of $\mathbf{L}\widehat{\boldsymbol{\beta}}$ is requested. For example, the EXP option for the ESTIMATE and LSMESTIMATE statements requests analysis based on $\exp(\mathbf{L}\widehat{\boldsymbol{\beta}})$, exponentiation of the estimable function. If this type of analysis is requested, the posterior sample of transformed estimable functions is constructed by transforming each of the estimable function evaluated at the posterior sample: $f(\mathbf{L}\widehat{\boldsymbol{\beta}}_i), i = 1, \ldots, N_p$. The posterior mean and variance for $f(\mathbf{L}\widehat{\boldsymbol{\beta}})$ are then computed from the constructed sample to make the inference:

$$\overline{f(\mathbf{L}\widehat{\boldsymbol{\beta}})} = \frac{1}{N_p}\sum_{i=1}^{N_p} f(\mathbf{L}\widehat{\boldsymbol{\beta}}_i)$$

$$\mathbf{V}\left(f(\mathbf{L}\widehat{\boldsymbol{\beta}})\right) = \frac{1}{N_p-1}\sum_{i=1}^{N_p}\left(f(\mathbf{L}\widehat{\boldsymbol{\beta}}_i) - \overline{f(\mathbf{L}\widehat{\boldsymbol{\beta}})}\right)^2$$

After obtaining the posterior mean and variance, the PLM procedure proceeds to perform statistical inference tasks based on them.

User-Defined Formats and the PLM Procedure

The PLM procedure does not support a FORMAT statement because it operates without an input data set, and also because changing the format properties of variables could alter the interpretation of parameter estimates, thus creating a dissonance with variable properties in effect when the item store was created. Instead, user-defined formats that are applied to classification variables when the item store is created are saved to the store and are by default reloaded by the PLM procedure. When the PLM procedure loads a format, notes are issued to the log.

You can change the load behavior for formats with the user-defined FORMAT= option in the PROC PLM statement.

User-defined formats do not need to be supplied in a new SAS session. However, when a user-defined format with the same name as a stored format exists and the default FORMAT=RELOAD option is in effect, the format definition loaded from the item store replaces the format currently in effect.

In the following statements, the format AFORM is created and applied to the variable a in the PROC GLM step. This format definition is transferred to the item store sasuser.glm through the STORE statement.

```
proc format;
  value aform 1='One' 2='Two' 3='Three';
run;
proc glm data=sp;
   format a aform.;
   class block a b;
   model y = block a b x;
   store sasuser.glm;
   weight x;
run;
```

The following statements replace the format definition for aform in the PROC FORMAT step. The PLM step then reloads the AFORM format and thereby restores its original state.

```
proc format;
  value aform 1='Un' 2='Deux' 3='Trois';
run;
proc plm source=sasuser.glm;
   show class;
   score data=sp out=plmout lcl lclm ucl uclm;
run;
```

The following notes, issued by the PLM procedure, inform you that the procedure loaded the format, the format already existed, and the existing format was replaced:

```
NOTE: The format AFORM was loaded from item store SASUSER.GLM.
NOTE: Format AFORM is already on the library.
NOTE: Format AFORM has been output.
```

After the PROC PLM run, the definition that is in effect for the format AFORM corresponds to the following SAS statements:

```
proc format;
  value aform 1='One' 2='Two' 3='Three';
run;
```

ODS Table Names

PROC PLM assigns a name to each table it creates. You can use these names to refer to the table when you use the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 68.9. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Each of the EFFECTPLOT, ESTIMATE, LSMEANS, LSMESTIMATE, and SLICE statements also creates tables, which are not listed in Table 68.9. For information about these tables, see the corresponding sections of Chapter 19, "Shared Concepts and Topics."

Table 68.9 ODS Tables Produced by PROC PLM

Table Name	Description	Required Option
ByVarInfo	Information about BY variables in source item store (if present)	SHOW BYVAR
ClassLevels	Level information from the CLASS statement	Default output when model effects depend on CLASS variables
Corr	Correlation matrix of parameter estimates	SHOW CORR
Cov	Covariance matrix of parameter estimates	SHOW COV
FitStatistics	Fit statistics	SHOW FIT
Hessian	Hessian matrix	SHOW HESSIAN
Hermite	Hermite matrix	SHOW HERMITE
ParameterEstimates	Parameter estimates	SHOW PARMS
ParameterSample	Sampled (posterior) parameter estimates	SHOW PARMS
Program	Originating source code	SHOW PROGRAM
StoreInfo	Information about source item store	Default
XpX	$\mathbf{X}'\mathbf{X}$ matrix	SHOW XPX
XpXI	$(\mathbf{X}'\mathbf{X})^{-}$ matrix	SHOW XPXI

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, "Statistical Graphics Using ODS."

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section "Enabling and Disabling ODS Graphics" on page 612 in Chapter 21, "Statistical Graphics Using ODS."

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section "A Primer on ODS Statistical Graphics" on page 611 in Chapter 21, "Statistical Graphics Using ODS."

When ODS Graphics is enabled, then each of the EFFECTPLOT, ESTIMATE, LSMEANS, LSMESTIMATE, and SLICE statements can produce plots associated with their analyses. For information about these plots, see the corresponding sections of Chapter 19, "Shared Concepts and Topics."

Examples: PLM Procedure

Example 68.1: Scoring with PROC PLM

Logistic regression with model selection is often used to extract useful information and build interpretable models for classification problems with many variables. This example demonstrates how you can use PROC LOGISTIC to build a spline model on a simulated data set and how you can later use the fitted model to classify new observations.

The following DATA step creates a data set named SimuData, which contains 5,000 observations and 100 continuous variables:

```
%let nObs   = 5000;
%let nVars  = 100;
data SimuData;
   array x{&nVars};
   do obsNum=1 to &nObs;
      do j=1 to &nVars;
         x{j}=ranuni(1);
      end;

      linp =  10 + 11*x1 - 10*sqrt(x2) + 2/x3 - 8*exp(x4) + 7*x5*x5
             - 6*x6**1.5 + 5*log(x7) - 4*sin(3.14*x8) + 3*x9 - 2*x10;
      TrueProb = 1/(1+exp(-linp));

      if ranuni(1) < TrueProb then y=1;
                              else y=0;
      output;
   end;
run;
```

The response is binary based on the inversely transformed logit values. The true logit is a function of only 10 of the 100 variables, including nonlinear transformations of seven variables, as follows:

$$\text{logit}(p) = 10 + 11x_1 - 10\sqrt{x_2} + \frac{2}{x_3} - 8\exp(x_4) + 7x_5^2 - 6x_6^{1.5} + 5\log(x_7) - 4\sin(3.14x_8) + 3x_9 - 2x_{10}$$

Now suppose the true model is not known. With some exploratory data analysis, you determine that the dependency of the logit on some variables is nonlinear. Therefore, you decide to use splines to model this nonlinear dependence. Also, you want to use stepwise regression to remove unimportant variable transformations. The following statements perform the task:

```
proc logistic data=SimuData;
   effect splines = spline(x1-x&nVars/separate);
   model y = splines/selection=stepwise;
   store sasuser.SimuModel;
run;
```

By default, PROC LOGISTIC models the probability that $y = 0$. The EFFECT statement requests an effect named splines constructed by all predictors in the data. The SEPARATE option specifies that the spline basis for each variable be treated as a separate set so that model selection applies to each individual set. The SELECTION=STEPWISE specifies the stepwise regression as the model selection technique. The STORE statement requests that the fitted model be saved to an item store sasuser.SimuModel. See "Example 68.2: Working with Item Stores" on page 5650 for an example with more details about working with item stores.

The spline effect for each predictor produces seven columns in the design matrix, making stepwise regression computationally intensive. For example, a typical Pentium 4 workstation takes around ten minutes to run the preceding statements. Real data sets for classification can be much larger. See examples at UCI Machine Learning Repository (Asuncion and Newman 2007). If new observations about which you want to make predictions are available at model fitting time, you can add the SCORE statement in the LOGISTIC procedure. However, if observations to predict become available after fitting the model, you must use the LOGISTIC procedure to refit the model to make predictions for new observations. With PROC PLM, you do not have to repeat the intimidating model-fitting processes multiple times. You can use the SCORE statement in the PLM procedure to score new observations based on the item store sasuser.SimuModel that was created during the initial model building. For example, to compute the probability of $y = 0$ for one new observation with all predictor values equal to 0.15 in the data set test, you can use the following statements:

```
data test;
   array x{&nVars};
   do j=1 to &nVars;
      x{j}=0.15;
   end;
   drop j;
   output;
run;

proc plm source=sasuser.SimuModel;
   score data=test out=testout predicted / ilink;
run;
```

The ILINK option in the SCORE statement requestes that predicted values be inversely transformed to the response scale. In this case, it is the predicted probability of $y = 0$. Output 68.1.1 shows the predicted probability for the new observation.

Output 68.1.1 Predicted Probability for One New Observation

Obs	Predicted
1	0.56649

Example 68.2: Working with Item Stores

This example demonstrates how procedures save statistical analysis context and results into item stores and how you can use PROC PLM to make post hoc inference based on saved item stores. The data are taken from McCullagh and Nelder (1989) and concern the effects on taste of various cheese additives. Four cheese additives were tested, and 52 response ratings for each additive were obtained. The response was measured on a scale of nine categories that range from strong dislike (1) to excellent taste (9). The following program saves the data in the data set Cheese. The variable y contains the taste rating, the variable Additive contains cheese additive types, and the variable freq contains the frequencies with which each additive received each rating.

```
data Cheese;
   do Additive = 1 to 4;
      do y = 1 to 9;
         input freq @@;
         output;
      end;
   end;
   label y='Taste Rating';
   datalines;
0  0  1  7  8  8 19  8 1
6  9 12 11  7  6  1  0 0
1  1  6  8 23  7  5  1 0
0  0  0  1  3  7 14 16 11
;
```

The response y is a categorical variable that contains nine ordered levels. You can use PROC LOGISTIC to fit an ordinal model to investigate the effects of the cheese additive types on taste ratings. Suppose you also want to save the ordinal model into an item store so that you can make statistical inference later. You can use the following statements to perform the tasks:

```
proc logistic data=cheese;
   freq freq;
   class additive y / param=glm;
   model y=additive;
   store sasuser.cheese;
   title 'Ordinal Model on Cheese Additives';
run;
```

By default, PROC LOGISTIC uses the cumulative logit model for the ordered categorical response. The STORE statement requests that the fitted model be saved to a SAS item store named sasuser.cheese. The name is a two-level SAS name of the form libname.membername. If libname is not specified in the STORE statement, the fitted results are saved in work.membername and the item store is deleted after the current SAS session ends. With this example, the fitted model is saved to an item store named sasuser.cheese in the SASUSER library. It is not deleted after the current SAS session ends. You can use PROC PLM to restore the results later.

The following statements use PROC PLM to load the saved model context and results by specifying SOURCE= with the target item store sasuser.cheese. Then they use two SHOW statements to display separate information saved in the item store. The first SHOW statement with the PROGRAM option displays the program that was used to generate the item store sasuser.cheese. The second SHOW statement with the PARMS option displays parameter estimates and associated statistics of the fitted ordinal model.

```
proc plm source=sasuser.cheese;
   show program;
   show parms;
run;
```

Output 68.2.1 displays the program that generated the item store sasuser.cheese. Except for the title information, it matches the original program.

Output 68.2.1 Program Information from sasuser.cheese

```
                    Ordinal Model on Cheese Additives

                              The PLM Procedure

                           SAS Program Information

         proc logistic data=cheese;
            freq freq;
            class additive y / param=glm;
            model y=additive;
            store sasuser.cheese;
         run;
```

Output 68.2.2 displays estimates of the intercept terms and covariates and associated statistics. The intercept terms correspond to eight cumulative logits defined on taste ratings; that is, the ith intercept for ith logit is

$$\log\left(\frac{\sum_{j\le i} p_j}{1-\sum_{j\le i} p_j}\right)$$

Output 68.2.2 Parameter Estimates of the Ordinal Model

Parameter Estimates

Parameter	Taste Rating	Estimate	Standard Error
Intercept	1	−7.0801	0.5624
Intercept	2	−6.0249	0.4755
Intercept	3	−4.9254	0.4272
Intercept	4	−3.8568	0.3902
Intercept	5	−2.5205	0.3431
Intercept	6	−1.5685	0.3086
Intercept	7	−0.06688	0.2658
Intercept	8	1.4930	0.3310
Additive 1		1.6128	0.3778
Additive 2		4.9645	0.4741
Additive 3		3.3227	0.4251
Additive 4		0	.

You can perform various statistical inference tasks from a saved item store, as long as the task is applicable under the model context. For example, you can perform group comparisons between different cheese additive types. See the next example for details.

Example 68.3: Group Comparisons in Ordinal Model

This example continues the study of the effects on taste of various cheese additives. You have finished fitting an ordinal logistic model and saved it to an item store named sasuser.cheese in the previous example. Suppose you want to make comparisons between any pair of cheese additives. You can conduct the analysis by using the ESTIMATE statement and constructing an appropriate **L** matrix, or by using the LSMEANS statement to compute least squares means differences. For an ordinal logistic model with the cumulative logit link, the least squares means are predicted population margins of the cumulative logits. The following statements compute and display differences between least squares means of cheese additive:

```
ods graphics on;
proc plm source=sasuser.cheese;
   lsmeans additive / cl diff oddsratio plot=diff;
run;
ods graphics off;
```

There are four options specified for the LSMEANS statement in the preceding statements. The DIFF option requests least squares means differences for cheese additives. Since the fitted model is an ordinal logistic model with the cumulative logit link, the least squares means differences represent log cumulative odds ratios. The ODDSRATIO option requests exponentiation of the LS-means differences which produces cumulative odds ratios. The CL option requests that confidence limits be constructed for the LS-means differences. When ODS Graphics is enabled, the PLOTS=DIFF option requests a display of all pairwise least squares means differences and their significance.

Output 68.3.1 displays the LS-means differences. The reported log odds ratios indicate the relative difference among the cheese additives. A negative log odds ratio indicates that the first category (displayed in the "Additive" column) having a lower taste rating is less likely than the second category (displayed in the "_Additive" column) having a lower taste rating. For example, the log odds ratio between cheese additive 1 and 2 is -3.3517 and the corresponding odds ratio is 0.035. This means the odds of cheese additive 1 receiving a poor rating is 0.035 times the odds of cheese additive 2 receiving a poor rating. In addition to the highly significant p-value (< 0.0001), the confidence limits for both the log odds ratio and the odds ratio indicate that you can reject the null hypothesis that the odds of cheese additive 1 having a lower taste rating is the same as that of cheese additive 2 having a lower rating. Similarly, the odds of cheese additive 2 having a lower rating is 143.241 (with 95% confidence limits (56.558, 362.777)) times the odds of cheese additive 4 having a lower rating. With the same logic, you can conclude that the preference order for the four cheese types from the most favorable to the least favorable is: 4, 1, 3 and 2.

Output 68.3.1 LS-Means Differences of Additive

Ordinal Model on Cheese Additives

The PLM Procedure

Differences of Additive Least Squares Means

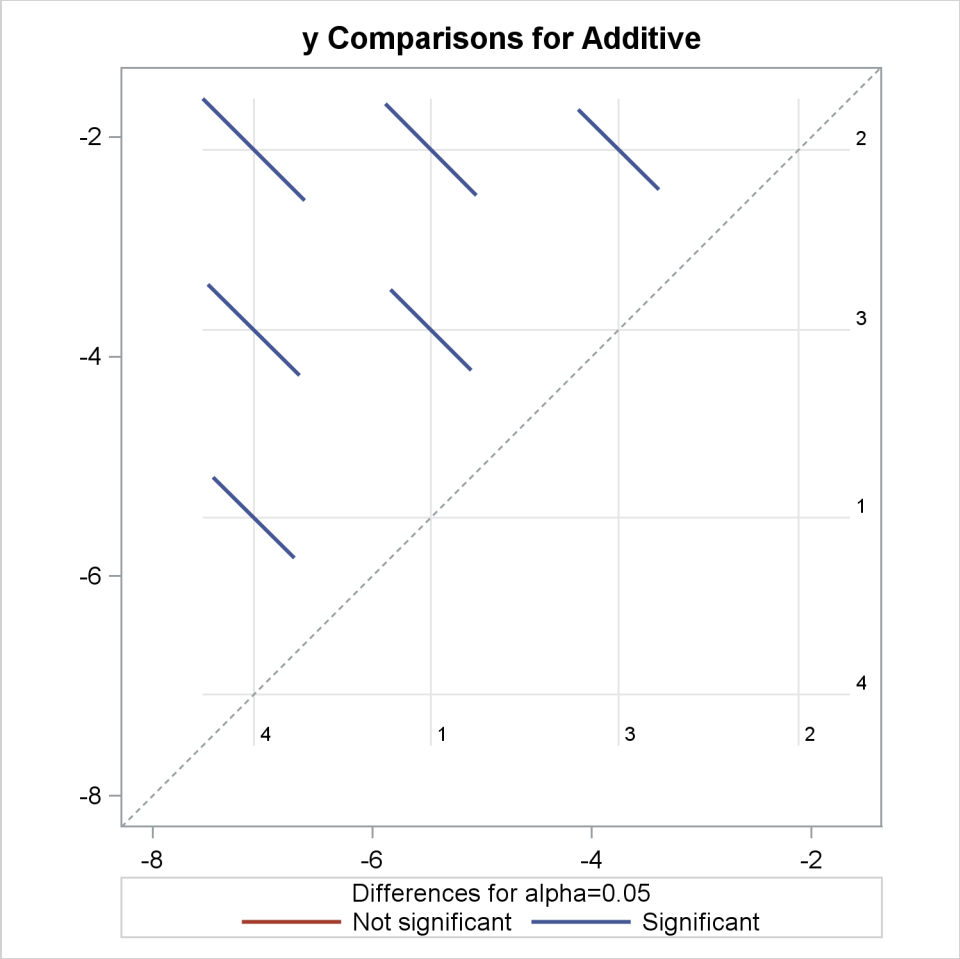
Additive	_Additive	Estimate	Standard Error	z Value	Pr > |z|	Alpha
1	2	−3.3517	0.4235	−7.91	<.0001	0.05
1	3	−1.7098	0.3731	−4.58	<.0001	0.05
1	4	1.6128	0.3778	4.27	<.0001	0.05
2	3	1.6419	0.3738	4.39	<.0001	0.05
2	4	4.9645	0.4741	10.47	<.0001	0.05
3	4	3.3227	0.4251	7.82	<.0001	0.05

Differences of Additive Least Squares Means

Additive	_Additive	Lower	Upper	Odds Ratio	Lower Confidence Limit for Odds Ratio	Upper Confidence Limit for Odds Ratio
1	2	−4.1818	−2.5216	0.035	0.015	0.080
1	3	−2.4410	−0.9787	0.181	0.087	0.376
1	4	0.8724	2.3532	5.017	2.393	10.520
2	3	0.9092	2.3746	5.165	2.482	10.746
2	4	4.0353	5.8938	143.241	56.558	362.777
3	4	2.4895	4.1558	27.734	12.055	63.805

Output 68.3.2 displays the DiffPlot. This shows that all pairs of LS-means differences, equivalent to log odds ratios in this case, are significant at the level of $\alpha = 0.05$. This means that the preference between any pair of the four cheese additive types are statistically significantly different.

Output 68.3.2 LS-Means Plot of Pairwise Differences



Example 68.4: Posterior Inference for Binomial Data

This example demonstrates how you can use PROC PLM to perform posterior inference from a Bayesian analysis. The data for this example are taken from Weisberg (1985) and concern the effect of small electrical currents on farm animals. The ultimate goal of the experiment was to understand the effects of high-voltage power lines on livestock and to better protect farm animals. Seven cows and six shock intensities were used in two experiments. In one experiment, each cow was given 30 electrical shocks with five at each shock intensity in random order. The number of shock responses was recorded for each cow at each shock level. The experiment was then repeated to investigate whether the response diminished due to fatigue of cows, or due to learning. So each cow received a total of 60 shocks. For the following analysis, the cow difference is ignored. The following DATA step lists the data where the variable current represents the shock level, the variable response represents the number of shock responses, the variable trial represents the total number

of trials at each shock level, and the variable experiment represents the experiment number (1 for the initial experiment and 2 for the repeated one):

```
data cow;
   input current response trial experiment;
   datalines;
0  0 35 1
0  0 35 2
1  6 35 1
1  3 35 2
2 13 35 1
2  8 35 2
3 26 35 1
3 21 35 2
4 33 35 1
4 27 35 2
5 34 35 1
5 29 35 2
;
```

Suppose you are interested in modeling the distribution of the shock response based on the level of the current and the experiment number. You can use the GENMOD procedure to fit a frequentist logistic model for the data. However, if you have some prior information about parameter estimates, you can fit a Bayesian logistic regression model to take this prior information into account. In this case, suppose you believe the logit of response has a positive association with the shock level but you are uncertain about the ranges of other regression coefficients. To incorporate this prior information in the regression model, you can use the following statements:

```
data prior;
    input _type_$ current;
    datalines;
mean 100
var   50
;

proc genmod data=cow;
   class experiment;
   bayes coeffprior=normal(input=prior) seed=1;
   model response/trial = current|experiment / dist=binomial;
   store cowgmd;
   title 'Bayesian Logistic Model on Cow';
run;
```

The DATA step before the GENMOD procedure creates a data set prior that specifies the prior distribution information for current, which in this case is a normal distribution with mean 100 and variance 50. This reflects a rough belief in a positive coefficient in a moderate range for current. The prior distribution parameters are not specified for experiment and the interaction between experiment and current, and so PROC GENMOD assigns a default prior for them, which is a normal distribution with mean 0 and variance 1E6.

After the DATA step, the BAYES statement in PROC GENMOD specifies that the regression coefficients follow a normal distribution with mean and variance specified in the input data set named prior. It also specifies 1 as the seed for the random number generator in the simulation of the posterior sample. The

MODEL statement requests a logistic regression model with a logit link. The STORE statement requests that the fitted results be saved into an item store named cowgmd.

The convergence diagnostics in the output of PROC GENMOD indicate that the Markov chain has converged. Output 68.4.1 displays summaries on the posterior sample of the regression coefficients. The posterior mean for the intercept is −3.5857 with a 95% HPD interval (−4.5226, −2.6303). The posterior mean of the coefficient for current is 1.1893 with a 95% HPD interval (0.8950, 1.4946), which indicates a positive association between the logit of response and the shock level. Further investigation about whether shock reaction was different between two experiment is warranted.

Output 68.4.1 Posterior Summaries on the Bayesian Logistic Model

Bayesian Logistic Model on Cow

The GENMOD Procedure

Bayesian Analysis

Posterior Summaries

Parameter	N	Mean	Standard Deviation	Percentiles 25%	50%	75%
Intercept	10000	−3.5857	0.4822	−3.9014	−3.5704	−3.2553
current	10000	1.1893	0.1536	1.0833	1.1843	1.2893
experiment1	10000	0.00727	0.7025	−0.4483	0.00849	0.4879
experiment1current	10000	0.3695	0.2529	0.1977	0.3651	0.5332

Posterior Intervals

Parameter	Alpha	Equal-Tail Interval		HPD Interval	
Intercept	0.050	−4.5814	−2.6799	−4.5226	−2.6303
current	0.050	0.9016	1.5047	0.8950	1.4946
experiment1	0.050	−1.4347	1.3517	−1.4390	1.3439
experiment1current	0.050	−0.1134	0.8802	−0.1105	0.8809

Bayesian model fitting typically involves a large amount of simulation. Using the item store and PROC PLM, you do not need to refit the model to perform further posterior inference. Suppose you want to determine whether the shock reaction for the current level is different between the two experiments. You can use PROC PLM with the ESTIMATE statement in the following statements:

```
proc plm source=cowgmd;
   estimate
   'Diff at current 0' experiment 1 -1 current*experiment [1, 0 1] [-1, 0 2],
   'Diff at current 1' experiment 1 -1 current*experiment [1, 1 1] [-1, 1 2],
   'Diff at current 2' experiment 1 -1 current*experiment [1, 2 1] [-1, 2 2],
   'Diff at current 3' experiment 1 -1 current*experiment [1, 3 1] [-1, 3 2],
   'Diff at current 4' experiment 1 -1 current*experiment [1, 4 1] [-1, 4 2],
   'Diff at current 5' experiment 1 -1 current*experiment [1, 5 1] [-1, 5 2]
    / exp cl;
run;
```

Each line in the ESTIMATE statement compares the fits between the two groups at each current level. The nonpositional syntax is used for the interaction effect current*experiment. For example, the first line requests coefficient 1 for the interaction effect at current level 0 for the initial experiment, and coefficient –1 for the effect at current level 0 for the repeated experiment. The two terms are then added to derive the difference. For more details about the nonpositional syntax, see "Positional and Nonpositional Syntax for Coefficients in Linear Functions" on page 462 of Chapter 19, "Shared Concepts and Topics."

The EXP option exponentiates log odds ratios to produce odds ratios. The CL option requests that confidence limits be constructed for both log odds ratios and odds ratios. Output 68.4.2 lists the posterior sample estimates for differences between experiments at different current levels.

Output 68.4.2 Comparisons between Experiments at Different Current Levels

Bayesian Logistic Model on Cow

Diff at current 5	4.0250	6.2849	9.9777	0.8604	20.2432

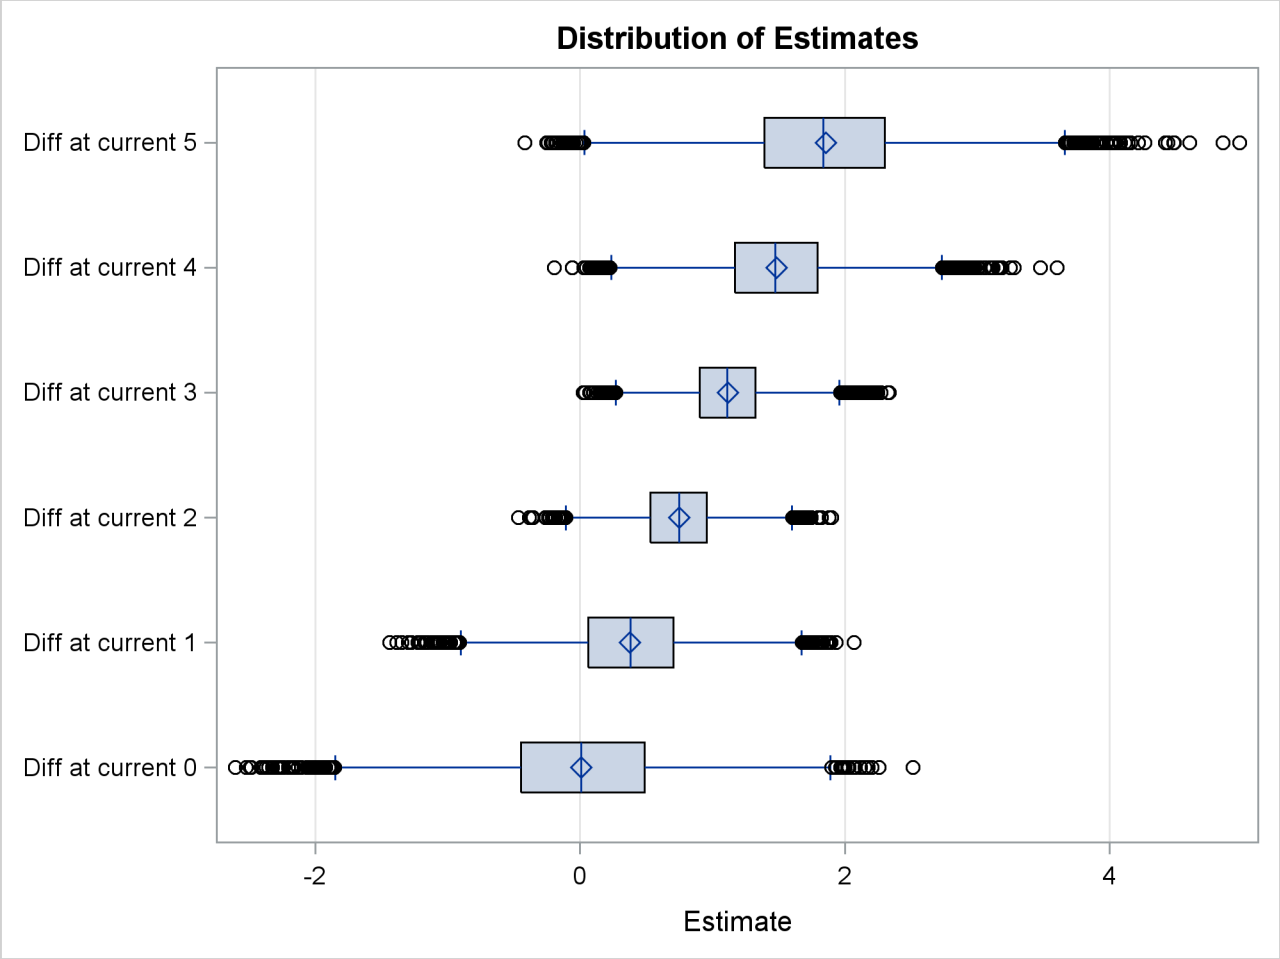
The sample statistics are constructed from the posterior sample saved in the item store cowgmd. From the output, the odds of a cow showing shock reaction at level 0 in the initial experiment is 1.2811 (with a 95% HPD interval (0.07387, 3.1001)) times the odds in the repeated experiment. The HPD interval for the odds ratio is constructed based on the mean and variance of the sample of the exponentiated log odds ratios, instead of based on the exponentiated mean and variance of the posterior sample of log odds ratios. The HPD interval suggests that there is not much evidence that the cows responded differently at current level 0 between the two experiments. Similar conclusions can be drawn for current level 1, 2, and 5. However, there is strong evidence that cows responded differently at current level 3 and 4 between the two experiments. The possible explanation is that, if the current level is so small that cows could hardly feel it or the current level is so strong that cows could hardly bear it, cows would respond consistently in the two experiment. If the current level is moderate, cows might get used to it and their response diminished in the repeated experiment.

You can visualize the distribution of the posterior sample of log odds ratios by specifying the PLOTS= option in the ESTIMATE statement. In the following statements, ODS Graphics is enabled by the ODS GRAPHICS ON statement, the PLOTS=BOXPLOT option requests a box plot of posterior distribution of log odds ratios. The suboption ORIENT=HORIZONTAL specifies a horizontal orientation of the boxes.

```
ods graphics on;
proc plm source=cowgmd;
   estimate
   'Diff at current 0' experiment 1 -1 current*experiment [1, 0 1] [-1, 0 2],
   'Diff at current 1' experiment 1 -1 current*experiment [1, 1 1] [-1, 1 2],
   'Diff at current 2' experiment 1 -1 current*experiment [1, 2 1] [-1, 2 2],
   'Diff at current 3' experiment 1 -1 current*experiment [1, 3 1] [-1, 3 2],
   'Diff at current 4' experiment 1 -1 current*experiment [1, 4 1] [-1, 4 2],
   'Diff at current 5' experiment 1 -1 current*experiment [1, 5 1] [-1, 5 2]
    / plots=boxplot(orient=horizontal);
run;
ods graphics off;
```

Output 68.4.3 displays the box plot of the posterior sample of log odds ratios. The two boxes for differences at current level 3 and 4 show that the corresponding log odds ratios are significantly larger than the reference value $x = 0$. This indicate that there is obvious evidence that the probability of cow response is larger in the initial experiment than in the repeated one at the two current levels. The other four boxes show that the corresponding log odds ratios are not significantly different from 0, which suggests that there is no obvious reaction difference at current level 0, 1, 2, and 5 between the two experiments.

Output 68.4.3 Box Plot of Difference between Two Experiments



Example 68.5: By-Group Processing

This example uses a data set on a study of the analgesic effects of treatments on elderly patients with neuralgia. The purpose of this example is to show how PROC PLM behaves under different situations when By-group processing is present. Two test treatments and a placebo are compared to test whether the patient reported pain or not. For each patient, the information of age, gender, and the duration of complaint before the treatment began were recorded. The following DATA step creates the data set named Neuralgia:

```
Data Neuralgia;
   input Treatment $ Sex $ Age Duration Pain $ @@;
   datalines;
P F 68  1 No  B M 74 16 No  P F 67 30 No

A F 74  1 No  B M 80 21 Yes A F 69  3 No
;
```

The data set contains five variables. Treatment is a classification variable that has three levels: A and B represent the two test treatments, and P represents the placebo treatment. Sex is a classification variable that indicates each patient's gender. Age is a continuous variable that indicates the age in years of each patient when a treatment began. Duration is a continuous variable that indicates the duration of complaint in months. The last variable Pain is the response variable with two levels: 'Yes' if pain was reported, 'No' if no pain was reported.

Suppose there is some preliminary belief that the dependency of pain on the explanatory variables is different for male and female patients, leading to separate models between genders. You believe there might be redundant information for predicting the probability of Pain. Thus, you want to perform model selection to eliminate unnecessary effects. You can use the following statements:

```
proc sort data=Neuralgia;
   by sex;
run;

proc logistic data=Neuralgia;
   class Treatment / param=glm;
   model pain = Treatment Age Duration / selection=backward;
   by sex;
   store painmodel;
   title 'Logistic Model on Neuralgia';
run;
```

PROC SORT is called to sort the data by variable Sex. The LOGISTIC procedure is then called to fit the probability of no pain. Three variables are specified for the full model: Treatment, Age, and Duration. The backward elimination is used as the model selection method. The BY statement specifies that separate models be fitted for male and female patients. Finally, the STORE statement specifies that the fitted results be saved to an item store named painmodel.

Output 68.5.1 lists parameter estimates from the two models after backward elimination is performed. From the model for female patients, Treatment is the only factor that affects the probability of no pain, and Treatment A and B have the same positive effect in predicting the probability of no pain. From the model for male patients, both Treatment and Age are included in the selected model. Treatment A and B have different positive effects, while Age has a negative effect in predicting the probability of no pain.

Output 68.5.1 Parameter Estimates for Male and Female Patients

```
                        Logistic Model on Neuralgia

---------------------------------- Sex=F -----------------------------------

     Parameter      DF    Estimate       Error    Chi-Square    Pr > ChiSq

     Intercept       1     -0.4055      0.6455        0.3946        0.5299
     Treatment A     1      2.6027      1.2360        4.4339        0.0352
     Treatment B     1      2.6027      1.2360        4.4339        0.0352
     Treatment P     0           0           .             .             .

---------------------------------- Sex=M -----------------------------------

                  Analysis of Maximum Likelihood Estimates

                                       Standard          Wald
     Parameter      DF    Estimate       Error    Chi-Square    Pr > ChiSq

     Intercept       1     20.6178      9.1638        5.0621        0.0245
     Treatment A     1      3.9982      1.7333        5.3208        0.0211
     Treatment B     1      4.5556      1.9252        5.5993        0.0180
     Treatment P     0           0           .             .             .
     Age             1     -0.3416      0.1408        5.8869        0.0153
```

Now the fitted models are saved to the item store painmodel. Suppose you want to use it to score several new observations. The following DATA steps create three data sets for scoring:

```
data score1;
   input Treatment $ Sex $ Age;
   datalines;
A F 20
B F 30
P F 40
A M 20
B M 30
P M 40
;

data score2;
   set score1(drop=sex);
run;

data score3;
   set score2(drop=Age);
run;
```

The first score data set score1 contains six observations and all the variables that are specified in the full model. The second score data set score2 is a duplicate of score1 except that Sex is dropped. The third score data set score3 is a duplicate of score2 except that Age is dropped. You can use the following statements to score the three data sets:

```
proc plm source=painmodel;
   score data=score1 out=score1out predicted;
   score data=score2 out=score2out predicted;
   score data=score3 out=score3out predicted;
run;
```

Output 68.5.2 lists the store information that PROC PLM reads from the item store painmodel. The "Model Effects" entry lists all three variables that are specified in the full model before the By-group processing.

Output 68.5.2 Item Store Information for painmodel

Logistic Model on Neuralgia

The PLM Procedure

Store Information

Item Store	WORK.PAINMODEL
Data Set Created From	WORK.NEURALGIA
Created By	PROC LOGISTIC
Date Created	18FEB11:10:49:28
By Variable	Sex
Response Variable	Pain
Link Function	Logit
Distribution	Binary
Class Variables	Treatment Pain
Model Effects	Intercept Treatment Age Duration

With the three SCORE statements, three data sets are thus produced: score1out, score2out, and score3out. They contain the linear predictors in addition to all original variables. The data set score1out contains the values shown in Output 68.5.3:

Output 68.5.3 Values of Data Set score1out

Logistic Model on Neuralgia

Obs	Treatment	Sex	Age	Predicted
1	A	F	20	2.1972
2	B	F	30	2.1972
3	P	F	40	-0.4055
4	A	M	20	17.7850
5	B	M	30	14.9269
6	P	M	40	6.9557

Linear predictors are computed for all six observations. Because the BY variable Sex is available in score1, PROC PLM uses separate models to score observations of male and female patients. So an observation with the same Treatment and Age has different linear predictors for different genders.

The data set score2out contains the values shown in Output 68.5.4:

Output 68.5.4 Values of Data Set score2out

Logistic Model on Neuralgia

Obs	Sex	Treatment	Age	Predicted
1	F	A	20	2.1972
2	F	B	30	2.1972
3	F	P	40	-0.4055
4	F	A	20	2.1972
5	F	B	30	2.1972
6	F	P	40	-0.4055
7	M	A	20	17.7850
8	M	B	30	14.9269
9	M	P	40	6.9557
10	M	A	20	17.7850
11	M	B	30	14.9269
12	M	P	40	6.9557

The second score data set score2 does not contain the BY variable Sex. PROC PLM continues to score the full data set two times. Each time the scoring is based on the fitted model for each corresponding By-group. In the output data set, Sex is added at the first column as the By-group indicator. The first six entries correspond to the model for female patients, and the next six entries correspond to the model for male patients. Age is not included in the first model, and Treatment A and B have the same parameter estimates, so observations 1, 2, 4, and 5 have the same linear predicted value.

The data set score3out contains the values shown in Output 68.5.5:

Output 68.5.5 Values of Data Set score3out

Logistic Model on Neuralgia

Obs	Sex	Treatment	Predicted
1	F	A	2.19722
2	F	B	2.19722
3	F	P	-0.40547
4	F	A	2.19722
5	F	B	2.19722
6	F	P	-0.40547
7	M	A	.
8	M	B	.
9	M	P	.
10	M	A	.
11	M	B	.
12	M	P	.

The third score data set score3 does not contain the BY variable Sex. PROC PLM scores the full data twice with separate models. Furthermore, it does not contain the variable Age, which is a selected variable for predicting the probability of no pain for male patients. Thus, PROC PLM computes linear predictor values for score3 by using the first model for female patients, and sets the linear predictor to missing when using the second model for male patients to score the data set.

Example 68.6: Comparing Multiple B-Splines

This example conducts an analysis similar to Example 15 in Chapter 40.33, "Examples: GLIMMIX Procedure." It uses simulated data to perform multiple comparisons among predicted values in a model with group-specific trends that are modeled through regression splines. The estimable functions are formed using nonpositional syntax with constructed effects. Consider the data in the following DATA step. Each of the 100 observations for the continuous response variable y is associated with one of two groups.

```
data spline;
  input group y @@;
  x = _n_;
  datalines;
 1    -.020 1    0.199 2    -1.36 1    -.026
 2    -.397 1    0.065 2    -.861 1    0.251
 1    0.253 2    -.460 2    0.195 2    -.108
 1    0.379 1    0.971 1    0.712 2    0.811
 2    0.574 2    0.755 1    0.316 2    0.961
 2    1.088 2    0.607 2    0.959 1    0.653
 1    0.629 2    1.237 2    0.734 2    0.299
 2    1.002 2    1.201 1    1.520 1    1.105

 2    2.105 2    1.828 2    1.368 1    2.252
 1    1.984 2    1.867 1    2.771 1    2.052
 2    1.522 2    2.200 1    2.562 1    2.517
 1    2.769 1    2.534 2    1.969 1    2.460
 1    2.873 1    2.678 1    3.135 2    1.705
 1    2.893 1    3.023 1    3.050 2    2.273
 2    2.549 1    2.836 2    2.375 2    1.841
 1    3.727 1    3.806 1    3.269 1    3.533
 1    2.948 2    1.954 2    2.326 2    2.017
 1    3.744 2    2.431 2    2.040 1    3.995
 2    1.996 2    2.028 2    2.321 2    2.479
 2    2.337 1    4.516 2    2.326 2    2.144
 2    2.474 2    2.221 1    4.867 2    2.453
 1    5.253 2    3.024 2    2.403 1    5.498
;
```

The following statements fit a model with separate trends for the two groups; the trends are modeled as B-splines.

```
proc orthoreg data=spline;
   class group;
   effect spl = spline(x);
   model y = group spl*group / noint;
   store ortho_spline;
   title 'B-splines Comparisons';
run;
```

Results from this analysis are shown in Output 68.6.1. The "Parameter Estimates" table shows the estimates for the spline coefficients in the two groups.

Output 68.6.1 Results for Group-Specific Spline Model

B-splines Comparisons

By default, the ORTHOREG procedure constructs B-splines with seven knots. Since B-spline coefficients satisfy a sum-to-one constraint and since the model contains group-specific intercepts, the last spline coefficient for each group is redundant and estimated as 0.

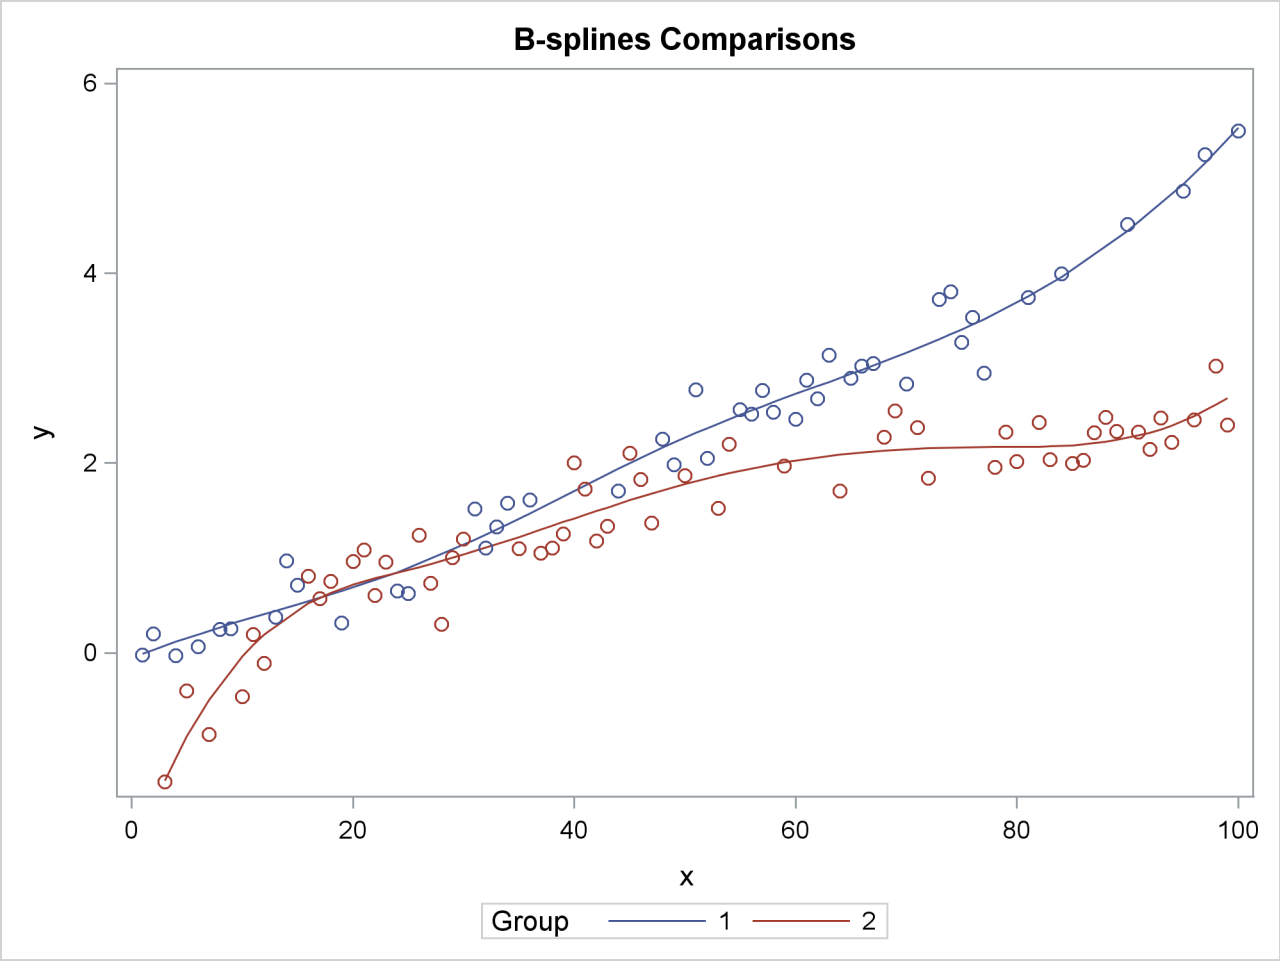
The following statements make a prediction for the input data set by using the SCORE statement with PROC PLM and graph the observed and predicted values in the two groups:

```
proc plm source=ortho_spline;
   score data=spline out=ortho_pred predicted=p;
run;

proc sgplot data=ortho_pred;
   series  y=p x=x / group=group name="fit";
   scatter y=y x=x / group=group;
   keylegend "fit" / title="Group";
run;
```

The prediction plot in Output 68.6.2 suggests that there is some separation of the group trends for small values of x and for values that exceed about $x = 40$.

Output 68.6.2 Observed Data and Predicted Values by Group



In order to determine the range on which the trends separate significantly, the PLM procedure is executed in the following statements with an ESTIMATE statement that applies group comparisons at a number of values for the spline variable x:

```
%macro GroupDiff;
   %do x=0 %to 75 %by 5;
      "Diff at x=&x" group 1 -1 group*spl [1,1  &x] [-1,2  &x],
   %end;
   'Diff at x=80' group 1 -1 group*spl [1,1 80] [-1,2 80]
%mend;

proc plm source=ortho_spline;
   show effects;
   estimate %GroupDiff / adjust=simulate seed=1 stepdown;
run;
```

For example, the following ESTIMATE statement compares the trends between the two groups at $x = 25$:

```
estimate 'Diff at x=25' group 1 -1 group*spl [1,1 25] [-1,2 25];
```

The nonpositional syntax is used for the group*spl effect. For example, the specification $[-1,\ 2\ 25]$ requests that the spline be computed at $x = 25$ for the second level of variable group. The resulting coefficients are added to the bL vector for the estimate after being multiplied with -1.

Because comparisons are made at a large number of values for x, a multiplicity correction is in order to adjust the p-values to reflect familywise error control. Simulated p-values with step-down adjustment are used here.

Output 68.6.3 displays the "Store Information" for the item store and information about the spline effect (the result of the SHOW statement).

Notice that the "Store Information" in Output 68.6.3 displays the classification variables (from the CLASS statement in PROC ORTHOREG), the constructed effects (from the EFFECT statement in PROC ORTHOREG), and the model effects (from the MODEL statement in PROC ORTHOREG). Output 68.6.4 shows that at the 5% significance level the trends are significantly different for $x \leq 10$ and for $x \geq 40$. Between those values you cannot reject the hypothesis of trend congruity.

To see this effect more clearly, you can filter the results by adding the following filtering statement to the previous PROC PLM run:

```
filter adjp > 0.05;
```

This produces Output 68.6.5, which displays the subset of the results in Output 68.6.4 that meets the condition in the FILTER expression.

Output 68.6.5 Filtered Estimate Results

Example 68.7: Linear Inference with Arbitrary Estimates

Suppose that you have calculated a vector of parameter estimates of dimension $(p \times 1)$ and its associated variance-covariance matrix by some statistical method. You are now interested in using these results to perform linear inference, or perhaps to score a data set and to calculate predicted values and their standard errors.

The following DATA steps create two SAS data sets. The first, called parms, contains six estimates that represent two uncorrelated groups. The data set cov contains the covariance matrix of the estimates. The lack of correlation between the two sets of three parameters is evident in the block-diagonal structure of the covariance matrix.

```
data parms;
   length name $6;
   input Name$ Value;
   datalines;
alpha1 -3.5671
beta1   0.4421
gamma1 -2.6230
alpha2 -3.0111
beta2   0.3977
gamma2 -2.4442
;
```

```
data cov;
   input Parm row col1-col6;
   datalines;
1 1  0.007462 -0.005222  0.010234  0.000000  0.000000  0.000000
1 2 -0.005222  0.048197 -0.010590  0.000000  0.000000  0.000000
1 3  0.010234 -0.010590  0.215999  0.000000  0.000000  0.000000
1 4  0.000000  0.000000  0.000000  0.031261 -0.009096  0.015785
1 5  0.000000  0.000000  0.000000 -0.009096  0.039487 -0.019996
1 6  0.000000  0.000000  0.000000  0.015785 -0.019996  0.126172
;
```

Suppose that you are interested in testing whether the parameters are homogeneous across groups—that is, whether $\alpha_1 = \alpha_2, \beta_1 = \beta_2, \gamma_1 = \gamma 2$. You are interested in testing the hypothesis jointly and separately with multiplicity adjustment.

In order to use the facilities of the PLM procedure, you first need to create an item store that contains the necessary information as if the preceding parameter vector and covariance matrix were the result of a statistical modeling procedure. The following statements use the multivariate facilities of the GLIMMIX procedure to create such an item store, by fitting a saturated linear model with the GLIMMIX procedure where the data set that contains the parameter estimates serves as the input data set:

```
proc glimmix data=parms order=data;
   class Name;
   model Value = Name / noint ddfm=none s;
   random _residual_ / type=lin(1) ldata=cov v;
   parms (1) / noiter;
   store ArtificialModel;
   title 'Linear Inference';
run;
```

The RANDOM statement is used to form the covariance structure for the estimates. The PARMS statement prevents iterative updates of the covariance parameters. The resulting marginal covariance matrix of the "data" is thus identical to the covariance matrix in the data set cov. The ORDER=DATA option in the PROC GLIMMIX statement is used to arrange the levels of the classification variable Name in the order in which they appear in the data set so that the order of the parameters matches that of the covariance matrix.

The results of this analysis are shown in Output 68.7.1. Note that the parameter estimates are identical to the values passed in the input data set and their standard errors equal the square root of the diagonal elements of the cov data set.

Output 68.7.1 "Fitted" Parameter Estimates and Covariance Matrix

Linear Inference

The GLIMMIX Procedure

Estimated V Matrix for Subject 1

Row	Col1	Col2	Col3	Col4	Col5	Col6
1	0.007462	−0.00522	0.01023			
2	−0.00522	0.04820	−0.01059			
3	0.01023	−0.01059	0.2160			
4				0.03126	−0.00910	0.01579
5				−0.00910	0.03949	−0.02000
6				0.01579	−0.02000	0.1262

Solutions for Fixed Effects

Effect	name	Estimate	Standard Error	DF	t Value	Pr > |t|
name	alpha1	−3.5671	0.08638	Infty	−41.29	<.0001
name	beta1	0.4421	0.2195	Infty	2.01	0.0440
name	gamma1	−2.6230	0.4648	Infty	−5.64	<.0001
name	alpha2	−3.0111	0.1768	Infty	−17.03	<.0001
name	beta2	0.3977	0.1987	Infty	2.00	0.0454
name	gamma2	−2.4442	0.3552	Infty	−6.88	<.0001

There are other ways to fit a saturated model with the GLIMMIX procedure. For example, you can use the TYPE=UN covariance structure in the RANDOM statement with a properly prepared input data set for the PDATA= option in the PARMS statement. See Example 17 in Chapter 40.33, "Examples: GLIMMIX Procedure," for details.

Once the item store exists, you can apply the linear inference capabilities of the PLM procedure. For example, the ESTIMATE statement in the following statements test the hypothesis of parameter homogeneity across groups:

```
proc plm source=ArtificialModel;
   estimate
        'alpha1 = alpha2' Name 1  0  0 -1  0  0,
        'beta1  = beta2 ' Name 0  1  0  0 -1  0,
        'gamma1 = gamma2' Name 0  0  1  0  0 -1 /
                 adjust=bon stepdown ftest(label='Homogeneity');
run;
```

Output 68.7.2 Results from the PLM Procedure

Linear Inference

The PLM Procedure

Estimates
Adjustment for Multiplicity: Holm

Label	Estimate	Standard Error	DF	t Value	Pr > |t|	Adj P
alpha1 = alpha2	−0.5560	0.1968	Infty	−2.83	0.0047	0.0142
beta1 = beta2	0.04440	0.2961	Infty	0.15	0.8808	1.0000
gamma1 = gamma2	−0.1788	0.5850	Infty	−0.31	0.7599	1.0000

F Test for Estimates

Label	Num DF	Den DF	F Value	Pr > F
Homogeneity	3	Infty	2.79	0.0389

The F test in Output 68.7.2 shows that the joint test of homogeneity is rejected. The individual tests with familywise control of the Type I error show that the overall difference is due to a significant change in the α parameters. The hypothesis of homogeneity across the two groups cannot be rejected for the β and γ parameters.

Chapter 69

The PLS Procedure

Contents

Overview: PLS Procedure

The PLS procedure fits models by using any one of a number of linear predictive methods, including *partial least squares* (PLS). Ordinary least squares regression, as implemented in SAS/STAT procedures such as PROC GLM and PROC REG, has the single goal of minimizing sample response prediction error, seeking linear functions of the predictors that explain as much variation in each response as possible. The techniques implemented in the PLS procedure have the additional goal of accounting for variation in the predictors, under the assumption that directions in the predictor space that are well sampled should provide better prediction for *new* observations when the predictors are highly correlated. All of the techniques implemented in the PLS procedure work by extracting successive linear combinations of the predictors, called *factors* (also called *components*, *latent vectors*, or *latent variables*), which optimally address one or both of these two goals—explaining response variation and explaining predictor variation. In particular, the method of partial least squares balances the two objectives, seeking factors that explain both response and predictor variation.

Note that the name "partial least squares" also applies to a more general statistical method that is *not* implemented in this procedure. The partial least squares method was originally developed in the 1960s by the econometrician Herman Wold (1966) for modeling "paths" of causal relation between any number of "blocks" of variables. However, the PLS procedure fits only *predictive* partial least squares models, with one "block" of predictors and one "block" of responses. If you are interested in fitting more general path models, you should consider using the CALIS procedure.

Basic Features

The techniques implemented by the PLS procedure are as follows:

- principal components regression, which extracts factors to explain as much predictor sample variation as possible
- reduced rank regression, which extracts factors to explain as much response variation as possible. This technique, also known as (maximum) redundancy analysis, differs from multivariate linear regression only when there are multiple responses.
- partial least squares regression, which balances the two objectives of explaining response variation and explaining predictor variation. Two different formulations for partial least squares are available: the original predictive method of Wold (1966) and the SIMPLS method of de Jong (1993).

The number of factors to extract depends on the data. Basing the model on more extracted factors improves the model fit to the observed data, but extracting too many factors can cause *overfitting*—that is, tailoring the model too much to the current data, to the detriment of future predictions. The PLS procedure enables you to choose the number of extracted factors by *cross validation*—that is, fitting the model to part of the data, minimizing the prediction error for the unfitted part, and iterating with different portions of the data in the roles of fitted and unfitted. Various methods of cross validation are available, including one-at-a-time

validation and splitting the data into blocks. The PLS procedure also offers test set validation, where the model is fit to the entire primary input data set and the fit is evaluated over a distinct test data set.

You can use the general linear modeling approach of the GLM procedure to specify a model for your design, allowing for general polynomial effects as well as classification or ANOVA effects. You can save the model fit by the PLS procedure in a data set and apply it to new data by using the SCORE procedure.

The PLS procedure uses ODS Graphics to create graphs as part of its output. For general information about ODS Graphics, see Chapter 21, "Statistical Graphics Using ODS." For specific information about the statistical graphics available with the PLS procedure, see the PLOTS options in the PROC PLS statements and the section "ODS Graphics" on page 5703.

Getting Started: PLS Procedure

Spectrometric Calibration

The example in this section illustrates basic features of the PLS procedure. The data are reported in Umetrics (1995); the original source is Lindberg, Persson, and Wold (1983). Suppose that you are researching pollution in the Baltic Sea, and you would like to use the spectra of samples of seawater to determine the amounts of three compounds present in samples from the Baltic Sea: lignin sulfonate (ls: pulp industry pollution), humic acids (ha: natural forest products), and optical whitener from detergent (dt). Spectrometric calibration is a type of problem in which partial least squares can be very effective. The predictors are the spectra emission intensities at different frequencies in sample spectrum, and the responses are the amounts of various chemicals in the sample.

For the purposes of calibrating the model, samples with known compositions are used. The calibration data consist of 16 samples of known concentrations of ls, ha, and dt, with spectra based on 27 frequencies (or, equivalently, wavelengths). The following statements create a SAS data set named Sample for these data.

Fitting a PLS Model

To isolate a few underlying spectral factors that provide a good predictive model, you can fit a PLS model to the 16 samples by using the following SAS statements:

```
proc pls data=sample;
   model ls ha dt = v1-v27;
run;
```

By default, the PLS procedure extracts at most 15 factors. The procedure lists the amount of variation accounted for by each of these factors, both individual and cumulative; this listing is shown in Figure 69.1.

Figure 69.1 PLS Variation Summary

The PLS Procedure

Percent Variation Accounted for by Partial Least Squares Factors

Number of Extracted Factors	Model Effects Current	Model Effects Total	Dependent Variables Current	Dependent Variables Total
1	97.4607	97.4607	41.9155	41.9155
2	2.1830	99.6436	24.2435	66.1590
3	0.1781	99.8217	24.5339	90.6929
4	0.1197	99.9414	3.7898	94.4827
5	0.0415	99.9829	1.0045	95.4873
6	0.0106	99.9935	2.2808	97.7681
7	0.0017	99.9952	1.1693	98.9374
8	0.0010	99.9961	0.5041	99.4415
9	0.0014	99.9975	0.1229	99.5645
10	0.0010	99.9985	0.1103	99.6747
11	0.0003	99.9988	0.1523	99.8270
12	0.0003	99.9991	0.1291	99.9561
13	0.0002	99.9994	0.0312	99.9873
14	0.0004	99.9998	0.0065	99.9938
15	0.0002	100.0000	0.0062	100.0000

Note that all of the variation in both the predictors and the responses is accounted for by only 15 factors; this is because there are only 16 sample observations. More important, almost all of the variation is accounted for with even fewer factors—one or two for the predictors and three to eight for the responses.

Selecting the Number of Factors by Cross Validation

A PLS model is not complete until you choose the number of factors. You can choose the number of factors by using cross validation, in which the data set is divided into two or more groups. You fit the model to all groups except one, and then you check the capability of the model to predict responses for the group omitted. Repeating this for each group, you then can measure the overall capability of a given form of the model. The predicted residual sum of squares (PRESS) statistic is based on the residuals generated by this process.

To select the number of extracted factors by cross validation, you specify the CV= option with an argument that says which cross validation method to use. For example, a common method is split-sample validation, in which the different groups are composed of every nth observation beginning with the first, every nth observation beginning with the second, and so on. You can use the CV=SPLIT option to specify split-sample validation with $n = 7$ by default, as in the following SAS statements:

```
proc pls data=sample cv=split;
   model ls ha dt = v1-v27;
run;
```

The resulting output is shown in Figure 69.2 and Figure 69.3.

Figure 69.2 Split-Sample Validated PRESS Statistics for Number of Factors

The PLS Procedure

Split-sample Validation for the Number of Extracted Factors

Number of Extracted Factors	Root Mean PRESS
0	1.107747
1	0.957983
2	0.931314
3	0.520222
4	0.530501
5	0.586786
6	0.475047

8	0.483138
9	0.485739
10	0.48946
11	0.521445
12	0.525653
13	0.531049
14	0.531049
15	0.531049

Minimum root mean PRESS	0.4750
Minimizing number of factors	6

Figure 69.3 PLS Variation Summary for Split-Sample Validated Model

Percent Variation Accounted for by Partial Least Squares Factors

Number of Extracted Factors	Model Effects		Dependent Variables	
	Current	Total	Current	Total
1	97.4607	97.4607	41.9155	41.9155
2	2.1830	99.6436	24.2435	66.1590
3	0.1781	99.8217	24.5339	90.6929
4	0.1197	99.9414	3.7898	94.4827
5	0.0415	99.9829	1.0045	95.4873
6	0.0106	99.9935	2.2808	97.7681

The absolute minimum PRESS is achieved with six extracted factors. Notice, however, that this is not much smaller than the PRESS for three factors. By using the CVTEST option, you can perform a statistical model comparison suggested by van der Voet (1994) to test whether this difference is significant, as shown in the following SAS statements:

```
proc pls data=sample cv=split cvtest(seed=12345);
   model ls ha dt = v1-v27;
run;
```

The model comparison test is based on a rerandomization of the data. By default, the seed for this randomization is based on the system clock, but it is specified here. The resulting output is shown in Figure 69.4 and Figure 69.5.

Figure 69.4 Testing Split-Sample Validation for Number of Factors

The PLS Procedure

Split-sample Validation for the Number of Extracted Factors

Number of Extracted Factors	Root Mean PRESS	T**2	Prob > T**2
0	1.107747	9.272858	0.0010
1	0.957983	10.62305	<.0001
2	0.931314	8.950878	0.0010

4	0.530501	5.168427	0.1340
5	0.586786	6.437266	0.0150
6	0.475047	0	1.0000
7	0.477595	2.809763	0.4750
8	0.483138	7.189526	0.0110
9	0.485739	7.931726	0.0070
10	0.48946	6.612597	0.0150
11	0.521445	6.666235	0.0130
12	0.525653	7.092861	0.0080
13	0.531049	7.538298	0.0030
14	0.531049	7.538298	0.0030
15	0.531049	7.538298	0.0030

Minimum root mean PRESS	0.4750
Minimizing number of factors	6
Smallest number of factors with p > 0.1	3

Figure 69.5 PLS Variation Summary for Tested Split-Sample Validated Model

Percent Variation Accounted for by Partial Least Squares Factors

Number of Extracted Factors	Model Effects Current	Model Effects Total	Dependent Variables Current	Dependent Variables Total
1	97.4607	97.4607	41.9155	41.9155
2	2.1830	99.6436	24.2435	66.1590
3	0.1781	99.8217	24.5339	90.6929

The p-value of 0.1430 in comparing the cross validated residuals from models with 6 and 3 factors indicates that the difference between the two models is insignificant; therefore, the model with fewer factors is preferred. The variation summary shows that over 99% of the predictor variation and over 90% of the response variation are accounted for by the three factors.

Predicting New Observations

Now that you have chosen a three-factor PLS model for predicting pollutant concentrations based on sample spectra, suppose that you have two new samples. The following SAS statements create a data set containing the spectra for the new samples:

```
data newobs;
   input obsnam $ v1-v27 @@;
   datalines;
EM17  3933 4518 5637 6006 5721 5187 4641 4149 3789
      3579 3447 3381 3327 3234 3078 2832 2571 2274
      2040 1818 1629 1470 1350 1245 1134 1050  987
EM25  2904 2997 3255 3150 2922 2778 2700 2646 2571
      2487 2370 2250 2127 2052 1713 1419 1200  984
       795  648  525  426  351  291  240  204  162
;
```

You can apply the PLS model to these samples to estimate pollutant concentration. To do so, append the new samples to the original 16, and specify that the predicted values for all 18 be output to a data set, as shown in the following statements:

```
data all;
   set sample newobs;
run;

proc pls data=all nfac=3;
   model ls ha dt = v1-v27;
   output out=pred p=p_ls p_ha p_dt;
run;
proc print data=pred;
   where (obsnam in ('EM17','EM25'));
   var obsnam p_ls p_ha p_dt;
run;
```

The new observations are not used in calculating the PLS model, since they have no response values. Their predicted concentrations are shown in Figure 69.6.

Figure 69.6 Predicted Concentrations for New Observations

Obs	obsnam	p_ls	p_ha	p_dt
17	EM17	2.54261	0.31877	81.4174
18	EM25	-0.24716	1.37892	46.3212

Finally, if ODS Graphics is enabled, PLS also displays by default a plot of the amount of variation accounted for by each factor, as well as a correlations loading plot that summarizes the first two dimensions of the PLS model. The following statements, which are the same as the previous split-sample validation analysis but with ODS Graphics enabled, additionally produce Figure 69.7 and Figure 69.8:

```
ods graphics on;

proc pls data=sample cv=split cvtest(seed=12345);
   model ls ha dt = v1-v27;
run;

ods graphics off;
```

Figure 69.7 Split-Sample Cross Validation Plot

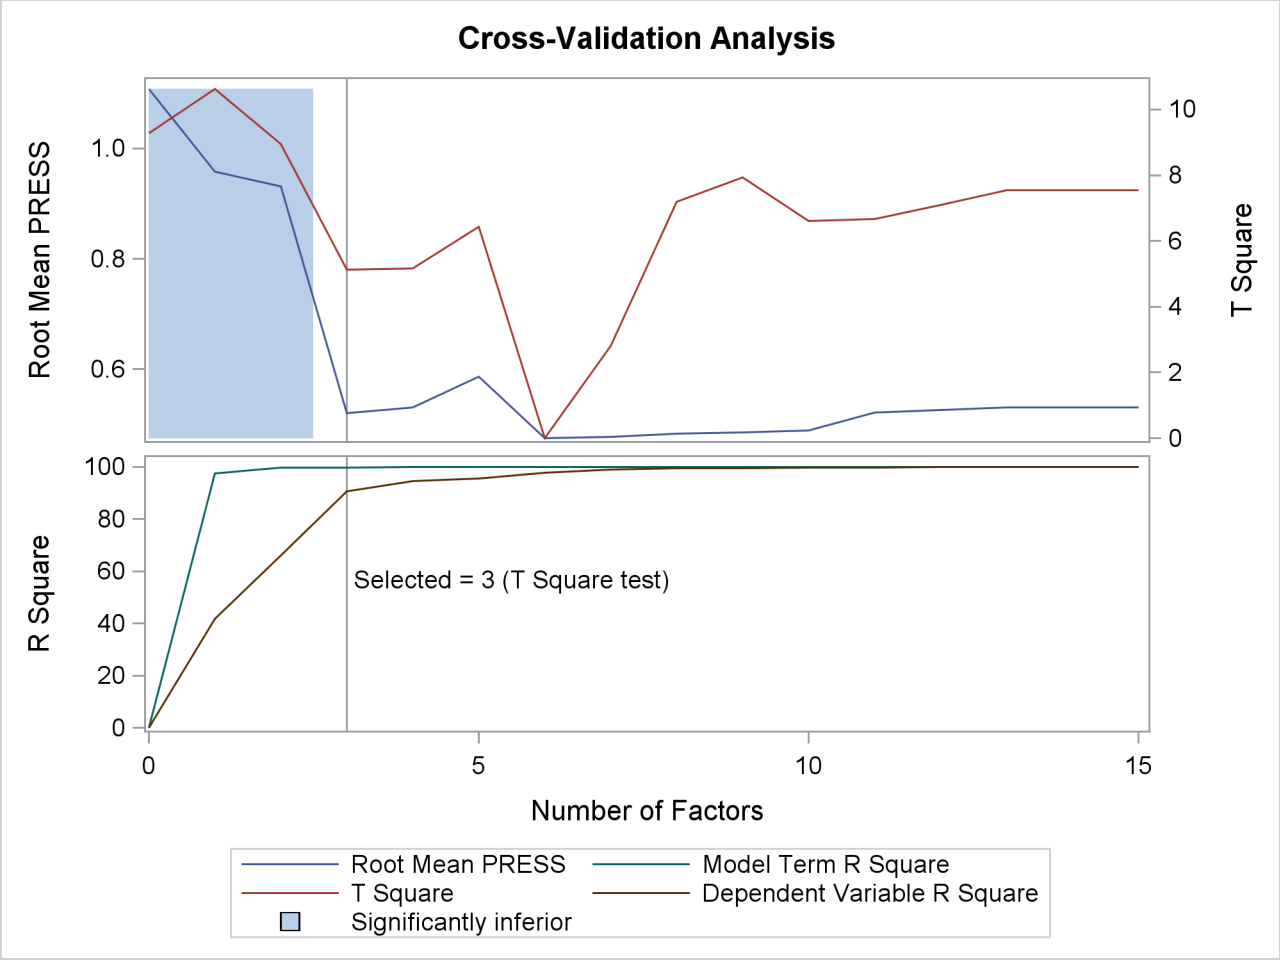

Figure 69.8 Correlation Loadings Plot

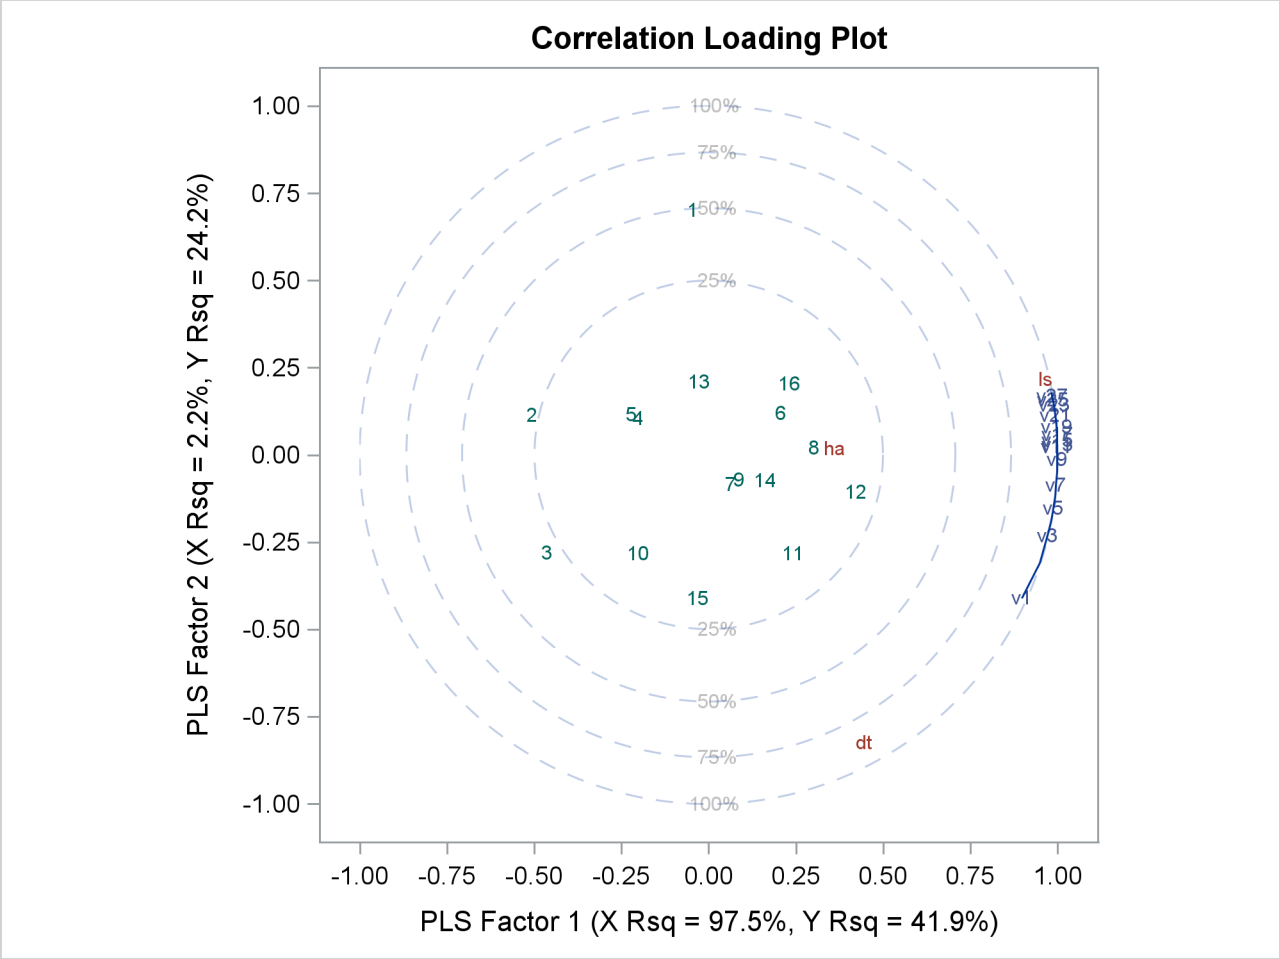


The cross validation plot in Figure 69.7 gives a visual representation of the selection of the optimum number of factors discussed previously. The correlation loadings plot is a compact summary of many features of the PLS model. For example, it shows that the first factor is highly positively correlated with all spectral values, indicating that it is approximately an average of them all; the second factor is positively correlated with the lowest frequencies and negatively correlated with the highest, indicating that it is approximately a contrast between the two ends of the spectrum. The observations, represented by their number in the data set on this plot, are generally spaced well apart, indicating that the data give good information about these first two factors. For more details on the interpretation of the correlation loadings plot, see the section "ODS Graphics" on page 5703 and Example 69.1.

Syntax: PLS Procedure

The following statements are available in PROC PLS. Items within the angle brackets are optional.

PROC PLS < *options* > ;
BY *variables* ;
CLASS *variables* < / *option* > ;
EFFECT *name* = *effect-type* (*variables* < / *options* >) ;
ID *variables* ;
MODEL *dependent-variables* = *effects* < / *options* > ;
OUTPUT OUT=*SAS-data-set* < *options* > ;

To analyze a data set, you must use the PROC PLS and MODEL statements. You can use the other statements as needed. CLASS and EFFECT statements, if present, must precede the MODEL statement.

PROC PLS Statement

PROC PLS < *options* > ;

You use the PROC PLS statement to invoke the PLS procedure and, optionally, to indicate the analysis data and method. The following options are available.

CENSCALE
lists the centering and scaling information for each response and predictor.

CV=ONE
CV=SPLIT < (*n*) >
CV=BLOCK < (*n*) >
CV=RANDOM < (*cv-random-opts*) >
CV=TESTSET(*SAS-data-set***)**
specifies the cross validation method to be used. By default, no cross validation is performed. The method CV=ONE requests one-at-a-time cross validation, CV=SPLIT requests that every nth observation be excluded, CV=BLOCK requests that n blocks of consecutive observations be excluded, CV=RANDOM requests that observations be excluded at random, and CV=TESTSET(*SAS-data-set*) specifies a test set of observations to be used for validation (formally, this is called "test set validation" rather than "cross validation"). You can, optionally, specify n for CV=SPLIT and CV=BLOCK; the default is $n = 7$. You can also specify the following optional *cv-random-options* in parentheses after the CV=RANDOM option:

NITER=*n* specifies the number of random subsets to exclude. The default value is 10.

NTEST=*n* specifies the number of observations in each random subset chosen for exclusion. The default value is one-tenth of the total number of observations.

SEED=*n* specifies an integer used to start the pseudo-random number generator for selecting the random test set. If you do not specify a seed, or specify a value less than or

equal to zero, the seed is by default generated from reading the time of day from the computer's clock.

CVTEST <(*cvtest-options*)>
specifies that van der Voet's (1994) randomization-based model comparison test be performed to test models with different numbers of extracted factors against the model that minimizes the predicted residual sum of squares; see the section "Cross Validation" on page 5699 for more information. You can also specify the following *cv-test-options* in parentheses after the CVTEST option:

PVAL=*n* specifies the cutoff probability for declaring an insignificant difference. The default value is 0.10.

STAT=*test-statistic* specifies the test statistic for the model comparison. You can specify either T2, for Hotelling's T^2 statistic, or PRESS, for the predicted residual sum of squares. The default value is T2.

NSAMP=*n* specifies the number of randomizations to perform. The default value is 1000.

SEED=*n* specifies the seed value for randomization generation (the clock time is used by default).

DATA=*SAS-data-set*
names the SAS data set to be used by PROC PLS. The default is the most recently created data set.

DETAILS
lists the details of the fitted model for each successive factor. The details listed are different for different extraction methods; see the section "Displayed Output" on page 5702 for more information.

METHOD=PLS <(*PLS-options*)>
METHOD=SIMPLS
METHOD=PCR
METHOD=RRR
specifies the general factor extraction method to be used. The value PLS requests partial least squares, SIMPLS requests the SIMPLS method of de Jong (1993), PCR requests principal components regression, and RRR requests reduced rank regression. The default is METHOD=PLS. You can also specify the following optional *PLS-options* in parentheses after METHOD=PLS:

ALGORITHM=NIPALS | SVD | EIG | RLGW
names the specific algorithm used to compute extracted PLS factors. NIPALS requests the usual iterative NIPALS algorithm, SVD bases the extraction on the singular value decomposition of $X'Y$, EIG bases the extraction on the eigenvalue decomposition of $Y'XX'Y$, and RLGW is an iterative approach that is efficient when there are many predictors. ALGORITHM=SVD is the most accurate but least efficient approach; the default is ALGORITHM=NIPALS.

MAXITER=*n* specifies the maximum number of iterations for the NIPALS and RLGW algorithms. The default value is 200.

EPSILON=*n* specifies the convergence criterion for the NIPALS and RLGW algorithms. The default value is 10^{-12}.

MISSING=NONE

MISSING=AVG

MISSING=EM <(*EM-options*)>

specifies how observations with missing values are to be handled in computing the fit. The default is MISSING=NONE, for which observations with any missing variables (dependent or independent) are excluded from the analysis. MISSING=AVG specifies that the fit be computed by filling in missing values with the average of the nonmissing values for the corresponding variable. If you specify MISSING=EM, then the procedure first computes the model with MISSING=AVG and then fills in missing values by their predicted values based on that model and computes the model again. For both methods of imputation, the imputed values contribute to the centering and scaling values, and the difference between the imputed values and their final predictions contributes to the percentage of variation explained. You can also specify the following optional *EM-options* in parentheses after MISSING=EM:

MAXITER=*n* specifies the maximum number of iterations for the imputation/fit loop. The default value is 1. If you specify a large value of MAXITER=, then the loop will iterate until it converges (as controlled by the EPSILON= option).

EPSILON=*n* specifies the convergence criterion for the imputation/fit loop. The default value is 10^{-8}. This option is effective only if you specify a large value for the MAXITER= option.

NFAC=*n*

specifies the number of factors to extract. The default is $\min\{15, p, N\}$, where p is the number of predictors (the number of dependent variables for METHOD=RRR) and N is the number of runs (observations). This is probably more than you need for most applications. Extracting too many factors can lead to an overfit model, one that matches the training data too well, sacrificing predictive ability. Thus, if you use the default NFAC= specification, you should also either use the CV= option to select the appropriate number of factors for the final model or consider the analysis to be preliminary and examine the results to determine the appropriate number of factors for a subsequent analysis.

NOCENTER

suppresses centering of the responses and predictors before fitting. This is useful if the analysis variables are already centered and scaled. See the section "Centering and Scaling" on page 5701 for more information.

NOCVSTDIZE

suppresses re-centering and rescaling of the responses and predictors before each model is fit in the cross validation. See the section "Centering and Scaling" on page 5701 for more information.

NOPRINT

suppresses the normal display of results. This is useful when you want only the output statistics saved in a data set. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 20, "Using the Output Delivery System" for more information.

NOSCALE

suppresses scaling of the responses and predictors before fitting. This is useful if the analysis variables are already centered and scaled. See the section "Centering and Scaling" on page 5701 for more information.

PLOTS <(*global-plot-options*)> <= *plot-request* <*(options)*> >

PLOTS <(*global-plot-options*)> <= (*plot-request* <*(options)*> <... *plot-request* <*(options)*> >) >

controls the plots produced through ODS Graphics. When you specify only one plot request, you can omit the parentheses from around the plot request. For example:

```
plots=none
plots=cvplot
plots=(diagnostics cvplot)
plots(unpack)=diagnostics
plots(unpack)=(diagnostics corrload(trace=off))
```

ODS Graphics must be enabled before requesting plots. For example:

```
ods graphics on;
proc pls data=pentaTrain;
   model log_RAI = S1-S5 L1-L5 P1-P5;
run;
ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section "Enabling and Disabling ODS Graphics" on page 612 in Chapter 21, "Statistical Graphics Using ODS."

If ODS Graphics is enabled but you do not specify the PLOTS= option, then PROC PLS produces by default a plot of the R-square analysis and a correlation loading plot summarizing the first two factors.

The global plot options include the following:

FLIP
interchanges the X-axis and Y-axis dimensions for the score, weight, and loading plots.

ONLY
suppresses the default plots. Only plots specifically requested are displayed.

UNPACKPANEL

UNPACK
suppresses paneling. By default, multiple plots can appear in some output panels. Specify UNPACKPANEL to get each plot in a separate panel. You can specify PLOTS(UNPACKPANEL) to unpack only the default plots. You can also specify UNPACKPANEL as a suboption for certain specific plots, as discussed in the following.

The plot requests include the following:

ALL
produces all appropriate plots. You can specify other options with ALL—for example, to request all plots and unpack only the residuals, specify PLOTS=(ALL RESIDUALS(UNPACK)).

CORRLOAD <(TRACE = ON | OFF)>
produces a correlation loading plot (default). The TRACE= option controls how points corresponding to the X-loadings in the correlation loadings plot are depicted. By default, these points are depicted by the name of the corresponding model effect if there are 20 or fewer of

them; otherwise, they are depicted by a connected "trace" through the points. You can use this option to change this behavior.

CVPLOT
produces a cross validation and R-square analysis. This plot requires the CV= option to be specified, and is displayed by default in this case.

DIAGNOSTICS < (UNPACK) >
produces a summary panel of the fit for each dependent variable. The summary by default consists of a panel for each dependent variable, with plots depicting the distribution of residuals and predicted values. You can use the UNPACK suboption to specify that the subplots be produced separately.

DMOD
produces the DMODX, DMODY, and DMODXY plots.

DMODX
produces a plot of the distance of each observation to the X model.

DMODXY
produces plots of the distance of each observation to the X and Y models.

DMODY
produces a plot of the distance of each observation to the Y model.

FIT
produces both the fit diagnostic panel and the ParmProfiles plot.

NONE
suppresses the display of graphics.

PARMPROFILES
produces profiles of the regression coefficients.

SCORES < (UNPACK | FLIP) >
produces the XScores, YScores, XYScores, and DModXY plots. You can use the UNPACK suboption to specify that the subplots for scores be produced separately, and the FLIP option to interchange their default X-axis and Y-axis dimensions.

RESIDUALS < (UNPACK) >
plots the residuals for each dependent variable against each independent variable. Residual plots are by default composed of multiple plots combined into a single panel. You can use the UNPACK suboption to specify that the subplots be produced separately.

VIP
produces profiles of variable importance factors.

WEIGHTS < (UNPACK | FLIP) >
produces all X and Y loading and weight plots, as well as the VIP plot. You can use the UNPACK suboption to specify that the subplots for weights and loadings be produced separately, and the FLIP option to interchange their default X-axis and Y-axis dimensions.

XLOADINGPLOT < (UNPACK | FLIP) >
produces a scatter plot matrix of X-loadings against each other. Loading scatter plot matrices are by default composed of multiple plots combined into a single panel. You can use the UNPACK suboption to specify that the subplots be produced separately, and the FLIP option to interchange the default X-axis and Y-axis dimensions.

XLOADINGPROFILES
produces profiles of the X-loadings.

XSCORES < (UNPACK | FLIP) >
produces a scatter plot matrix of X-scores against each other. Score scatter plot matrices are by default composed of multiple plots combined into a single panel. You can use the UNPACK suboption to specify that the subplots be produced separately, and the FLIP option to interchange the default X-axis and Y-axis dimensions.

XWEIGHTPLOT < (UNPACK | FLIP) >
produces a scatter plot matrix of X-weights against each other. Weight scatter plot matrices are by default composed of multiple plots combined into a single panel. You can use the UNPACK suboption to specify that the subplots be produced separately, and the FLIP option to interchange the default X-axis and Y-axis dimensions.

XWEIGHTPROFILES
produces profiles of the X-weights.

XYSCORES < (UNPACK) >
produces a scatter plot matrix of X-scores against Y-scores. Score scatter plot matrices are by default composed of multiple plots combined into a single panel. You can use the UNPACK suboption to specify that the subplots be produced separately.

YSCORES < (UNPACK | FLIP) >
produces a scatter plot matrix of Y-scores against each other. Score scatter plot matrices are by default composed of multiple plots combined into a single panel. You can use the UNPACK suboption to specify that the subplots be produced separately, and the FLIP option to interchange the default X-axis and Y-axis dimensions.

YWEIGHTPLOT < (UNPACK | FLIP) >
produces a scatter plot matrix of Y-weights against each other. Weight scatter plot matrices are by default composed of multiple plots combined into a single panel. You can use the UNPACK suboption to specify that the subplots be produced separately, and the FLIP option to interchange the default X-axis and Y-axis dimensions.

VARSCALE
specifies that continuous model variables be centered and scaled prior to centering and scaling the model effects in which they are involved. The rescaling specified by the VARSCALE option is sometimes more appropriate if the model involves crossproducts between model variables; however, the VARSCALE option still might not produce the model you expect. See the section "Centering and Scaling" on page 5701 for more information.

VARSS
lists, in addition to the average response and predictor sum of squares accounted for by each successive factor, the amount of variation accounted for in each response and predictor.

BY Statement

BY *variables* **;**

You can specify a BY statement with PROC PLS to obtain separate analyses on observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the PLS procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variables* < / **TRUNCATE** > **;**

The CLASS statement names the classification variables to be used in the model. Typical classification variables are Treatment, Sex, Race, Group, and Replication. If you use the CLASS statement, it must appear before the MODEL statement statement.

Classification variables can be either character or numeric. By default, class levels are determined from the entire set of formatted values of the CLASS variables.

NOTE: Prior to SAS 9, class levels were determined by using no more than the first 16 characters of the formatted values. To revert to this previous behavior, you can use the TRUNCATE option in the CLASS statement.

In any case, you can use formats to group values into levels. See the discussion of the FORMAT procedure in the *Base SAS Procedures Guide* and the discussions of the FORMAT statement and SAS formats in *SAS Language Reference: Dictionary*.

You can specify the following option in the CLASS statement after a slash (/):

TRUNCATE
specifies that class levels should be determined by using only up to the first 16 characters of the formatted values of CLASS variables. When formatted values are longer than 16 characters, you can use this option to revert to the levels as determined in releases prior to SAS 9.

EFFECT Statement

EFFECT *name = effect-type (variables < / options >)* **;**

The EFFECT statement enables you to construct special collections of columns for design matrices. These collections are referred to as *constructed effects* to distinguish them from the usual model effects formed from continuous or classification variables, as discussed in the section "GLM Parameterization of Classification Variables and Effects" on page 397 of Chapter 19, "Shared Concepts and Topics."

The following *effect-types* are available.

COLLECTION — is a collection effect that defines one or more variables as a single effect with multiple degrees of freedom. The variables in a collection are considered as a unit for estimation and inference.

LAG — is a classification effect in which the level that is used for a given period corresponds to the level in the preceding period.

Note: The LAG *effect-type* is experimental in this release.

MULTIMEMBER | MM — is a multimember classification effect whose levels are determined by one or more variables that appear in a CLASS statement.

POLYNOMIAL | POLY — is a multivariate polynomial effect in the specified numeric variables.

SPLINE — is a regression spline effect whose columns are univariate spline expansions of one or more variables. A spline expansion replaces the original variable with an expanded or larger set of new variables.

Table 69.1 summarizes important options for each type of EFFECT statement.

Table 69.1 Important EFFECT Statement Options

Option	Description
Options for Collection Effects	
DETAILS	Displays the constituents of the collection effect
Options for Lag Effects	
DESIGNROLE=	Names a variable that controls to which lag design an observation is assigned
DETAILS	Displays the lag design of the lag effect
NLAG=	Specifies the number of periods in the lag
PERIOD=	Names the variable that defines the period
WITHIN=	Names the variable or variables that define the group within which each period is defined

Table 69.1 *continued*

Option	Description
Options for Multimember Effects	
NOEFFECT	Specifies that observations with all missing levels for the multimember variables should have zero values in the corresponding design matrix columns
WEIGHT=	Specifies the weight variable for the contributions of each of the classification effects
Options for Polynomial Effects	
DEGREE=	Specifies the degree of the polynomial
MDEGREE=	Specifies the maximum degree of any variable in a term of the polynomial
STANDARDIZE=	Specifies centering and scaling suboptions for the variables that define the polynomial
Options for Spline Effects	
BASIS=	Specifies the type of basis (B-spline basis or truncated power function basis) for the spline expansion
DEGREE=	Specifies the degree of the spline transformation
KNOTMETHOD=	Specifies how to construct the knots for spline effects

For further details about the syntax of these *effect-types* and how columns of constructed effects are computed, see the section "EFFECT Statement" on page 406 of Chapter 19, "Shared Concepts and Topics."

ID Statement

ID *variables* **;**

The ID statement names variables whose values are used to label observations in plots. If you do not specify an ID statement, then each observations is labeled in plots by its corresponding observation number.

MODEL Statement

MODEL *response-variables = predictor-effects* < / *options* > **;**

The MODEL statement names the responses and the predictors, which determine the **Y** and **X** matrices of the model, respectively. Usually you simply list the names of the predictor variables as the model effects, but you can also use the effects notation of PROC GLM to specify polynomial effects and interactions; see the section "Specification of Effects" on page 3209 in Chapter 41, "The GLM Procedure" for further details.

The MODEL statement is required. You can specify only one MODEL statement (in contrast to the REG procedure, for example, which allows several MODEL statements in the same PROC REG run).

You can specify the following options in the MODEL statement after a slash (/).

INTERCEPT
By default, the responses and predictors are centered; thus, no intercept is required in the model. You can specify the INTERCEPT option to override the default.

SOLUTION
lists the coefficients of the final predictive model for the responses. The coefficients for predicting the centered and scaled responses based on the centered and scaled predictors are displayed, as well as the coefficients for predicting the raw responses based on the raw predictors.

OUTPUT Statement

OUTPUT *OUT= SAS-data-set keyword=names < . . . keyword=names >* **;**

You use the OUTPUT statement to specify a data set to receive quantities that can be computed for every input observation, such as extracted factors and predicted values. The following *keywords* are available:

PREDICTED	predicted values for responses
YRESIDUAL	residuals for responses
XRESIDUAL	residuals for predictors
XSCORE	extracted factors (X-scores, latent vectors, latent variables, T)
YSCORE	extracted responses (Y-scores, U)
STDY	standardized (centered and scaled) responses
STDX	standardized (centered and scaled) predictors
H	approximate leverage
PRESS	approximate predicted residuals
TSQUARE	scaled sum of squares of score values
STDXSSE	sum of squares of residuals for standardized predictors
STDYSSE	sum of squares of residuals for standardized responses

Suppose that there are N_x predictors and N_y responses and that the model has N_f selected factors.

- The keywords XRESIDUAL and STDX define an output variable for each predictor, so N_x names are required after each one.
- The keywords PREDICTED, YRESIDUAL, STDY, and PRESS define an output variable for each response, so N_y names are required after each of these keywords.

- The keywords XSCORE and YSCORE specify an output variable for each selected model factor. For these keywords, you provide only one base name, and the variables corresponding to each successive factor are named by appending the factor number to the base name. For example, if $N_f = 3$, then a specification of XSCORE=T would produce the variables T1, T2, and T3.
- Finally, the keywords H, TSQUARE, STDXSSE, and STDYSSE each specify a single output variable, so only one name is required after each of these keywords.

Details: PLS Procedure

Regression Methods

All of the predictive methods implemented in PROC PLS work essentially by finding linear combinations of the predictors (factors) to use to predict the responses linearly. The methods differ only in how the factors are derived, as explained in the following sections.

Partial Least Squares

Partial least squares (PLS) works by extracting one factor at a time. Let $\mathbf{X} = \mathbf{X}_0$ be the centered and scaled matrix of predictors and let $\mathbf{Y} = \mathbf{Y}_0$ be the centered and scaled matrix of response values. The PLS method starts with a linear combination $\mathbf{t} = \mathbf{X}_0\mathbf{w}$ of the predictors, where $\mathbf{t}$ is called a *score* vector and $\mathbf{w}$ is its associated *weight* vector. The PLS method predicts both $\mathbf{X}_0$ and $\mathbf{Y}_0$ by regression on $\mathbf{t}$:

$$\begin{aligned} \hat{\mathbf{X}}_0 &= \mathbf{t}\mathbf{p}', \quad \text{where} \quad \mathbf{p}' = (\mathbf{t}'\mathbf{t})^{-1}\mathbf{t}'\mathbf{X}_0 \\ \hat{\mathbf{Y}}_0 &= \mathbf{t}\mathbf{c}', \quad \text{where} \quad \mathbf{c}' = (\mathbf{t}'\mathbf{t})^{-1}\mathbf{t}'\mathbf{Y}_0 \end{aligned}$$

The vectors $\mathbf{p}$ and $\mathbf{c}$ are called the X- and Y-*loadings*, respectively.

The specific linear combination $\mathbf{t} = \mathbf{X}_0\mathbf{w}$ is the one that has maximum covariance $\mathbf{t}'\mathbf{u}$ with some response linear combination $\mathbf{u} = \mathbf{Y}_0\mathbf{q}$. Another characterization is that the X- and Y-weights $\mathbf{w}$ and $\mathbf{q}$ are proportional to the first left and right singular vectors of the covariance matrix $\mathbf{X}_0'\mathbf{Y}_0$ or, equivalently, the first eigenvectors of $\mathbf{X}_0'\mathbf{Y}_0\mathbf{Y}_0'\mathbf{X}_0$ and $\mathbf{Y}_0'\mathbf{X}_0\mathbf{X}_0'\mathbf{Y}_0$, respectively.

This accounts for how the first PLS factor is extracted. The second factor is extracted in the same way by replacing $\mathbf{X}_0$ and $\mathbf{Y}_0$ with the X- and Y-residuals from the first factor:

$$\begin{aligned} \mathbf{X}_1 &= \mathbf{X}_0 - \hat{\mathbf{X}}_0 \\ \mathbf{Y}_1 &= \mathbf{Y}_0 - \hat{\mathbf{Y}}_0 \end{aligned}$$

These residuals are also called the *deflated* $\mathbf{X}$ and $\mathbf{Y}$ blocks. The process of extracting a score vector and deflating the data matrices is repeated for as many extracted factors as are wanted.

SIMPLS

Note that each extracted PLS factor is defined in terms of different X-variables $\mathbf{X}_i$. This leads to difficulties in comparing different scores, weights, and so forth. The SIMPLS method of de Jong (1993) overcomes these difficulties by computing each score $\mathbf{t}_i = \mathbf{X}\mathbf{r}_i$ in terms of the original (centered and scaled) predictors $\mathbf{X}$. The SIMPLS X-weight vectors r_i are similar to the eigenvectors of $\mathbf{S}\mathbf{S}' = \mathbf{X}'\mathbf{Y}\mathbf{Y}'\mathbf{X}$, but they satisfy a different orthogonality condition. The $\mathbf{r}_1$ vector is just the first eigenvector $\mathbf{e}_1$ (so that the first SIMPLS score is the same as the first PLS score), but whereas the second eigenvector maximizes

$$\mathbf{e}_1' S S' \mathbf{e}_2 \text{ subject to } \mathbf{e}_1'\mathbf{e}_2 = 0$$

the second SIMPLS weight $\mathbf{r}_2$ maximizes

$$\mathbf{r}_1' S S' \mathbf{r}_2 \text{ subject to } \mathbf{r}_1' X' X \mathbf{r}_2 = \mathbf{t}_1'\mathbf{t}_2 = 0$$

The SIMPLS scores are identical to the PLS scores for one response but slightly different for more than one response; see de Jong (1993) for details. The X- and Y-loadings are defined as in PLS, but since the scores are all defined in terms of $\mathbf{X}$, it is easy to compute the overall model coefficients $\mathbf{B}$:

$$\begin{aligned} \hat{\mathbf{Y}} &= \sum_i \mathbf{t}_i \mathbf{c}_i' \\ &= \sum_i \mathbf{X}\mathbf{r}_i \mathbf{c}_i' \\ &= \mathbf{X}\mathbf{B}, \text{ where } \mathbf{B} = \mathbf{R}\mathbf{C}' \end{aligned}$$

Principal Components Regression

Like the SIMPLS method, principal components regression (PCR) defines all the scores in terms of the original (centered and scaled) predictors $\mathbf{X}$. However, unlike both the PLS and SIMPLS methods, the PCR method chooses the X-weights/X-scores without regard to the response data. The X-scores are chosen to explain as much variation in $\mathbf{X}$ as possible; equivalently, the X-weights for the PCR method are the eigenvectors of the predictor covariance matrix $\mathbf{X}'\mathbf{X}$. Again, the X- and Y-loadings are defined as in PLS; but, as in SIMPLS, it is easy to compute overall model coefficients for the original (centered and scaled) responses $\mathbf{Y}$ in terms of the original predictors $\mathbf{X}$.

Reduced Rank Regression

As discussed in the preceding sections, partial least squares depends on selecting factors $\mathbf{t} = \mathbf{X}\mathbf{w}$ of the predictors and $\mathbf{u} = \mathbf{Y}\mathbf{q}$ of the responses that have maximum covariance, whereas principal components regression effectively ignores $\mathbf{u}$ and selects $\mathbf{t}$ to have maximum variance, subject to orthogonality constraints. In contrast, reduced rank regression selects $\mathbf{u}$ to account for as much variation in the *predicted* responses as possible, effectively ignoring the predictors for the purposes of factor extraction. In reduced rank regression, the Y-weights $\mathbf{q}_i$ are the eigenvectors of the covariance matrix $\hat{\mathbf{Y}}_{\mathrm{LS}}'\hat{\mathbf{Y}}_{\mathrm{LS}}$ of the responses predicted by ordinary least squares regression; the X-scores are the projections of the Y-scores $\mathbf{Y}\mathbf{q}_i$ onto the X space.

Relationships between Methods

When you develop a predictive model, it is important to consider not only the explanatory power of the model for current responses, but also how well sampled the predictive functions are, since this affects how well the model can extrapolate to future observations. All of the techniques implemented in the PLS procedure work by extracting successive factors, or linear combinations of the predictors, that optimally address one or both of these two goals—explaining response variation and explaining predictor variation. In particular, principal components regression selects factors that explain as much predictor variation as possible, reduced rank regression selects factors that explain as much response variation as possible, and partial least squares balances the two objectives, seeking for factors that explain both response and predictor variation.

To see the relationships between these methods, consider how each one extracts a single factor from the following artificial data set consisting of two predictors and one response:

```
data data;
   input x1 x2 y;
   datalines;
    3.37651  2.30716        0.75615
    0.74193 -0.88845        1.15285
    4.18747  2.17373        1.42392
    0.96097  0.57301        0.27433
   -1.11161 -0.75225       -0.25410
   -1.38029 -1.31343       -0.04728
    1.28153 -0.13751        1.00341
   -1.39242 -2.03615        0.45518
    0.63741  0.06183        0.40699
   -2.52533 -1.23726       -0.91080
    2.44277  3.61077       -0.82590
   ;

proc pls data=data nfac=1 method=rrr;
   model y = x1 x2;
run;

proc pls data=data nfac=1 method=pcr;
   model y = x1 x2;
run;

proc pls data=data nfac=1 method=pls;
   model y = x1 x2;
run;
```

The amount of model and response variation explained by the first factor for each method is shown in Figure 69.9 through Figure 69.11.

Figure 69.9 Variation Explained by First Reduced Rank Regression Factor

The PLS Procedure

Percent Variation Accounted for by Reduced Rank Regression Factors

Number of Extracted Factors	Model Effects Current	Model Effects Total	Dependent Variables Current	Dependent Variables Total
1	15.0661	15.0661	100.0000	100.0000

Figure 69.10 Variation Explained by First Principal Components Regression Factor

The PLS Procedure

Percent Variation Accounted for by Principal Components

Number of Extracted Factors	Model Effects Current	Model Effects Total	Dependent Variables Current	Dependent Variables Total
1	92.9996	92.9996	9.3787	9.3787

Figure 69.11 Variation Explained by First Partial Least Squares Regression Factor

The PLS Procedure

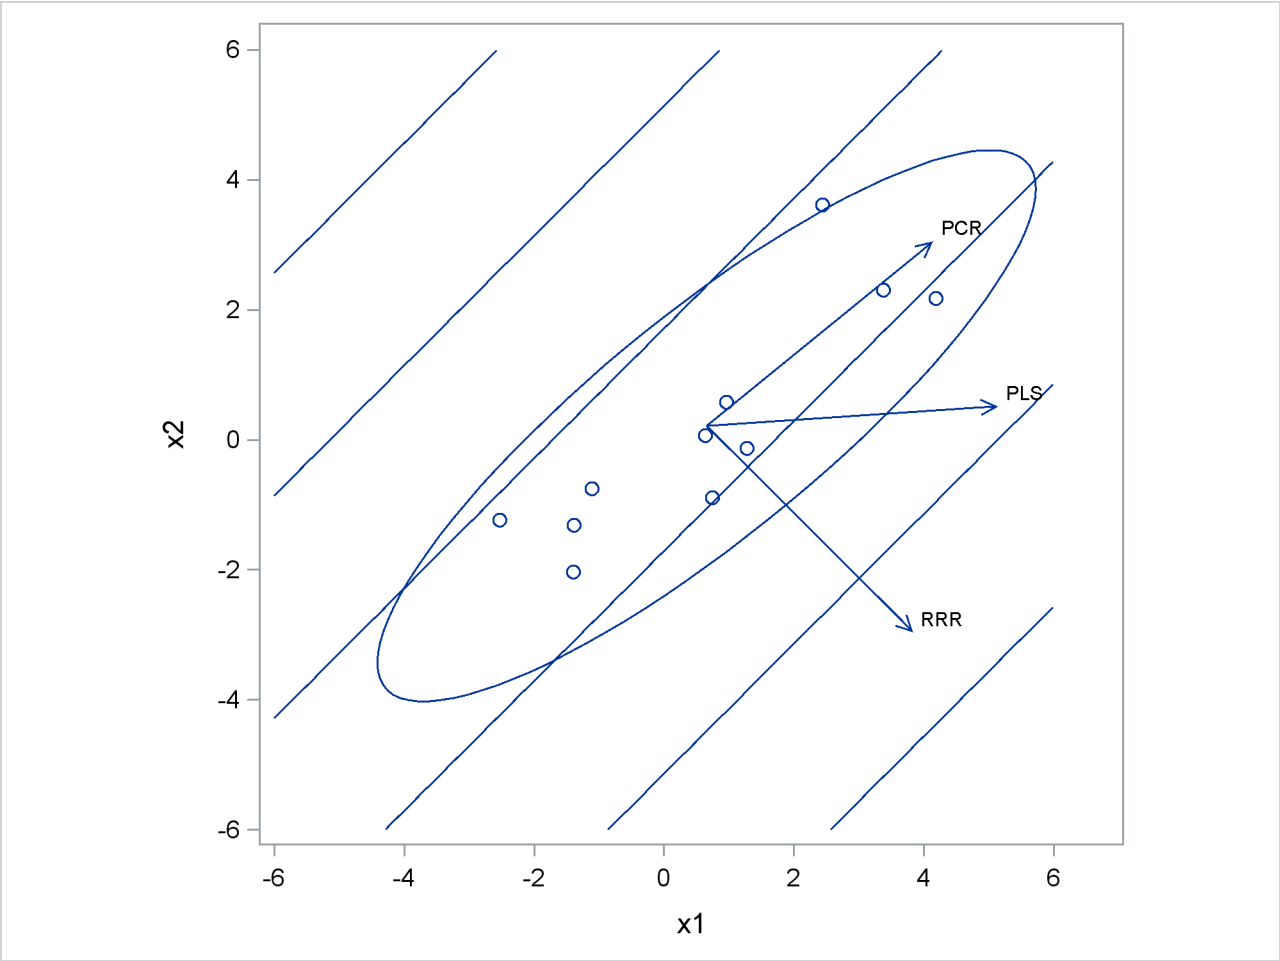
Percent Variation Accounted for by Partial Least Squares Factors

Number of Extracted Factors	Model Effects Current	Model Effects Total	Dependent Variables Current	Dependent Variables Total
1	88.5357	88.5357	26.5304	26.5304

Notice that, while the first reduced rank regression factor explains *all* of the response variation, it accounts for only about 15% of the predictor variation. In contrast, the first principal components regression factor accounts for most of the predictor variation (93%) but only 9% of the response variation. The first partial least squares factor accounts for only slightly less predictor variation than principal components but about three times as much response variation.

Figure 69.12 illustrates how partial least squares balances the goals of explaining response and predictor variation in this case.

Figure 69.12 Depiction of First Factors for Three Different Regression Methods



The ellipse shows the general shape of the 11 observations in the predictor space, with the contours of increasing y overlaid. Also shown are the directions of the first factor for each of the three methods. Notice that, while the predictors vary most in the x1 = x2 direction, the response changes most in the orthogonal x1 = -x2 direction. This explains why the first principal component accounts for little variation in the response and why the first reduced rank regression factor accounts for little variation in the predictors. The direction of the first partial least squares factor represents a compromise between the other two directions.

Cross Validation

None of the regression methods implemented in the PLS procedure fit the observed data any better than ordinary least squares (OLS) regression; in fact, all of the methods approach OLS as more factors are extracted. The crucial point is that, when there are many predictors, OLS can *overfit* the observed data; biased regression methods with fewer extracted factors can provide better predictability of *future* observations. However, as the preceding observations imply, the quality of the observed data fit cannot be used to choose the number of factors to extract; the number of extracted factors must be chosen on the basis of how well the model fits observations not involved in the modeling procedure itself.

One method of choosing the number of extracted factors is to fit the model to only part of the available data (the *training set*) and to measure how well models with different numbers of extracted factors fit the other part of the data (the *test set*). This is called *test set validation*. However, it is rare that you have enough data to make both parts large enough for pure test set validation to be useful. Alternatively, you can make several different divisions of the observed data into training set and test set. This is called *cross validation*, and there are several different types. In *one-at-a-time* cross validation, the first observation is held out as a single-element test set, with all other observations as the training set; next, the second observation is held out, then the third, and so on. Another method is to hold out successive blocks of observations as test sets—for example, observations 1 through 7, then observations 8 through 14, and so on; this is known as *blocked* validation. A similar method is *split-sample* cross validation, in which successive groups of widely separated observations are held out as the test set—for example, observations {1, 11, 21, ...}, then observations {2, 12, 22, ...}, and so on. Finally, test sets can be selected from the observed data randomly; this is known as *random sample* cross validation.

Which validation you should use depends on your data. Test set validation is preferred when you have enough data to make a division into a sizable training set and test set that represent the predictive population well. You can specify that the number of extracted factors be selected by test set validation by using the CV=TESTSET(*data set*) option, where *data set* is the name of the data set containing the test set. If you do not have enough data for test set validation, you can use one of the cross validation techniques. The most common technique is one-at-a-time validation (which you can specify with the CV=ONE option or just the CV option), unless the observed data are serially correlated, in which case either blocked or split-sample validation might be more appropriate (CV=BLOCK or CV=SPLIT); you can specify the number of test sets in blocked or split-sample validation with a number in parentheses after the CV= option. Note that CV=ONE is the most computationally intensive of the cross validation methods, since it requires a recomputation of the PLS model for every input observation. Also, note that using random subset selection with CV=RANDOM might lead two different researchers to produce different PLS models on the same data (unless the same seed is used).

Whichever validation method you use, the number of factors chosen is usually the one that minimizes the predicted residual sum of squares (PRESS); this is the default choice if you specify any of the CV methods with PROC PLS. However, often models with fewer factors have PRESS statistics that are only marginally larger than the absolute minimum. To address this, van der Voet (1994) has proposed a statistical test for comparing the predicted residuals from different models; when you apply van der Voet's test, the number of factors chosen is the fewest with residuals that are insignificantly larger than the residuals of the model with minimum PRESS.

To see how van der Voet's test works, let $R_{i,jk}$ be the jth predicted residual for response k for the model with i extracted factors; the PRESS statistic is $\sum_{jk} R^2_{i,jk}$. Also, let $i_{\min}$ be the number of factors for which PRESS is minimized. The critical value for van der Voet's test is based on the differences between squared predicted residuals

$$D_{i,jk} = R^2_{i,jk} - R^2_{i_{\min},jk}$$

One alternative for the critical value is $C_i = \sum_{jk} D_{i,jk}$, which is just the difference between the PRESS statistics for i and $i_{\min}$ factors; alternatively, van der Voet suggests Hotelling's T^2 statistic $C_i = \mathbf{d}'_{i,\cdot} S_i^{-1} \mathbf{d}_{i,\cdot}$, where $\mathbf{d}_{i,\cdot}$ is the sum of the vectors $\mathbf{d}_{i,j} = \{D_{i,j1}, \ldots, D_{i,jN_y}\}'$ and S_i is the sum of squares and crossproducts matrix

$$S_i = \sum_j \mathbf{d}_{i,j} \mathbf{d}'_{i,j}$$

Virtually, the significance level for van der Voet's test is obtained by comparing C_i with the distribution of values that result from randomly exchanging $R^2_{i,jk}$ and $R^2_{i_{\min},jk}$. In practice, a Monte Carlo sample of such values is simulated and the significance level is approximated as the proportion of simulated critical values that are greater than C_i. If you apply van der Voet's test by specifying the CVTEST option, then, by default, the number of extracted factors chosen is the least number with an approximate significance level that is greater than 0.10.

Centering and Scaling

By default, the predictors and the responses are centered and scaled to have mean 0 and standard deviation 1. Centering the predictors and the responses ensures that the criterion for choosing successive factors is based on how much *variation* they explain, in either the predictors or the responses or both. (See the section "Regression Methods" on page 5695 for more details on how different methods explain variation.) Without centering, both the mean variable value and the variation around that mean are involved in selecting factors. Scaling serves to place all predictors and responses on an equal footing relative to their variation in the data. For example, if Time and Temp are two of the predictors, then scaling says that a change of std(Time) in Time is roughly equivalent to a change of std(Temp) in Temp.

Usually, both the predictors and responses should be centered and scaled. However, if their values already represent variation around a nominal or target value, then you can use the NOCENTER option in the PROC PLS statement to suppress centering. Likewise, if the predictors or responses are already all on comparable scales, then you can use the NOSCALE option to suppress scaling.

Note that, if the predictors involve crossproduct terms, then, by default, the variables are *not* standardized before standardizing the crossproduct. That is, if the ith values of two predictors are denoted x_i^1 and x_i^2, then the default standardized ith value of the crossproduct is

$$\frac{x_i^1 x_i^2 - \text{mean}_j(x_j^1 x_j^2)}{\text{std}_j(x_j^1 x_j^2)}$$

If you want the crossproduct to be based instead on standardized variables

$$\frac{x_i^1 - m^1}{s^1} \times \frac{x_i^2 - m^2}{s^2}$$

where $m^k = \text{mean}_j(x_j^k)$ and $s^k = \text{std}_j(x_j^k)$ for $k = 1, 2$, then you should use the VARSCALE option in the PROC PLS statement. Standardizing the variables separately is usually a good idea, but unless the model also contains all crossproducts nested within each term, the resulting model might not be equivalent to a simple linear model in the same terms. To see this, note that a model involving the crossproduct of two standardized variables

$$\frac{x_i^1 - m^1}{s^1} \times \frac{x_i^2 - m^2}{s^2} = x_i^1 x_i^2 \frac{1}{s^1 s^2} - x_i^1 \frac{m^2}{s^1 s^2} - x_i^2 \frac{m^1}{s^1 s^2} + \frac{m^1 m^2}{s^1 s^2}$$

involves both the crossproduct term and the linear terms for the unstandardized variables.

When cross validation is performed for the number of effects, there is some disagreement among practitioners as to whether each cross validation training set should be retransformed. By default, PROC PLS does so, but you can suppress this behavior by specifying the NOCVSTDIZE option in the PROC PLS statement.

Missing Values

By default, PROC PLS handles missing values very simply. Observations with any missing independent variables (including all classification variables) are excluded from the analysis, and no predictions are computed for such observations. Observations with no missing independent variables but any missing dependent variables are also excluded from the analysis, but predictions are computed.

However, the MISSING= option in the PROC PLS statement provides more sophisticated ways of modeling in the presence of missing values. If you specify MISSING=AVG or MISSING=EM, then all observations in the input data set contribute to both the analysis and the OUTPUT OUT= data set. With MISSING=AVG, the fit is computed by filling in missing values with the average of the nonmissing values for the corresponding variable. With MISSING=EM, the procedure first computes the model with MISSING=AVG, then fills in missing values with their predicted values based on that model and computes the model again. Alternatively, you can specify MISSING=EM(MAXITER=*n*) with a large value of *n* in order to perform this imputation/fit loop until convergence.

Displayed Output

By default, PROC PLS displays just the amount of predictor and response variation accounted for by each factor.

If you perform a cross validation for the number of factors by specifying the CV option in the PROC PLS statement, then the procedure displays a summary of the cross validation for each number of factors, along with information about the optimal number of factors.

If you specify the DETAILS option in the PROC PLS statement, then details of the fitted model are displayed for each successive factor. These details for each number of factors include the following:

- the predictor loadings
- the predictor weights
- the response weights
- the coded regression coefficients (for METHOD=SIMPLS, PCR, or RRR)

If you specify the CENSCALE option in the PROC PLS statement, then centering and scaling information for each response and predictor is displayed.

If you specify the VARSS option in the PROC PLS statement, the procedure displays, in addition to the average response and predictor sum of squares accounted for by each successive factor, the amount of variation accounted for in each response and predictor.

If you specify the SOLUTION option in the MODEL statement, then PROC PLS displays the coefficients of the final predictive model for the responses. The coefficients for predicting the centered and scaled responses based on the centered and scaled predictors are displayed, as well as the coefficients for predicting the raw responses based on the raw predictors.

ODS Table Names

PROC PLS assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 69.2. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 69.2 ODS Tables Produced by PROC PLS

ODS Table Name	Description	Statement	Option
CVResults	Results of cross validation	PROC	CV
CenScaleParms	Parameter estimates for centered and scaled data	MODEL	SOLUTION
CodedCoef	Coded coefficients	PROC	DETAILS
MissingIterations	Iterations for missing value imputation	PROC	MISSING=EM
ModelInfo	Model information	PROC	default
NObs	Number of observations	PROC	default
ParameterEstimates	Parameter estimates for raw data	MODEL	SOLUTION
PercentVariation	Variation accounted for by each factor	PROC	default
ResidualSummary	Residual summary from cross validation	PROC	CV
XEffectCenScale	Centering and scaling information for predictor effects	PROC	CENSCALE

YWeights	Weights for dependents	PROC	DETAILS

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, "Statistical Graphics Using ODS."

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section "Enabling and Disabling ODS Graphics" on page 612 in Chapter 21, "Statistical Graphics Using ODS."

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section "A Primer on ODS Statistical Graphics" on page 611 in Chapter 21, "Statistical Graphics Using ODS."

When ODS Graphics is enabled, by default the PLS procedure produces a plot of the variation accounted for by each extracted factor, as well as a *correlation loading plot* for the first two extracted factors (if the final model has at least two factors). The plot of the variation accounted for can take several forms:

- If the PLS analysis does not include cross validation, then the plot shows the total R square for both model effects and the dependent variables against the number of factors.
- If you specify the CV= option to select the number of factors in the final model by cross validation, then the plot shows the R-square analysis discussed previously as well as the root mean PRESS from the cross validation analysis, with the selected number of factors identified by a vertical line.

The correlation loading plot for the first two factors summarizes many aspects of the two most significant dimensions of the model. It consists of overlaid scatter plots of the scores of the first two factors, the loadings of the model effects, and the loadings of the dependent variables. The loadings are scaled so that the amount of variation in the variables that is explained by the model is proportional to the distance from the origin; circles indicating various levels of explained variation are also overlaid on the correlation loading plot. Also, the correlation between the model approximations for any two variables is proportional to the length of the projection of the point corresponding to one variable on a line through the origin passing through the point corresponding to the other variable; the sign of the correlation corresponds to which side of the origin the projected point falls on.

The R square and the first two correlation loadings are plotted by default when ODS Graphics is enabled, but you can produce many other plots for the PROC PLS analysis.

ODS Graph Names

PROC PLS assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in Table 69.3.

Table 69.3 Graphs Produced by PROC GLM

ODS Graph Name	Plot Description	Option
CorrLoadPlot	Correlation loading plot (default)	PLOT=CORRLOAD(*option*)
CVPlot	Cross validation and R-square analysis (default, as appropriate)	CV=
DModXPlot	Distance of each observation to the X model	PLOT=DMODX
DModXYPlot	Distance of each observation to the X and Y models	PLOT=DMODXY
DModYPlot	Distance of each observation to the Y model	PLOT=DMODY
DiagnosticsPanel	Panel of diagnostic plots for the fit	PLOT=DIAGNOSTICS
AbsResidualByPredicted	Absolute residual by predicted values	PLOT=DIAGNOSTICS(UNPACK)
ObservedByPredicted	Observed by predicted	PLOT=DIAGNOSTICS(UNPACK)
QQPlot	Residual Q-Q plot	PLOT=DIAGNOSTICS(UNPACK)
ResidualByPredicted	Residual by predicted values	PLOT=DIAGNOSTICS(UNPACK)
ResidualHistogram	Residual histogram	PLOT=DIAGNOSTICS(UNPACK)

Table 69.3 *continued*

ODS Graph Name	Plot Description	Option
RFPlot	RF plot	PLOT=DIAGNOSTICS(UNPACK)
ParmProfiles	Profiles of regression coefficients	PLOT=PARMPROFILES
R2Plot	R-square analysis (default, as appropriate)	
ResidualPlots	Residuals for each dependent variable	PLOT=RESIDUALS
VariableImportancePlot	Profile of variable importance factors	PLOT=VIP
XLoadingPlot	Scatter plot matrix of X-loadings against each other	PLOT=XLOADINGPLOT
XLoadingProfiles	Profiles of the X-loadings	PLOT=XLOADINGPROFILES
XScorePlot	Scatter plot matrix of X-scores against each other	PLOT=XSCORES
XWeightPlot	Scatter plot matrix of X-weights against each other	PLOT=XWEIGHTPLOT
XWeightProfiles	Profiles of the X-weights	PLOT=XWEIGHTPROFILES
XYScorePlot	Scatter plot matrix of X-scores against Y-scores	PLOT=XYSCORES
YScorePlot	Scatter plot matrix of Y-scores against each other	PLOT=YSCORES
YWeightPlot	Scatter plot matrix of Y-weights against each other	PLOT=YWEIGHTPLOT

Examples: PLS Procedure

Example 69.1: Examining Model Details

This example, from Umetrics (1995), demonstrates different ways to examine a PLS model. The data come from the field of drug discovery. New drugs are developed from chemicals that are biologically active. Testing a compound for biological activity is an expensive procedure, so it is useful to be able to predict biological activity from cheaper chemical measurements. In fact, computational chemistry makes it possible to calculate certain chemical measurements without even making the compound. These measurements include size, lipophilicity, and polarity at various sites on the molecule. The following statements create a data set named pentaTrain, which contains these data.

```
data pentaTrain;
   input obsnam $ S1 L1 P1 S2 L2 P2

;
```

You would like to study the relationship between these measurements and the activity of the compound, represented by the logarithm of the relative Bradykinin activating activity (log_RAI). Notice that these data consist of many predictors relative to the number of observations. Partial least squares is especially appropriate in this situation as a useful tool for finding a few underlying predictive factors that account for most of the variation in the response. Typically, the model is fit for part of the data (the "training" or "work" set), and the quality of the fit is judged by how well it predicts the other part of the data (the "test" or "prediction" set). For this example, the first 15 observations serve as the training set and the rest constitute the test set (refer to Ufkes et al. 1978, 1982).

When you fit a PLS model, you hope to find a few PLS factors that explain most of the variation in both predictors and responses. Factors that explain response variation provide good predictive models for new responses, and factors that explain predictor variation are well represented by the observed values of the predictors. The following statements fit a PLS model with two factors and save predicted values, residuals, and other information for each data point in a data set named outpls.

```
proc pls data=pentaTrain;
   model log_RAI = S1-S5 L1-L5 P1-P5;
run;
```

The PLS procedure displays a table, shown in Output 69.1.1, showing how much predictor and response variation is explained by each PLS factor.

Output 69.1.1 Amount of Training Set Variation Explained

The PLS Procedure

Percent Variation Accounted for by Partial Least Squares Factors

Number of Extracted Factors	Model Effects Current	Model Effects Total	Dependent Variables Current	Dependent Variables Total
1	16.9014	16.9014	89.6399	89.6399
2	12.7721	29.6735	7.8368	97.4767
3	14.6554	44.3289	0.4636	97.9403
4	11.8421	56.1710	0.2485	98.1889
5	10.5894	66.7605	0.1494	98.3383
6	5.1876	71.9481	0.2617	98.6001
7	6.1873	78.1354	0.2428	98.8428
8	7.2252	85.3606	0.1926	99.0354
9	6.7285	92.0891	0.0725	99.1080
10	7.9076	99.9967	0.0000	99.1080
11	0.0033	100.0000	0.0099	99.1179
12	0.0000	100.0000	0.0000	99.1179
13	0.0000	100.0000	0.0000	99.1179
14	0.0000	100.0000	0.0000	99.1179
15	0.0000	100.0000	0.0000	99.1179

From Output 69.1.1, note that 97% of the response variation is already explained by just two factors, but only 29% of the predictor variation is explained.

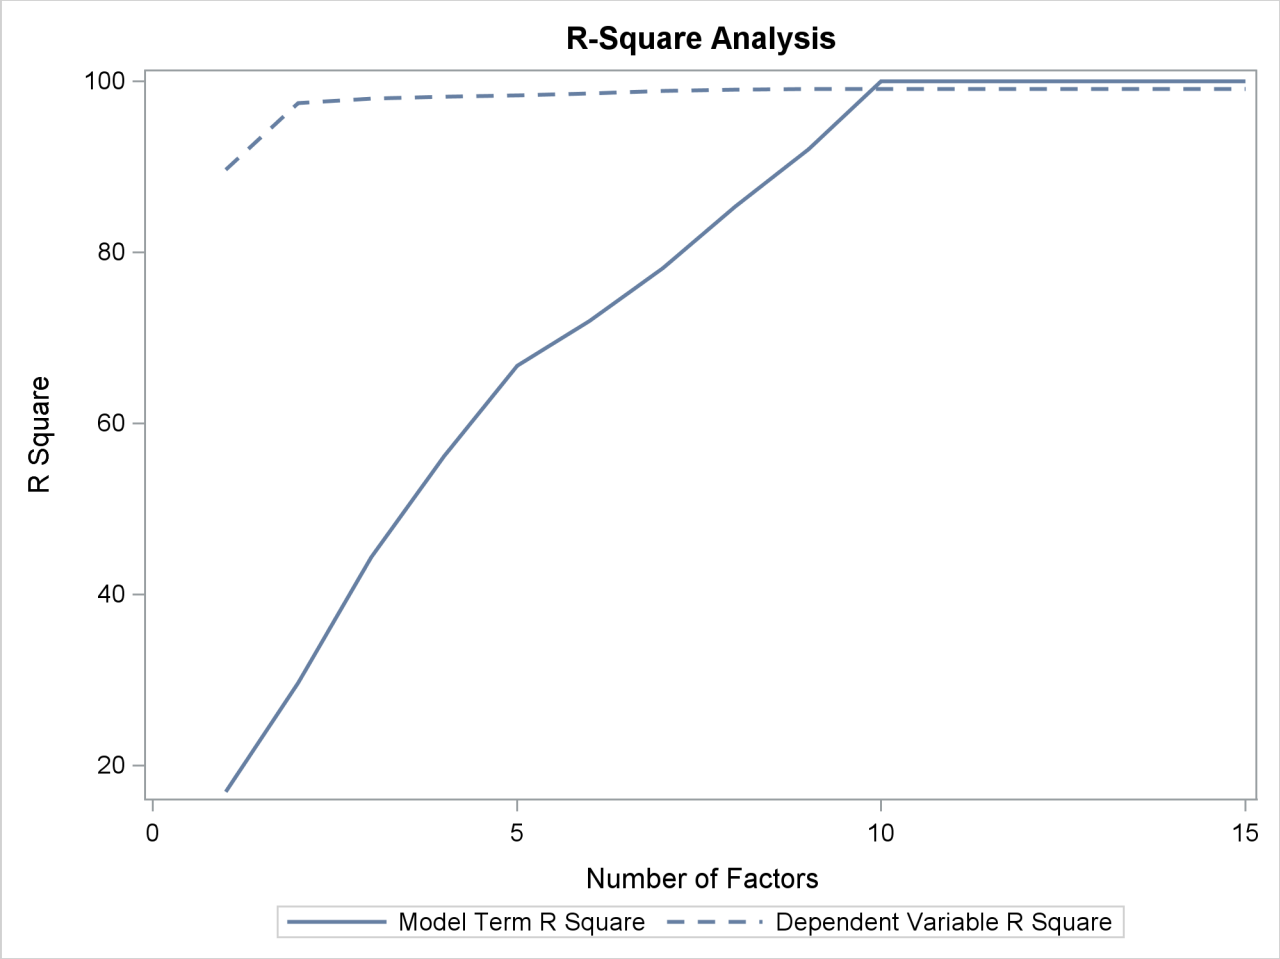
The graphics in PROC PLS, available when ODS Graphics is enabled, make it easier to see features of the PLS model.

If ODS Graphics is enabled, then in addition to the tables discussed previously, PROC PLS displays a graphical depiction of the R-square analysis as well as a correlation loadings plot summarizing the model based on the first two PLS factors. The following statements perform the previous analysis with ODS Graphics enabled, producing Output 69.1.2 and Output 69.1.3.

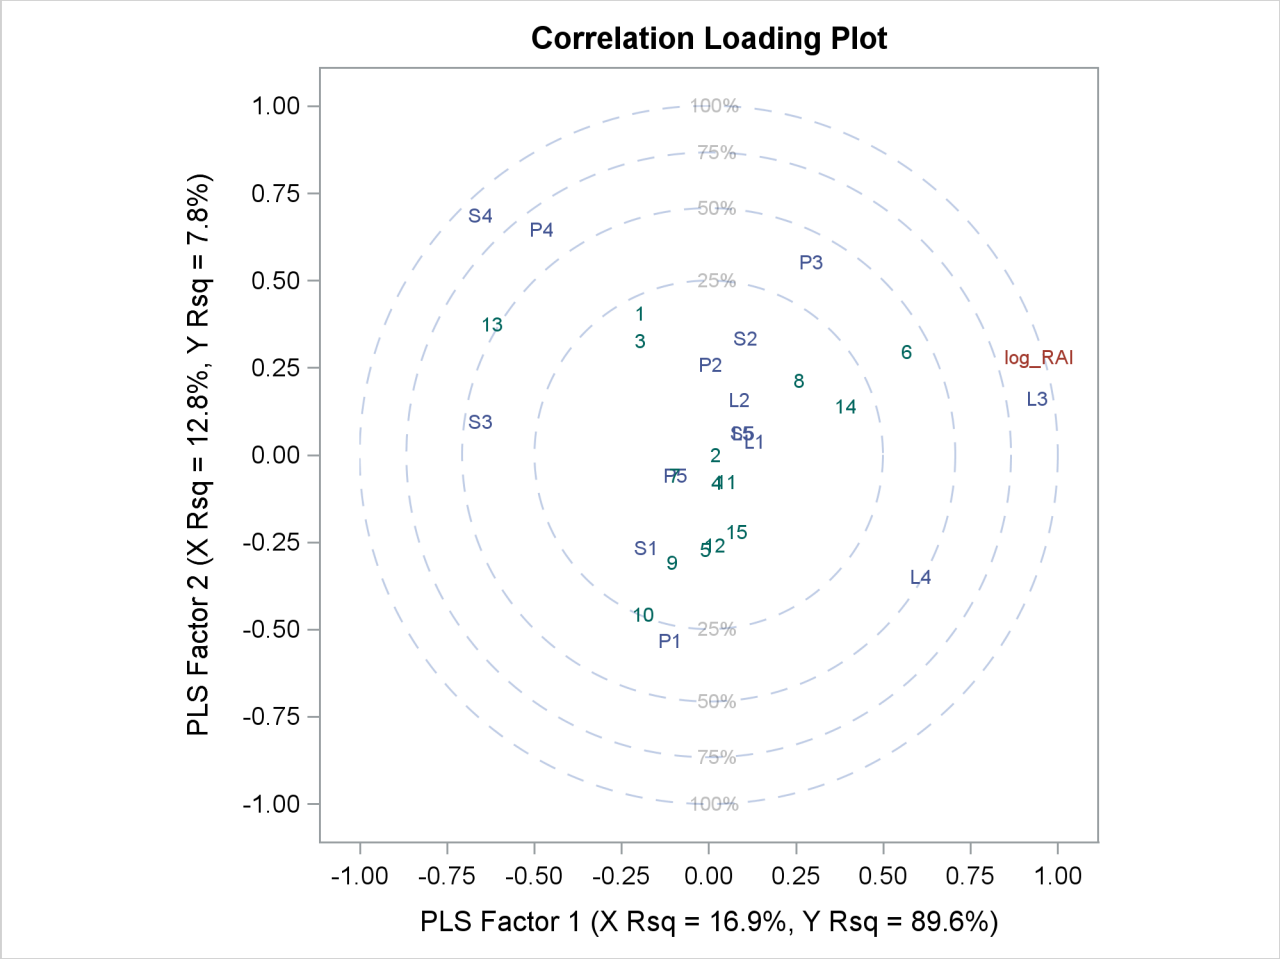
```
ods graphics on;

proc pls data=pentaTrain;
   model log_RAI = S1-S5 L1-L5 P1-P5;
run;
```

Output 69.1.2 Plot of Proportion of Variation Accounted For



Output 69.1.3 Correlation Loadings Plot



The plot in Output 69.1.2 of the proportion of variation explained (or R square) makes it clear that there is a plateau in the response variation after two factors are included in the model. The correlation loading plot in Output 69.1.3 summarizes many features of this two-factor model, including the following:

- The X-scores are plotted as numbers for each observation. You should look for patterns or clearly grouped observations. If you see a curved pattern, for example, you might want to add a quadratic term. Two or more groupings of observations indicate that it might be better to analyze the groups separately, perhaps by including classification effects in the model. This plot appears to show most of the observations close together, with a few being more spread out with larger positive X-scores for factor 2. There are no clear grouping patterns, but observation 13 stands out.
- The loadings show how much variation in each variable is accounted for by the first two factors, jointly by the distance of the corresponding point from the origin and individually by the distance for the projections of this point onto the horizontal and vertical axes. That the dependent variable is well explained by the model is reflected in the fact that the point for log_RAI is near the 100% circle.
- You can also use the projection interpretation to relate variables to each other. For example, projecting other variables' points onto the line that runs through the log_RAI point and the origin, you can see that the PLS approximation for the predictor L3 is highly positively correlated with log_RAI, S3 is

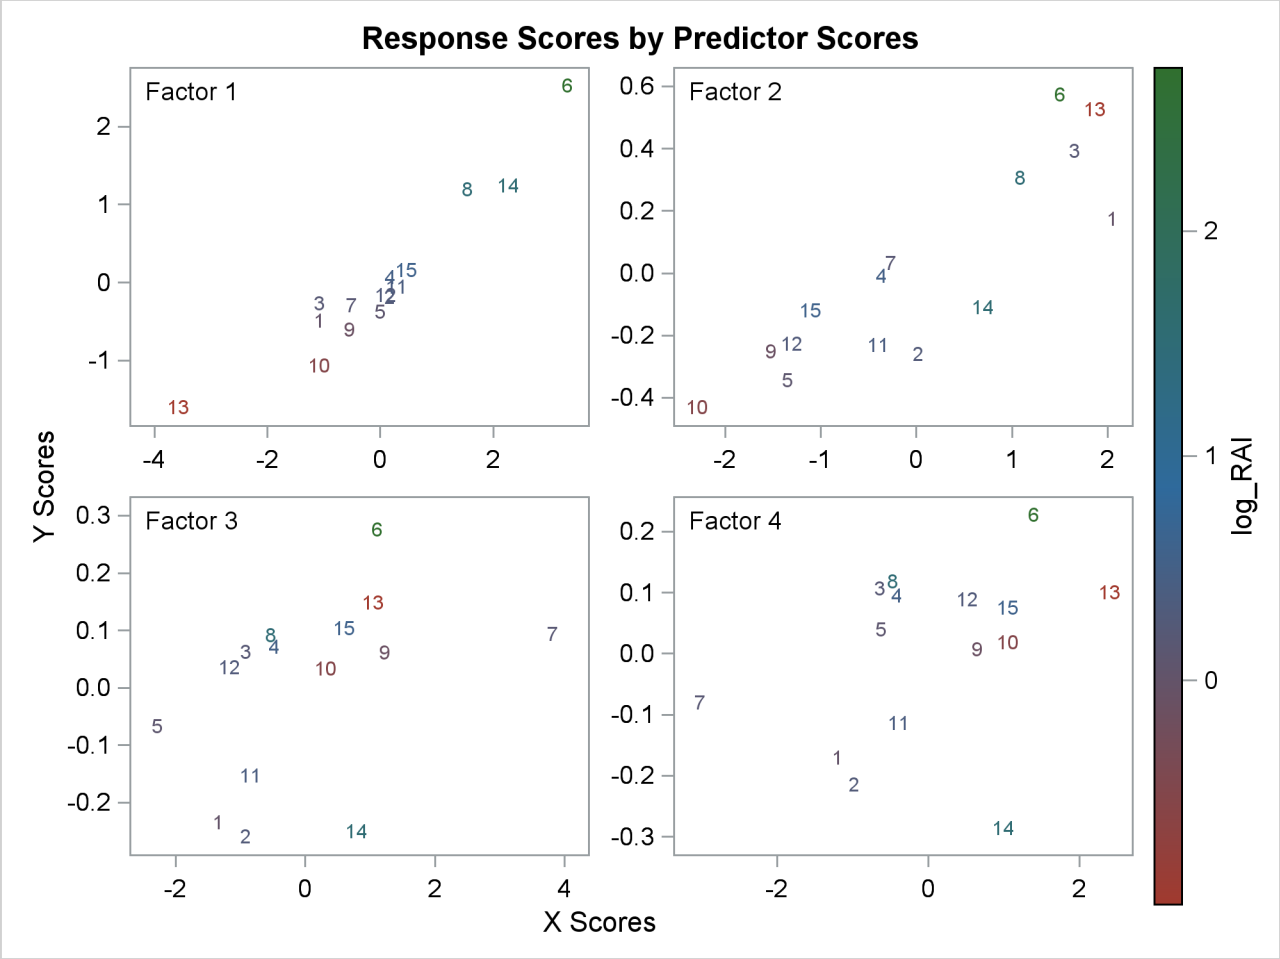
somewhat less correlated but in the negative direction, and several predictors including L1, L5, and S5 have very little correlation with log_RAI.

Other graphics enable you to explore more of the features of the PLS model. For example, you can examine the X-scores versus the Y-scores to explore how partial least squares chooses successive factors. For a good PLS model, the first few factors show a high correlation between the X- and Y-scores. The correlation usually decreases from one factor to the next. When ODS Graphics is enabled, you can plot the X-scores versus the Y-scores by using the PLOT=XYSCORES option, as shown in the following statements.

```
proc pls data=pentaTrain nfac=4 plot=XYScores;
   model log_RAI = S1-S5 L1-L5 P1-P5;
run;
```

The plot of the X-scores versus the Y-scores for the first four factors is shown in Output 69.1.4.

Output 69.1.4 X-Scores versus Y-Scores



For this example, Output 69.1.4 shows high correlation between X- and Y-scores for the first factor but somewhat lower correlation for the second factor and sharply diminishing correlation after that. This adds strength to the judgment that NFAC=2 is the right number of factors for these data and this model. Note that observation 13 is again extreme in the first two plots. This run might be overly influential for the PLS analysis; thus, you should check to make sure it is reliable.

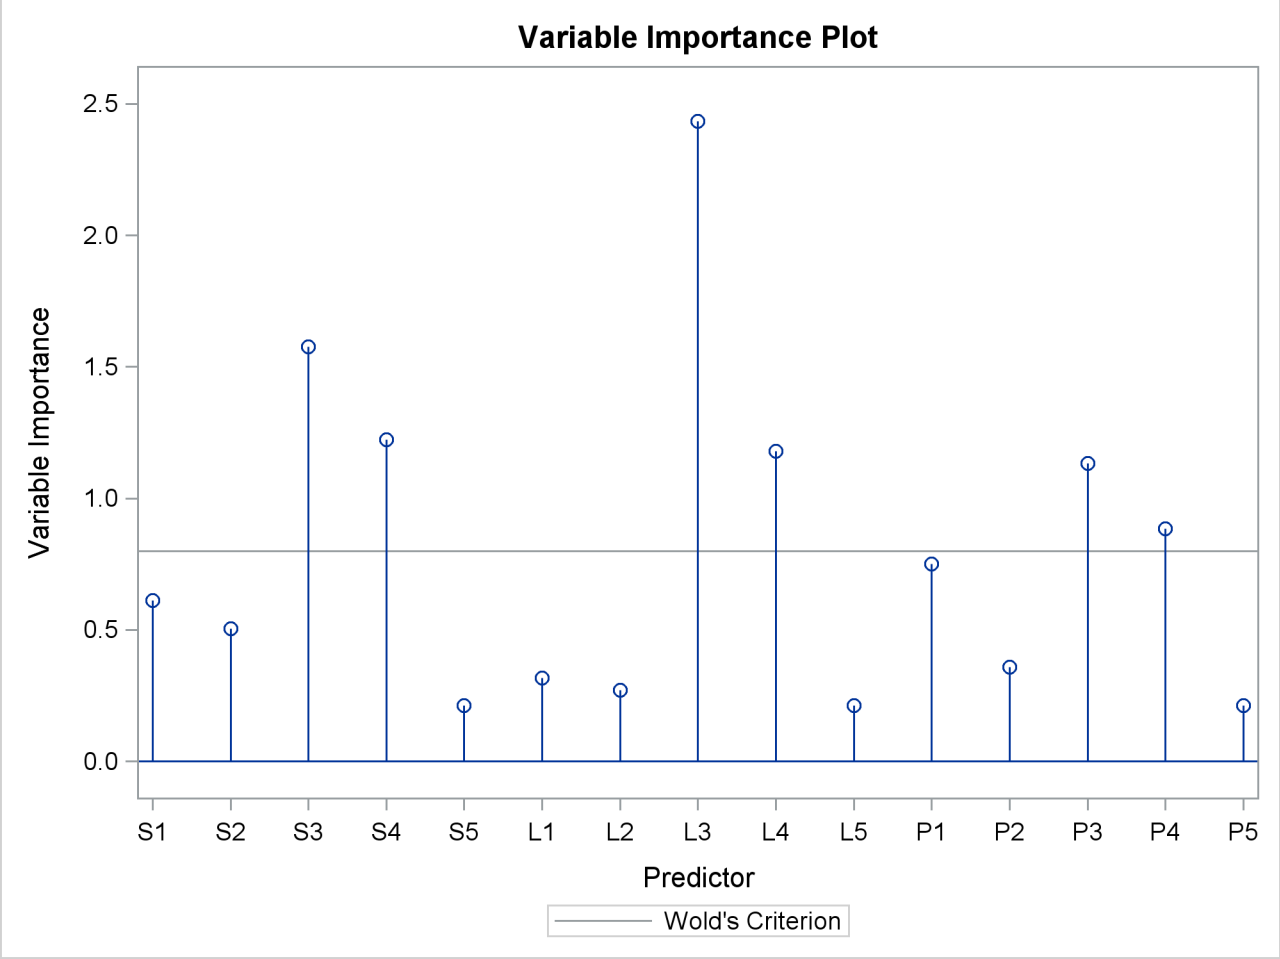
As explained earlier, you can draw some inferences about the relationship between individual predictors and the dependent variable from the correlation loading plot. However, the regression coefficient profile and the variable importance plot give a more direct indication of which predictors are most useful for predicting the dependent variable. The regression coefficients represent the importance each predictor has in the prediction of just the response. The variable importance plot, on the other hand, represents the contribution of each predictor in fitting the PLS model for both predictors and response. It is based on the *Variable Importance for Projection* (VIP) statistic of Wold (1994), which summarizes the contribution a variable makes to the model. If a predictor has a relatively small coefficient (in absolute value) *and* a small value of VIP, then it is a prime candidate for deletion. Wold in Umetrics (1995) considers a value less than 0.8 to be "small" for the VIP. The following statements fit a two-factor PLS model and display these two additional plots.

```
proc pls data=pentaTrain nfac=2 plot=(ParmProfiles VIP);
   model log_RAI = S1-S5 L1-L5 P1-P5;
run;

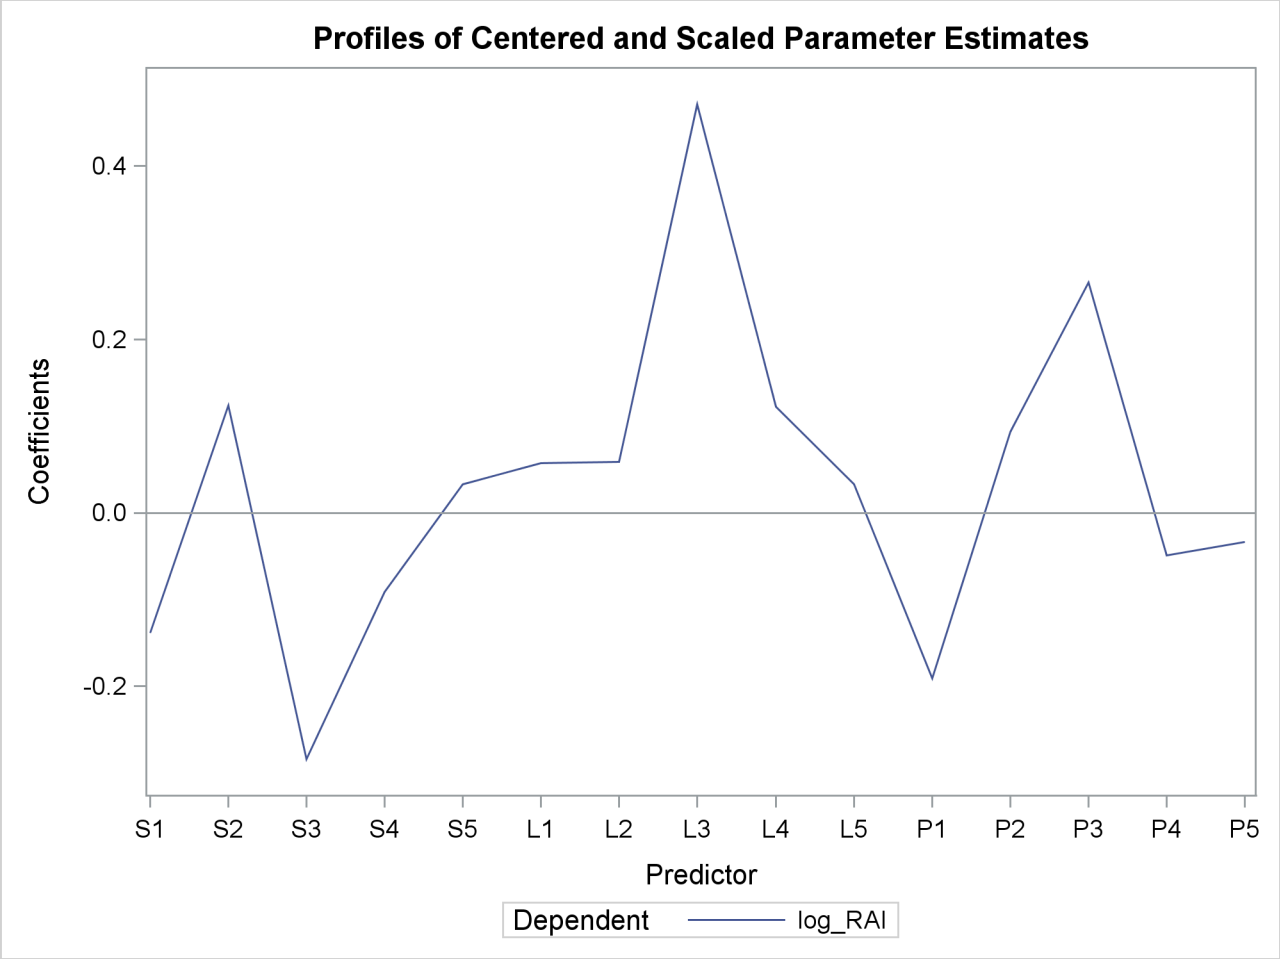
ods graphics off;
```

The additional graphics are shown in Output 69.1.5 and Output 69.1.6.

Output 69.1.5 Variable Importance Plots



Output 69.1.6 Regression Parameter Profile



In these two plots, the variables L1, L2, P2, S5, L5, and P5 have small absolute coefficients and small VIP. Looking back at the correlation loadings plot in Output 69.1.2, you can see that these variables tend to be the ones near zero for both PLS factors. You should consider dropping these variables from the model.

Example 69.2: Examining Outliers

This example is a continuation of Example 69.1.

Standard diagnostics for statistical models focus on the response, allowing you to look for patterns that indicate the model is inadequate or for outliers that do not seem to follow the trend of the rest of the data. However, partial least squares effectively models the predictors as well as the responses, so you should consider the pattern of the fit for both. The DModX and DModY statistics give the distance from each point to the PLS model with respect to the predictors and the responses, respectively, and ODS Graphics enables you to plot these values. No point should be dramatically farther from the model than the rest. If there is a group of points that are all farther from the model than the rest, they might have something in common, in which case they should be analyzed separately.

The following statements fit a reduced model to the data discussed in Example 69.1 and plot a panel of standard diagnostics as well as the distances of the observations to the model.

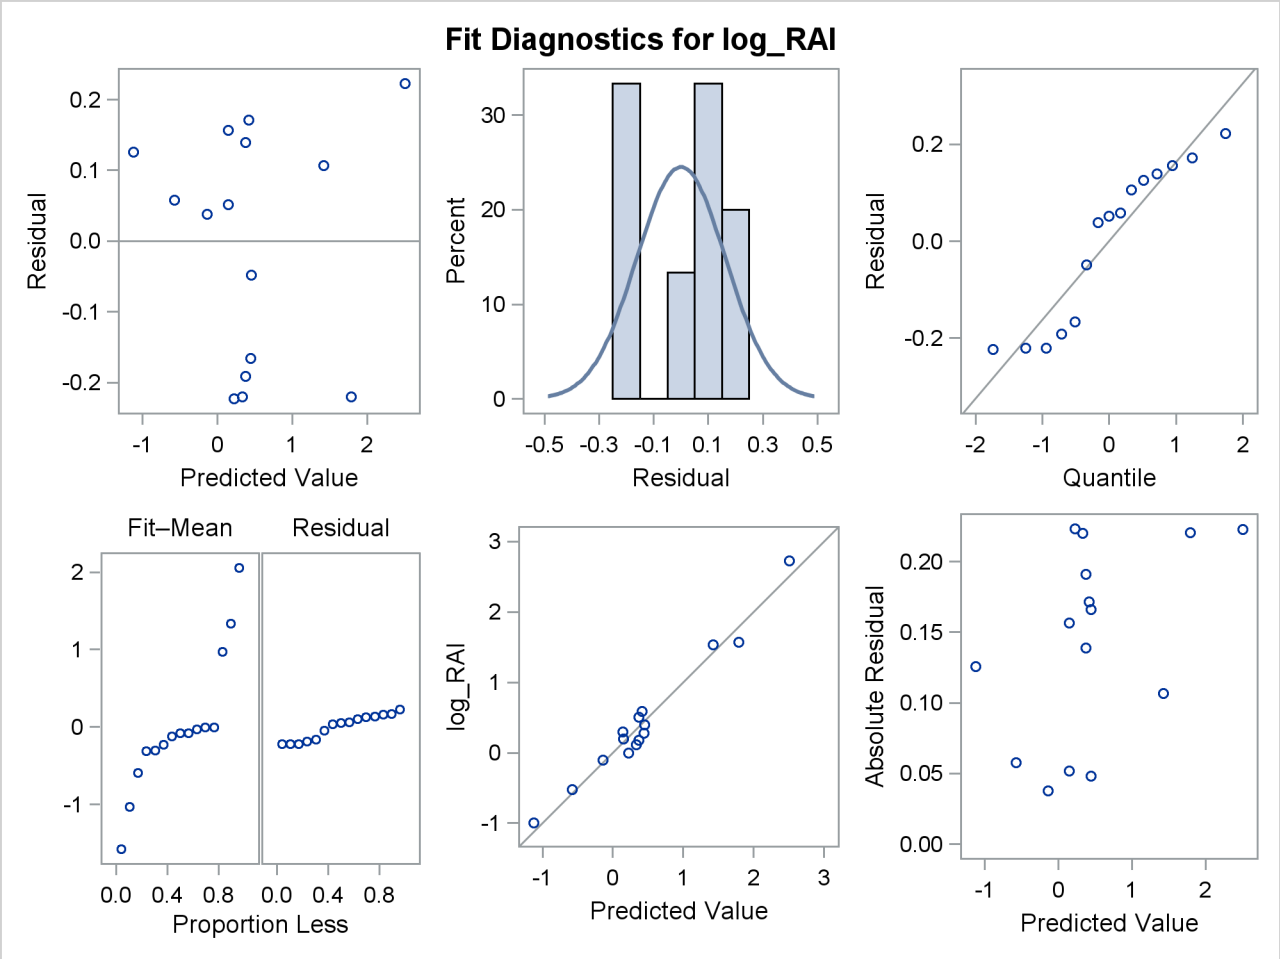
```
ods graphics on;

proc pls data=pentaTrain nfac=2 plot=(diagnostics dmod);
   model log_RAI = S1    P1
                   S2
                   S3 L3 P3
                   S4 L4   ;
run;

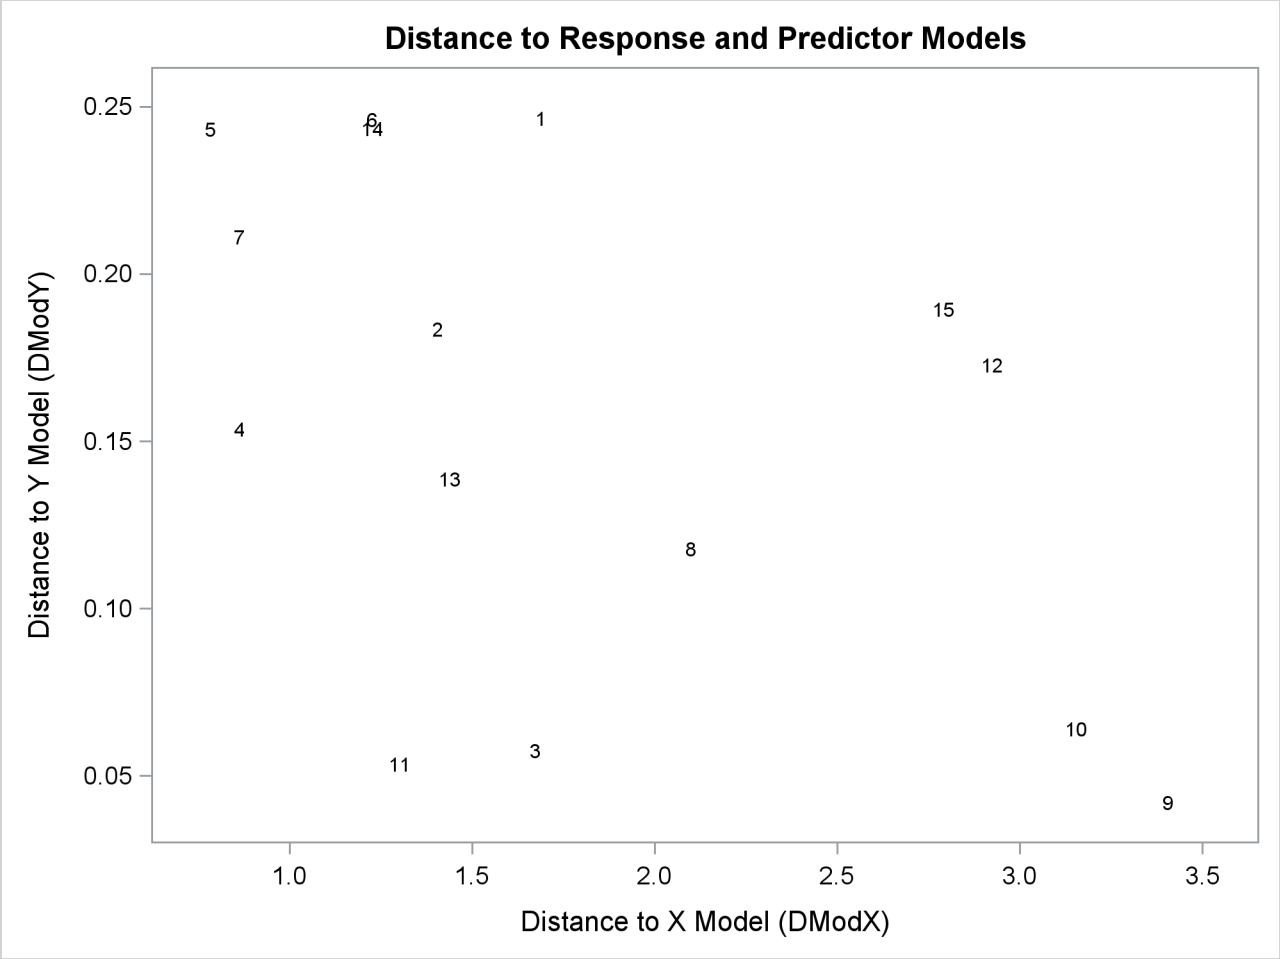
ods graphics off;
```

The plots are shown in Output 69.2.1 and Output 69.2.2.

Output 69.2.1 Model Fit Diagnostics



Output 69.2.2 Predictor versus Response Distances to the Model

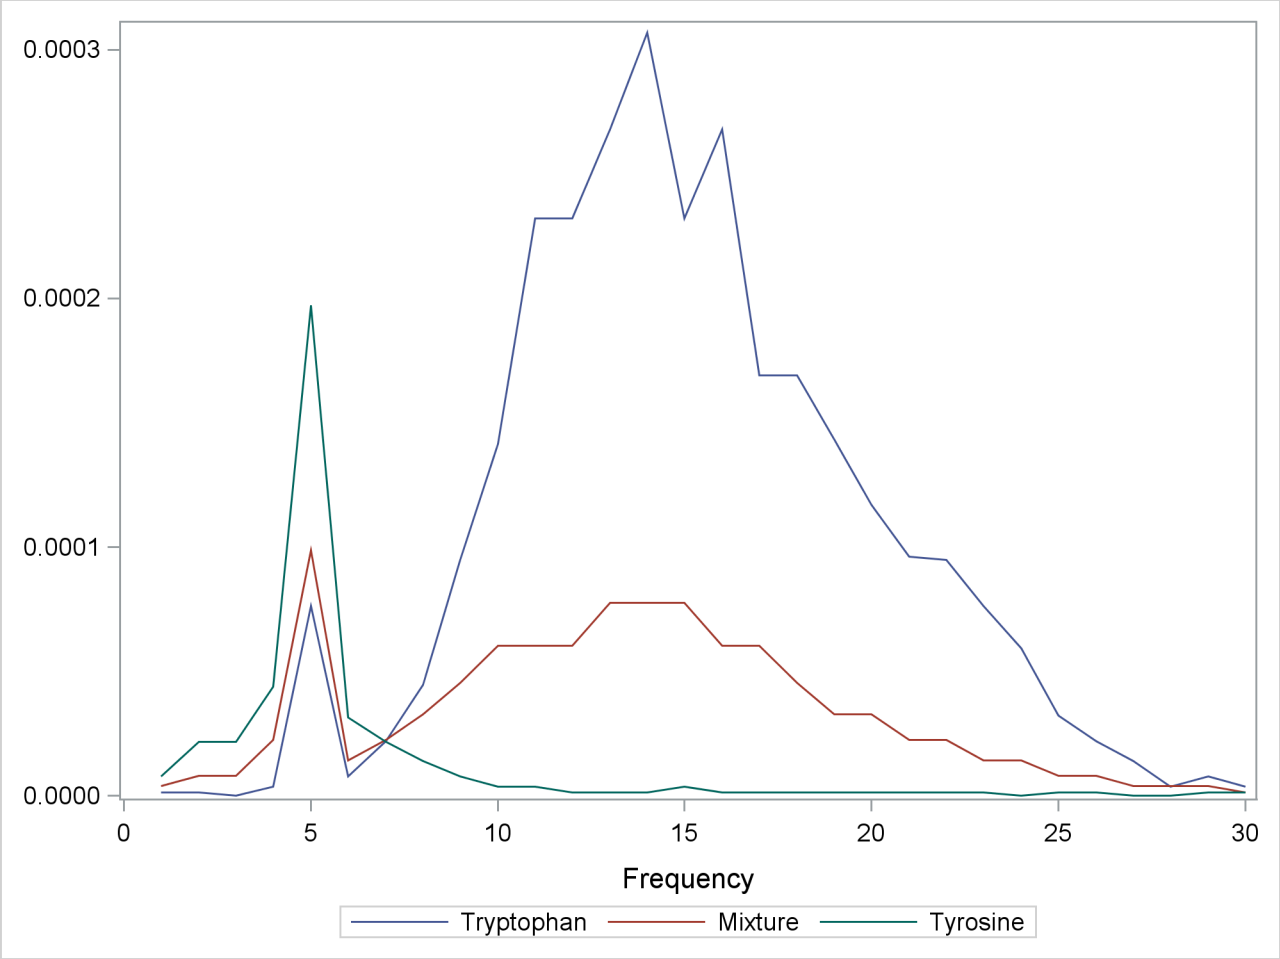


There appear to be no profound outliers in either the predictor space or the response space.

Example 69.3: Choosing a PLS Model by Test Set Validation

This example demonstrates issues in spectrometric calibration. The data (Umetrics 1995) consist of spectrographic readings on 33 samples containing known concentrations of two amino acids, tyrosine and tryptophan. The spectra are measured at 30 frequencies across the overall range of frequencies. For example, Figure 69.3.1 shows the observed spectra for three samples, one with only tryptophan, one with only tyrosine, and one with a mixture of the two, all at a total concentration of 10^{-6}.

Output 69.3.1 Spectra for Three Samples of Tyrosine and Tryptophan



Of the 33 samples, 18 are used as a training set and 15 as a test set. The data originally appear in McAvoy et al. (1989).

These data were created in a lab, with the concentrations fixed in order to provide a wide range of applicability for the model. You want to use a linear function of the logarithms of the spectra to predict the logarithms of tyrosine and tryptophan concentration, as well as the logarithm of the total concentration. Actually, because of the possibility of zeros in both the responses and the predictors, slightly different transformations are used. The following statements create SAS data sets containing the training and test data, named ftrain and ftest, respectively.

```
data ftrain;
   input obsnam $ tot tyr f1-f30 @@;
   try = tot - tyr;
   if (tyr) then tyr_log = log10(tyr); else tyr_log = -8;
   if (try) then try_log = log10(try); else try_log = -8;
   tot_log = log10(tot);

;
```

The following statements fit a PLS model with 10 factors.

```
proc pls data=ftrain nfac=10;
   model tot_log tyr_log try_log = f1-f30;
run;
```

The table shown in Output 69.3.2 indicates that only three or four factors are required to explain almost all of the variation in both the predictors and the responses.

Output 69.3.2 Amount of Training Set Variation Explained

The PLS Procedure

Percent Variation Accounted for by Partial Least Squares Factors

Number of Extracted Factors	Model Effects Current	Model Effects Total	Dependent Variables Current	Dependent Variables Total
1	81.1654	81.1654	48.3385	48.3385
2	16.8113	97.9768	32.5465	80.8851
3	1.7639	99.7407	11.4438	92.3289
4	0.1951	99.9357	3.8363	96.1652
5	0.0276	99.9634	1.6880	97.8532
6	0.0132	99.9765	0.7247	98.5779
7	0.0052	99.9817	0.2926	98.8705
8	0.0053	99.9870	0.1252	98.9956
9	0.0049	99.9918	0.1067	99.1023
10	0.0034	99.9952	0.1684	99.2707

In order to choose the optimal number of PLS factors, you can explore how well models based on the training data with different numbers of factors fit the test data. To do so, use the CV=TESTSET option, with an argument pointing to the test data set ftest. The following statements also employ the ODS Graphics features in PROC PLS to display the cross validation results in a plot.

```
ods graphics on;

proc pls data=ftrain nfac=10 cv=testset(ftest)
                             cvtest(stat=press seed=12345);
   model tot_log tyr_log try_log = f1-f30;
run;
```

The tabular results of the test set validation are shown in Output 69.3.3, and the graphical results are shown in Output 69.3.4. They indicate that, although five PLS factors give the minimum predicted residual sum of squares, the residuals for four factors are insignificantly different from those for five. Thus, the smaller model is preferred.

Output 69.3.3 Test Set Validation for the Number of PLS Factors

The PLS Procedure

Test Set Validation for the Number of Extracted Factors

Number of Extracted Factors	Root Mean PRESS	Prob > PRESS
0	3.056797	<.0001
1	2.630561	<.0001

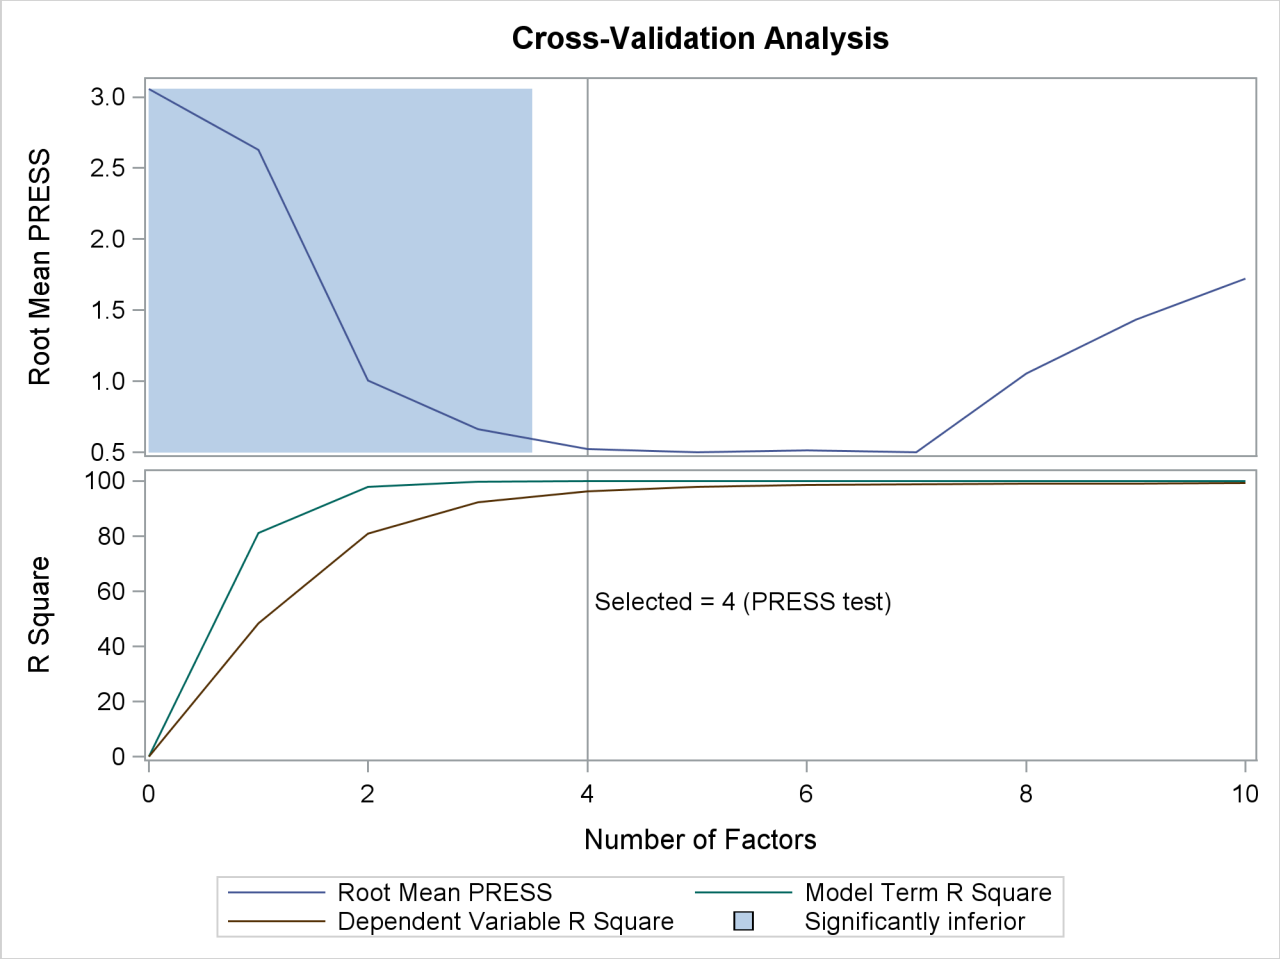
4	0.1951	99.9357	3.8363	96.1652

Output 69.3.4 Test Set Validation Plot



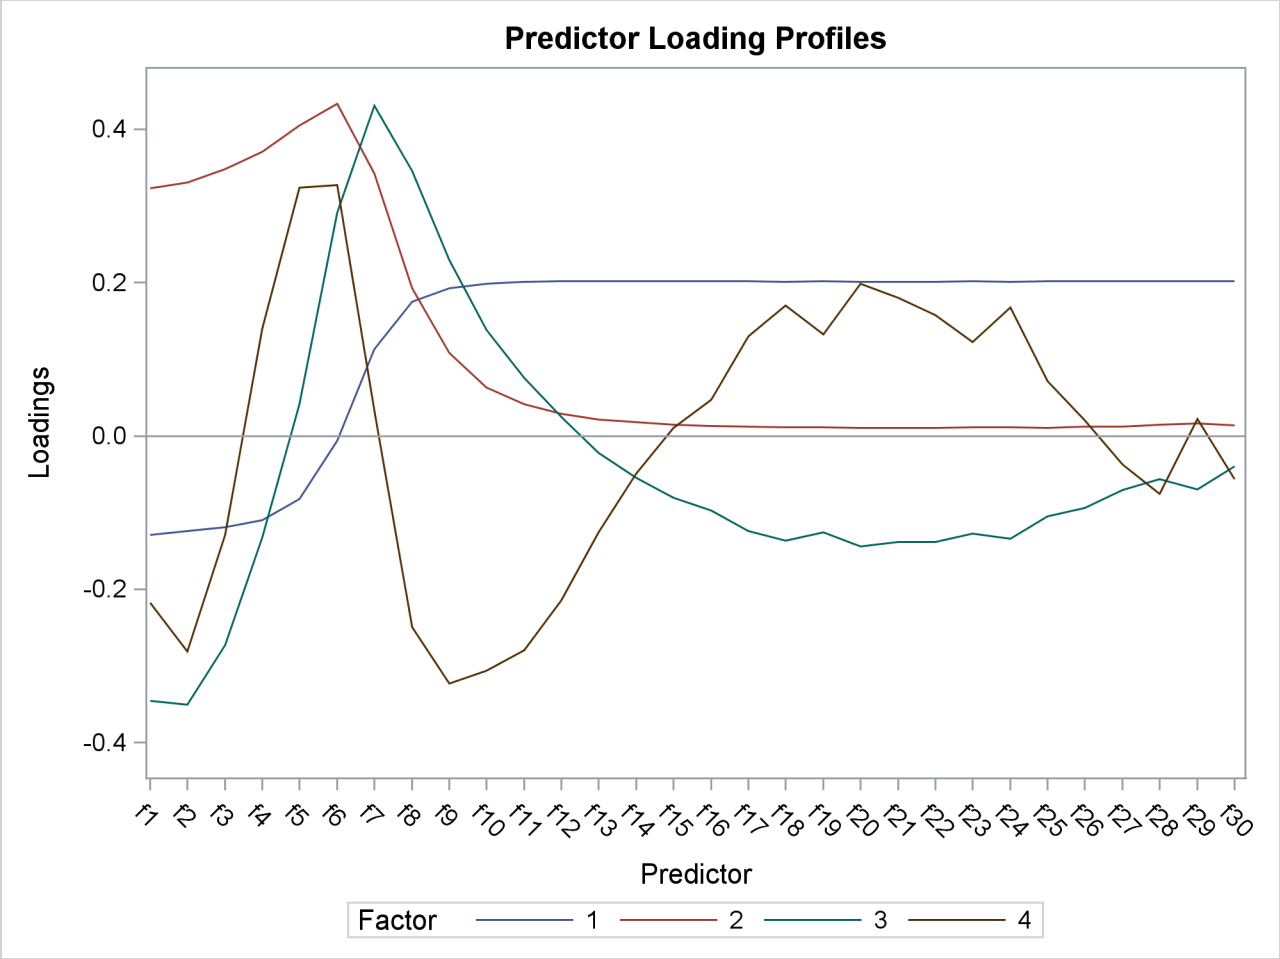
The factor loadings show how the PLS factors are constructed from the centered and scaled predictors. For spectral calibration, it is useful to plot the loadings against the frequency. In many cases, the physical meanings that can be attached to factor loadings help to validate the scientific interpretation of the PLS model. You can use ODS Graphics with PROC PLS to plot the loadings for the four PLS factors against frequency, as shown in the following statements.

```
proc pls data=ftrain nfac=4 plot=XLoadingProfiles;
   model tot_log tyr_log try_log = f1-f30;
run;

ods graphics off;
```

The resulting plot is shown in Output 69.3.5.

Output 69.3.5 Predictor Loadings across Frequencies



Notice that all four factors handle frequencies below and above about 7 or 8 differently. For example, the first factor is very nearly a simple contrast between the averages of the two sets of frequencies, and the second factor appears to be approximately a weighted sum of only the frequencies in the first set.

Example 69.4: Partial Least Squares Spline Smoothing

The EFFECT statement makes it easy to construct a wide variety of linear models. In particular, you can use the spline effect to add smoothing terms to a model. A particular benefit of using spline effects in PROC PLS is that, when operating on spline basis functions, the partial least squares algorithm effectively chooses the amount of smoothing automatically, especially if you combine it with cross validation for the selecting the number of factors. This example employs the EFFECT statement to demonstrate partial least squares spline smoothing of agricultural data.

Weibe (1935) presents data from a study of uniformity of wheat yields over a certain rectangular plot of land. The following statements read these wheat yield measurements, indexed by row and column distances, into the SAS data set Wheat:

```
data Wheat; keep Row Column Yield;
   input Yield @@;
   iRow = int((_N_-1)/12);
   iCol = mod( _N_-1 ,12);
   Column = iCol*15 + 1; /* Column distance, in feet */
   Row    = iRow* 1 + 1; /* Row    distance, in feet */
   Row = 125 - Row + 1;  /* Invert rows              */
datalines;
 715 595 580 580 615 610 540 515 557 665 560 612
 770 710 655 675 700 690 565 585 550 574 511 618

 665 615 685 555 585 630 550 520 553 616 573 570
 755 730 670 580 545 620 580 525 495 565 599 612
 745 670 585 560 550 710 590 545 538 587 600 664
 645 690 550 520 450 630 535 505 530 536 611 578

   ... more lines ...

 570 585 635 765 550 675 765 620 608 705 677 660
 505 500 580 655 470 565 570 555 537 585 589 619
 465 430 510 680 460 600 670 615 620 594 616 784
;
```

The following statements use the PLS procedure to smooth these wheat yields using two spline effects, one for rows and another for columns, in addition to their crossproduct. Each spline effect has, by default, seven basis columns; thus their crossproduct has $49 = 7^2$ columns, for a total of 63 parameters in the full linear model. However, the predictive PLS model does not actually need to have 63 degrees of freedom. Rather, the degree of smoothing is controlled by the number of PLS factors, which in this case is chosen automatically by random subset validation with the CV=RANDOM option.

```
ods graphics on;

proc pls data=Wheat cv=random(seed=1) cvtest(seed=12345)
         plot(only)=contourfit(obs=gradient);
   effect splCol = spline(Column);
   effect splRow = spline(Row   );
   model Yield = splCol|splRow;
run;

ods graphics off;
```

These statements produce the output shown in Output 69.4.1 through Output 69.4.4.

Output 69.4.1 Default Spline Basis: Model and Data Information

The PLS Procedure

Data Set	WORK.WHEAT
Factor Extraction Method	Partial Least Squares

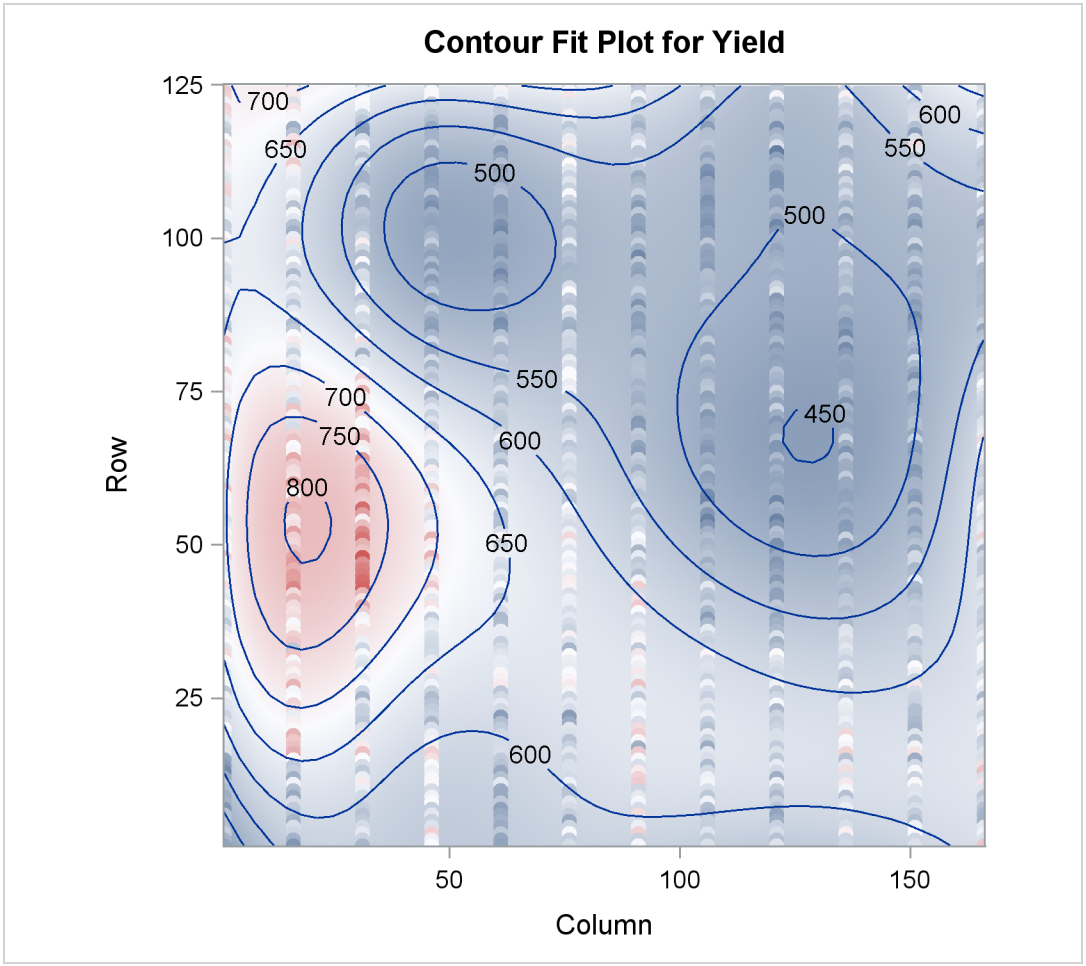
Output 69.4.3 Default Spline Basis: PLS Variation Summary for Split-Sample Validated Model

Percent Variation Accounted for by Partial Least Squares Factors

Number of Extracted Factors	Model Effects Current	Model Effects Total	Dependent Variables Current	Dependent Variables Total
1	11.5269	11.5269	40.2471	40.2471
2	7.2314	18.7583	10.4908	50.7379
3	6.9147	25.6730	2.6523	53.3902
4	3.8433	29.5163	2.8806	56.2708
5	6.4795	35.9958	1.3197	57.5905
6	7.6201	43.6159	1.1700	58.7605
7	7.3214	50.9373	0.7186	59.4790
8	4.8363	55.7736	0.4548	59.9339

Output 69.4.4 Default Spline Basis: Smoothed Yield



The cross validation results in Output 69.4.2 point to a model with eight PLS factors; this is the smallest model whose predicted residual sum of squares (PRESS) is insignificantly different from the model

with the absolute minimum PRESS. The variation summary in Output 69.4.3 shows that this model accounts for about 60% of the variation in the Yield values. The OBS=GRADIENT suboption for the PLOT=CONTOURFIT option specifies that the observations in the resulting plot, Output 69.4.4, be colored according to the same scheme as the surface of predicted yield. This coloration enables you to easily tell which observations are above the surface of predicted yield and which are below.

The surface of predicted yield is somewhat smoother than what Weibe (1935) settled on originally, with a predominance of simple, elliptically shaped contours. You can easily specify a potentially more granular model by increasing the number of knots in the spline bases. Even though the more granular model increases the number of predictor parameters, cross validation can still protect you from overfitting the data. The following statements are the same as those shown before, except that the spline effects now have twice as many basis functions:

```
ods graphics on;

proc pls data=Wheat cv=random(seed=1) cvtest(seed=12345)
         plot(only)=contourfit(obs=gradient);
   effect splCol = spline(Column / knotmethod=equal(14));
   effect splRow = spline(Row    / knotmethod=equal(14));
   model Yield = splCol|splRow;
run;

ods graphics off;
```

The resulting output is shown in Output 69.4.5 through Output 69.4.8.

Output 69.4.5 More Granular Spline Basis: Model and Data Information

The PLS Procedure

Data Set	WORK.WHEAT
Factor Extraction Method	Partial Least Squares
PLS Algorithm	NIPALS
Number of Response Variables	1
Number of Predictor Parameters	360
Missing Value Handling	Exclude
Maximum Number of Factors	15
Validation Method	10-fold Random Subset Validation
Random Subset Seed	1

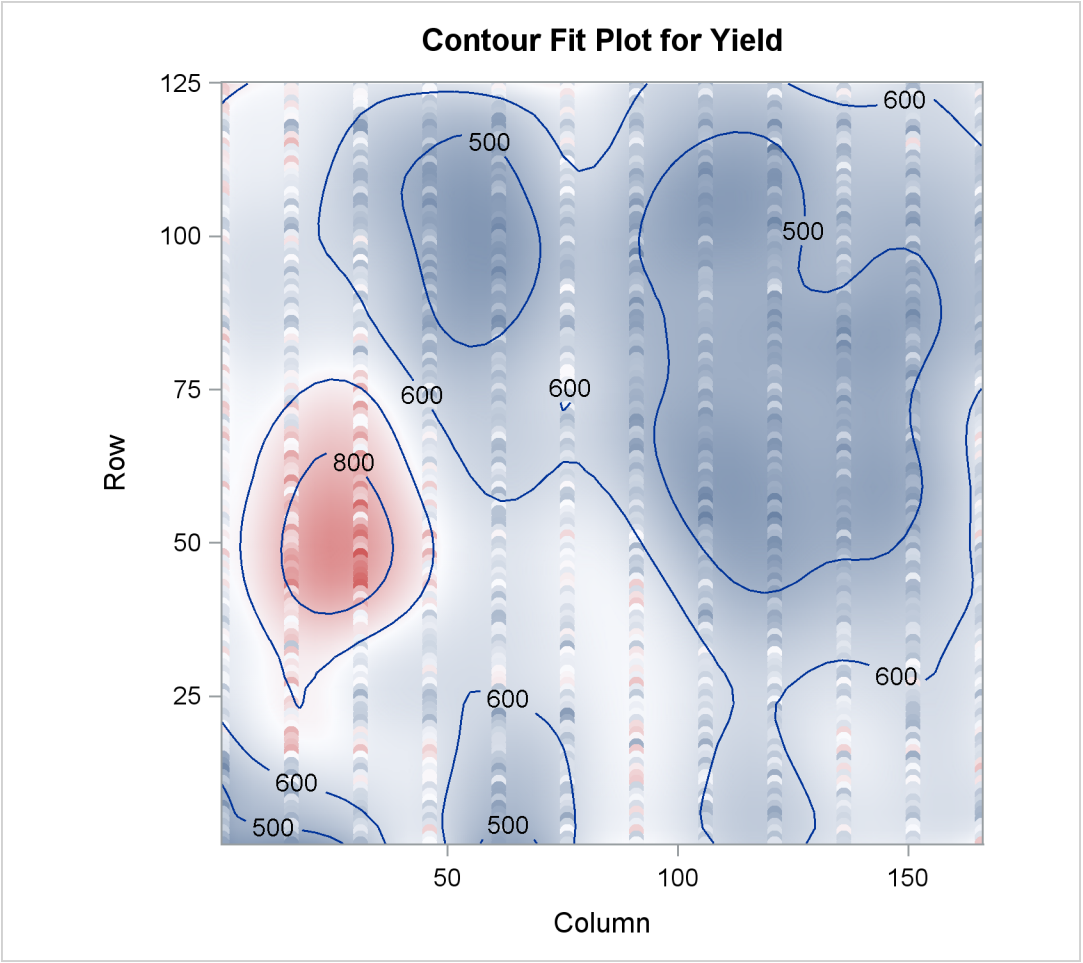
Minimum root mean PRESS	0.6141
Minimizing number of factors	3
Smallest number of factors with p > 0.1	2

Output 69.4.7 More Granular Spline Basis: PLS Variation Summary for Split-Sample Validated Model

Percent Variation Accounted for by Partial Least Squares Factors

Number of Extracted Factors	Model Effects		Dependent Variables	
	Current	Total	Current	Total
1	1.7967	1.7967	64.7792	64.7792
2	1.3719	3.1687	6.3163	71.0955

Output 69.4.8 More Granular Spline Basis: Smoothed Yield



Output 69.4.5 shows that the model now has 360 parameters, many more than before. In Output 69.4.6 you can see that with more granular spline effects, fewer PLS factors are required—only two, in fact. However, Output 69.4.7 shows that this model now accounts for over 70% of the variation in the Yield values, and the contours of predicted values in Output 69.4.8 are less inclined to be simple elliptical shapes.

Chapter 70

The POWER Procedure

Contents

Overview: POWER Procedure

Power and sample size analysis optimizes the resource usage and design of a study, improving chances of conclusive results with maximum efficiency. The POWER procedure performs prospective power and sample size analyses for a variety of goals, such as the following:

- determining the sample size required to get a significant result with adequate probability (power)
- characterizing the power of a study to detect a meaningful effect
- conducting what-if analyses to assess sensitivity of the power or required sample size to other factors

Here *prospective* indicates that the analysis pertains to planning for a future study. This is in contrast to *retrospective* power analysis for a past study, which is not supported by the procedure.

A variety of statistical analyses are covered:

- t tests, equivalence tests, and confidence intervals for means
- tests, equivalence tests, and confidence intervals for binomial proportions
- multiple regression
- tests of correlation and partial correlation
- one-way analysis of variance
- rank tests for comparing two survival curves
- logistic regression with binary response
- Wilcoxon-Mann-Whitney (rank-sum) test

For more complex linear models, see Chapter 43, "The GLMPOWER Procedure."

Input for PROC POWER includes the components considered in study planning:

- design
- statistical model and test
- significance level (alpha)
- surmised effects and variability
- power
- sample size

You designate one of these components by a missing value in the input, in order to identify it as the result parameter. The procedure calculates this result value over one or more scenarios of input values for all other components. Power and sample size are the most common result values, but for some analyses the result can be something else. For example, you can solve for the sample size of a single group for a two-sample t test.

In addition to tabular results, PROC POWER produces graphs. You can produce the most common types of plots easily with default settings and use a variety of options for more customized graphics. For example, you can control the choice of axis variables, axis ranges, number of plotted points, mapping of graphical features (such as color, line style, symbol and panel) to analysis parameters, and legend appearance.

If ODS Graphics is enabled, then PROC POWER uses ODS Graphics to create graphs; otherwise, traditional graphs are produced.

For more information about enabling and disabling ODS Graphics, see the section "Enabling and Disabling ODS Graphics" on page 612 in Chapter 21, "Statistical Graphics Using ODS."

For specific information about the statistical graphics and options available with the POWER procedure, see the PLOT statement and the section "ODS Graphics" on page 5896.

The POWER procedure is one of several tools available in SAS/STAT software for power and sample size analysis. PROC GLMPOWER supports more complex linear models. The Power and Sample Size application provides a user interface and implements many of the analyses supported in the procedures. See Chapter 43, "The GLMPOWER Procedure," and Chapter 71, "The Power and Sample Size Application," for details.

The following sections of this chapter describe how to use PROC POWER and discuss the underlying statistical methodology. The section "Getting Started: POWER Procedure" on page 5732 introduces PROC POWER with simple examples of power computation for a one-sample t test and sample size determination for a two-sample t test. The section "Syntax: POWER Procedure" on page 5740 describes the syntax of the procedure. The section "Details: POWER Procedure" on page 5831 summarizes the methods employed by PROC POWER and provides details on several special topics. The section "Examples: POWER Procedure" on page 5898 illustrates the use of the POWER procedure with several applications.

For an overview of methodology and SAS tools for power and sample size analysis, see Chapter 18, "Introduction to Power and Sample Size Analysis." For more discussion and examples, see O'Brien and Castelloe (2007), Castelloe (2000), Castelloe and O'Brien (2001), Muller and Benignus (1992), O'Brien and Muller (1993), and Lenth (2001).

Getting Started: POWER Procedure

Computing Power for a One-Sample *t* Test

Suppose you want to improve the accuracy of a machine used to print logos on sports jerseys. The logo placement has an inherently high variability, but the horizontal alignment of the machine can be adjusted. The operator agrees to pay for a costly adjustment if you can establish a nonzero mean horizontal displacement in either direction with high confidence. You have 150 jerseys at your disposal to measure, and you want to determine your chances of a significant result (power) by using a one-sample t test with a two-sided $\alpha = 0.05$.

You decide that 8 mm is the smallest displacement worth addressing. Hence, you will assume a true mean of 8 in the power computation. Experience indicates that the standard deviation is about 40.

Use the ONESAMPLEMEANS statement in the POWER procedure to compute the power. Indicate power as the result parameter by specifying the POWER= option with a missing value (.). Specify your conjectures for the mean and standard deviation by using the MEAN= and STDDEV= options and for the sample size

by using the NTOTAL= option. The statements required to perform this analysis are as follows:

```
proc power;
   onesamplemeans
      mean   = 8
      ntotal = 150
      stddev = 40
      power  = .;
run;
```

Default values for the TEST=, DIST=, ALPHA=, NULLMEAN=, and SIDES= options specify a two-sided t test for a mean of 0, assuming a normal distribution with a significance level of $\alpha = 0.05$.

Figure 70.1 shows the output.

Figure 70.1 Sample Size Analysis for One-Sample *t* Test

The POWER Procedure
One-sample t Test for Mean

Fixed Scenario Elements

Distribution	Normal
Method	Exact
Mean	8
Standard Deviation	40
Total Sample Size	150
Number of Sides	2
Null Mean	0
Alpha	0.05

Computed Power

Power
0.682

The power is about 0.68. In other words, there is about a 2/3 chance that the t test will produce a significant result demonstrating the machine's average off-center displacement. This probability depends on the assumptions for the mean and standard deviation.

Now, suppose you want to account for some of your uncertainty in conjecturing the true mean and standard deviation by evaluating the power for four scenarios, using reasonable low and high values, 5 and 10 for the mean, and 30 and 50 for the standard deviation. Also, you might be able to measure more than 150 jerseys, and you would like to know under what circumstances you could get by with fewer. You want to plot power for sample sizes between 100 and 200 to visualize how sensitive the power is to changes in sample size for these four scenarios of means and standard deviations. The following statements perform this analysis:

```
ods listing style=htmlbluecml;
ods graphics on;

proc power;
   onesamplemeans
      mean   = 5 10
      ntotal = 150
      stddev =  30 50
      power  = .;
   plot x=n min=100 max=200;
run;

ods graphics off;
```

The new mean and standard deviation values are specified by using the MEAN= and STDDEV= options in the ONESAMPLEMEANS statement. The PLOT statement with X=N produces a plot with sample size on the X axis. (The result parameter, in this case the power, is always plotted on the other axis.) The MIN= and MAX= options in the PLOT statement determine the sample size range. The ODS GRAPHICS ON statement enables ODS Graphics. The ODS LISTING STYLE=HTMLBLUECML statement specifies the HTMLBLUECML style, which is suitable for use with PROC POWER because it allows both marker symbols and line styles to vary. See the section "ODS Styles Suitable for Use with PROC POWER" on page 5897 for more information.

Figure 70.2 shows the output, and Figure 70.3 shows the plot.

Figure 70.2 Sample Size Analysis for One-Sample *t* Test with Input Ranges

The POWER Procedure
One-sample t Test for Mean

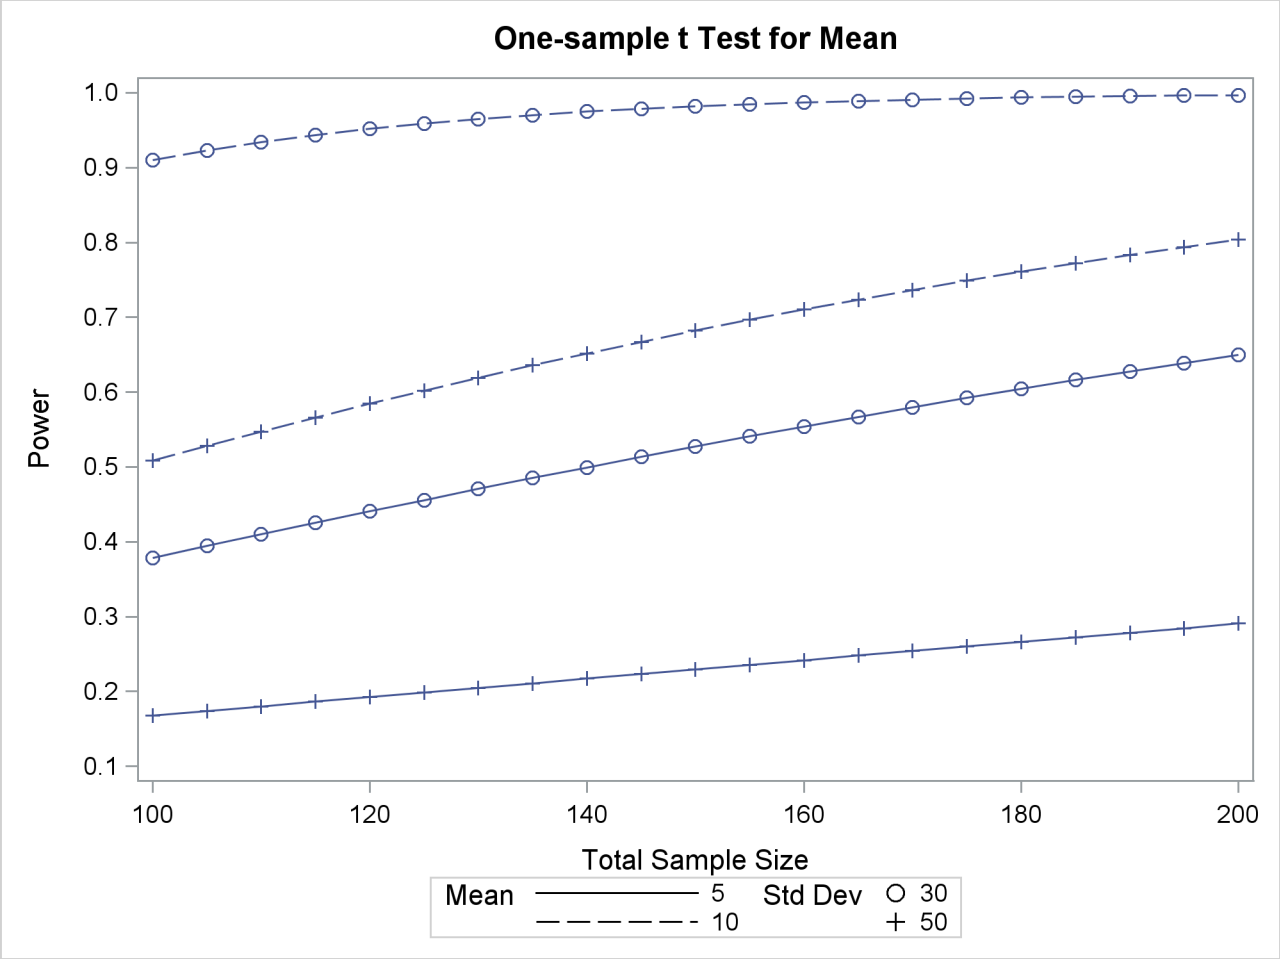
Fixed Scenario Elements

Distribution	Normal
Method	Exact
Total Sample Size	150
Number of Sides	2
Null Mean	0
Alpha	0.05

Computed Power

Index	Mean	Std Dev	Power
1	5	30	0.527
2	5	50	0.229
3	10	30	0.982
4	10	50	0.682

Figure 70.3 Plot of Power versus Sample Size for One-Sample t Test with Input Ranges



The power ranges from about 0.23 to 0.98 for a sample size of 150 depending on the mean and standard deviation. In Figure 70.3, the line style identifies the mean, and the plotting symbol identifies the standard deviation. The locations of plotting symbols indicate computed powers; the curves are linear interpolations of these points. The plot suggests sufficient power for a mean of 10 and standard deviation of 30 (for any of the sample sizes) but insufficient power for the other three scenarios.

Determining Required Sample Size for a Two-Sample *t* Test

In this example you want to compare two physical therapy treatments designed to increase muscle flexibility. You need to determine the number of patients required to achieve a power of at least 0.9 to detect a group mean difference in a two-sample t test. You will use $\alpha = 0.05$ (two-tailed).

The mean flexibility with the standard treatment (as measured on a scale of 1 to 20) is well known to be about 13 and is thought to be between 14 and 15 with the new treatment. You conjecture three alternative scenarios for the means:

1. $\mu_1 = 13, \mu_2 = 14$
2. $\mu_1 = 13, \mu_2 = 14.5$
3. $\mu_1 = 13, \mu_2 = 15$

You conjecture two scenarios for the common group standard deviation:

1. $\sigma = 1.2$
2. $\sigma = 1.7$

You also want to try three weighting schemes:

1. equal group sizes (balanced, or 1:1)
2. twice as many patients with the new treatment (1:2)
3. three times as many patients with the new treatment (1:3)

This makes $3 \times 2 \times 3 = 18$ scenarios in all.

Use the TWOSAMPLEMEANS statement in the POWER procedure to determine the sample sizes required to give 90% power for each of these 18 scenarios. Indicate total sample size as the result parameter by specifying the NTOTAL= option with a missing value (.). Specify your conjectures for the means by using the GROUPMEANS= option. Using the "matched" notation (discussed in the section "Specifying Value Lists in Analysis Statements" on page 5834), enclose the two group means for each scenario in parentheses. Use the STDDEV= option to specify scenarios for the common standard deviation. Specify the weighting schemes by using the GROUPWEIGHTS= option. You could again use the matched notation. But for illustrative purposes, specify the scenarios for each group weight separately by using the "crossed" notation, with scenarios for each group weight separated by a vertical bar (|). The statements that perform the analysis are as follows:

```
proc power;
   twosamplemeans
      groupmeans   = (13 14) (13 14.5) (13 15)
      stddev       = 1.2 1.7
      groupweights = 1 | 1 2 3
      power        = 0.9
      ntotal       = .;
run;
```

Default values for the TEST=, DIST=, NULLDIFF=, ALPHA=, and SIDES= options specify a two-sided t test of group mean difference equal to 0, assuming a normal distribution with a significance level of $\alpha = 0.05$. The results are shown in Figure 70.4.

Figure 70.4 Sample Size Analysis for Two-Sample *t* Test Using Group Means

The POWER Procedure
Two-Sample t Test for Mean Difference

Fixed Scenario Elements

Distribution	Normal
Method	Exact
Group 1 Weight	1
Nominal Power	0.9
Number of Sides	2
Null Difference	0
Alpha	0.05

Computed N Total

Index	Mean1	Mean2	Std Dev	Weight2	Actual Power	N Total
1	13	14.0	1.2	1	0.907	64
2	13	14.0	1.2	2	0.908	72
3	13	14.0	1.2	3	0.905	84
4	13	14.0	1.7	1	0.901	124
5	13	14.0	1.7	2	0.905	141
6	13	14.0	1.7	3	0.900	164
7	13	14.5	1.2	1	0.910	30
8	13	14.5	1.2	2	0.906	33
9	13	14.5	1.2	3	0.916	40
10	13	14.5	1.7	1	0.900	56
11	13	14.5	1.7	2	0.901	63
12	13	14.5	1.7	3	0.908	76
13	13	15.0	1.2	1	0.913	18
14	13	15.0	1.2	2	0.927	21
15	13	15.0	1.2	3	0.922	24
16	13	15.0	1.7	1	0.914	34
17	13	15.0	1.7	2	0.921	39
18	13	15.0	1.7	3	0.910	44

The interpretation is that in the best-case scenario (large mean difference of 2, small standard deviation of 1.2, and balanced design), a sample size of $N = 18$ ($n_1 = n_2 = 9$) patients is sufficient to achieve a power of at least 0.9. In the worst-case scenario (small mean difference of 1, large standard deviation of 1.7, and a 1:3 unbalanced design), a sample size of $N = 164$ ($n_1 = 41, n_2 = 123$) patients is necessary. The Nominal Power of 0.9 in the "Fixed Scenario Elements" table represents the input target power, and the Actual Power column in the "Computed N Total" table is the power at the sample size (N Total) adjusted to achieve the specified sample weighting exactly.

Note the following characteristics of the analysis, and ways you can modify them if you want:

- The total sample sizes are rounded up to multiples of the weight sums (2 for the 1:1 design, 3 for the 1:2 design, and 4 for the 1:3 design) to ensure that each group size is an integer. To request raw fractional sample size solutions, use the NFRACTIONAL option.
- Only the group weight that varies (the one for group 2) is displayed as an output column, while the

weight for group 1 appears in the "Fixed Scenario Elements" table. To display the group weights together in output columns, use the matched version of the value list rather than the crossed version.

- If you can specify only differences between group means (instead of their individual values), or if you want to display the mean differences instead of the individual means, use the MEANDIFF= option instead of the GROUPMEANS= option.

The following statements implement all of these modifications:

```
proc power;
   twosamplemeans
      nfractional
      meandiff     = 1 to 2 by 0.5
      stddev       = 1.2 1.7
      groupweights = (1 1) (1 2) (1 3)
      power        = 0.9
      ntotal       = .;
run;
```

Figure 70.5 shows the new results.

Figure 70.5 Sample Size Analysis for Two-Sample *t* Test Using Mean Differences

The POWER Procedure
Two-Sample t Test for Mean Difference

Fixed Scenario Elements

Distribution	Normal
Method	Exact
Nominal Power	0.9
Number of Sides	2
Null Difference	0
Alpha	0.05

Figure 70.5 *continued*

Computed Ceiling N Total

Index	Mean Diff	Std Dev	Weight1	Weight2	Fractional N Total	Actual Power	Ceiling N Total
1	1.0	1.2	1	1	62.507429	0.902	63
2	1.0	1.2	1	2	70.065711	0.904	71
3	1.0	1.2	1	3	82.665772	0.901	83
4	1.0	1.7	1	1	123.418482	0.901	124
5	1.0	1.7	1	2	138.598159	0.901	139
6	1.0	1.7	1	3	163.899094	0.900	164
7	1.5	1.2	1	1	28.961958	0.900	29
8	1.5	1.2	1	2	32.308867	0.906	33
9	1.5	1.2	1	3	37.893351	0.901	38
10	1.5	1.7	1	1	55.977156	0.900	56
11	1.5	1.7	1	2	62.717357	0.901	63
12	1.5	1.7	1	3	73.954291	0.900	74
13	2.0	1.2	1	1	17.298518	0.913	18
14	2.0	1.2	1	2	19.163836	0.913	20
15	2.0	1.2	1	3	22.282926	0.910	23
16	2.0	1.7	1	1	32.413512	0.905	33
17	2.0	1.7	1	2	36.195531	0.907	37
18	2.0	1.7	1	3	42.504535	0.903	43

Note that the Nominal Power of 0.9 applies to the raw computed sample size (Fractional N Total), and the Actual Power column applies to the rounded sample size (Ceiling N Total). Some of the adjusted sample sizes in Figure 70.5 are lower than those in Figure 70.4 because underlying group sample sizes are allowed to be fractional (for example, the first Ceiling N Total of 63 corresponding to equal group sizes of 31.5).

Syntax: POWER Procedure

The following statements are available in PROC POWER:

PROC POWER < *options* > ;
  LOGISTIC < *options* > ;
  MULTREG < *options* > ;
  ONECORR < *options* > ;
  ONESAMPLEFREQ < *options* > ;
  ONESAMPLEMEANS < *options* > ;
  ONEWAYANOVA < *options* > ;
  PAIREDFREQ < *options* > ;
  PAIREDMEANS < *options* > ;
  PLOT < *plot-options* > < / *graph-options* > ;
  TWOSAMPLEFREQ < *options* > ;
  TWOSAMPLEMEANS < *options* > ;
  TWOSAMPLESURVIVAL < *options* > ;
  TWOSAMPLEWILCOXON < *options* > ;

The statements in the POWER procedure consist of the PROC POWER statement, a set of *analysis statements* (for requesting specific power and sample size analyses), and the PLOT statement (for producing graphs). The PROC POWER statement and at least one of the analysis statements are required. The analysis statements are LOGISTIC, MULTREG, ONECORR, ONESAMPLEFREQ, ONESAMPLEMEANS, ONEWAYANOVA, PAIREDFREQ, PAIREDMEANS, TWOSAMPLEFREQ, TWOSAMPLEMEANS, TWOSAMPLESURVIVAL, and TWOSAMPLEWILCOXON.

You can use multiple analysis statements and multiple PLOT statements. Each analysis statement produces a separate sample size analysis. Each PLOT statement refers to the previous analysis statement and generates a separate graph (or set of graphs).

The name of an analysis statement describes the framework of the statistical analysis for which sample size calculations are desired. You use options in the analysis statements to identify the result parameter to compute, to specify the statistical test and computational options, and to provide one or more scenarios for the values of relevant analysis parameters.

Table 70.1 summarizes the basic functions of each statement in PROC POWER. The syntax of each statement in Table 70.1 is described in the following pages.

Table 70.1 Statements in the POWER Procedure

Statement	Description
PROC POWER	Invokes the procedure
LOGISTIC	Likelihood ratio chi-square test of a single predictor in logistic regression with binary response
MULTREG	Tests of one or more coefficients in multiple linear regression
ONECORR	Fisher's z test and t test of (partial) correlation

Table 70.1 *continued*

Statement	Description
ONESAMPLEFREQ	Tests, confidence interval precision, and equivalence tests of a single binomial proportion
ONESAMPLEMEANS	One-sample *t* test, confidence interval precision, or equivalence test
ONEWAYANOVA	One-way ANOVA including single-degree-of-freedom contrasts
PAIREDFREQ	McNemar's test for paired proportions
PAIREDMEANS	Paired *t* test, confidence interval precision, or equivalence test
PLOT	Displays plots for previous sample size analysis
TWOSAMPLEFREQ	Chi-square, likelihood ratio, and Fisher's exact tests for two independent proportions
TWOSAMPLEMEANS	Two-sample *t* test, confidence interval precision, or equivalence test
TWOSAMPLESURVIVAL	Log-rank, Gehan, and Tarone-Ware tests for comparing two survival curves
TWOSAMPLEWILCOXON	Wilcoxon-Mann-Whitney (rank-sum) test for 2 independent groups

See the section "Summary of Analyses" on page 5831 for a summary of the analyses available and the syntax required for them.

PROC POWER Statement

PROC POWER < *options* > **;**

The PROC POWER statement invokes the POWER procedure. You can specify the following option.

PLOTONLY
specifies that only graphical results from the PLOT statement should be produced.

LOGISTIC Statement

LOGISTIC < *options* > **;**

The LOGISTIC statement performs power and sample size analyses for the likelihood ratio chi-square test of a single predictor in binary logistic regression, possibly in the presence of one or more covariates. All predictor variables are assumed to be independent of each other. So, this analysis is not applicable to studies with correlated predictors—for example, most observational studies (as opposed to randomized studies).

Summary of Options

Table 70.2 summarizes categories of options available in the LOGISTIC statement.

Table 70.2 Summary of Options in the LOGISTIC Statement

Task	Options
Define analysis	TEST=
Specify analysis information	ALPHA= COVARIATES= TESTPREDICTOR= VARDIST=
Specify effects	RESPONSEPROB= COVODDSRATIOS= COVREGCOEFFS= DEFAULTUNIT= INTERCEPT= TESTODDSRATIO= TESTREGCOEFF= UNITS=
Specify sample size	NTOTAL=
Specify power	POWER=
Control sample size rounding	NFRACTIONAL
Specify computational method	DEFAULTNBINS= NBINS=
Control ordering in output	OUTPUTORDER=

Table 70.3 summarizes the valid result parameters in the LOGISTIC statement.

Table 70.3 Summary of Result Parameters in the LOGISTIC Statement

Analyses	Solve For	Syntax
TEST=LRCHI	Power	POWER=.
	Sample size	NTOTAL=.

Dictionary of Options

ALPHA=*number-list*

specifies the level of significance of the statistical test. The default is 0.05, corresponding to the usual $0.05 \times 100\% = 5\%$ level of significance. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

COVARIATES=*grouped-name-list*

specifies the distributions of any predictor variables in the model but not being tested, using labels

specified with the VARDIST= option. The distributions are assumed to be independent of each other and of the tested predictor. If this option is omitted, then the tested predictor specified by the TESTED-PREDICTOR= option is assumed to be the only predictor in the model. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-name-list*.

COVODDSRATIOS=*grouped-number-list*

specifies the odds ratios for the covariates in the full model (including variables in the TESTPREDICTOR= and COVARIATES= options). The ordering of the values corresponds to the ordering in the COVARIATES= option. If the response variable is coded as $Y = 1$ for success and $Y = 0$ for failure, then the odds ratio for each covariate X is the odds of $Y = 1$ when $X = a$ divided by the odds of $Y = 1$ when $X = b$, where a and b are determined from the DEFAULTUNIT= and UNITS= options. Values must be greater than zero. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

COVREGCOEFFS=*grouped-number-list*

specifies the regression coefficients for the covariates in the full model including the test predictor (as specified by the TESTPREDICTOR= option). The ordering of the values corresponds to the ordering in the COVARIATES= option. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

DEFAULTNBINS=*number*

specifies the default number of categories (or "bins") into which the distribution for each predictor variable is divided in internal calculations. Higher values increase computational time and memory requirements but generally lead to more accurate results. Each test predictor or covariate that is absent from the NBINS= option derives its bin number from the DEFAULTNBINS= option. The default value is DEFAULTNBINS=10.

There are two variable distributions for which the number of bins can be overridden internally:

- For an ordinal distribution, the number of ordinal values is always used as the number of bins.
- For a binomial distribution, if the requested number of bins is larger than $n + 1$, where n is the sample size parameter of the binomial distribution, then exactly $n + 1$ bins are used.

DEFAULTUNIT=*change-spec*

specifies the default change in the predictor variables assumed for odds ratios specified with the COVODDSRATIOS= and TESTODDSRATIO= options. Each test predictor or covariate that is absent from the UNITS= option derives its change value from the DEFAULTUNIT= option. The value must be nonzero. The default value is DEFAULTUNIT=1. This option can be used only if at least one of the COVODDSRATIOS= and TESTODDSRATIO= options is used.

Valid specifications for *change-spec* are as follows:

number defines the odds ratio as the ratio of the response variable odds when $X = a$ to the odds when $X = a - number$ for any constant a.

<+|->SD defines the odds ratio as the ratio of the odds when $X = a$ to the odds when $X = a - \sigma$ (or $X = a + \sigma$, if SD is preceded by a minus sign (–)) for any constant a, where σ is the standard deviation of X (as determined from the VARDIST= option).

*multiple**SD defines the odds ratio as the ratio of the odds when $X = a$ to the odds when $X = a - multiple * \sigma$ for any constant a, where σ is the standard deviation of X (as determined from the VARDIST= option).

PERCENTILES(*p1*, *p2*) defines the odds ratio as the ratio of the odds when X is equal to its $p2 *$ 100th percentile to the odds when X is equal to its $p1 *$ 100th percentile (where the percentiles are determined from the distribution specified in the VARDIST= option). Values for *p1* and *p2* must be strictly between 0 and 1.

INTERCEPT=*number-list*

specifies the intercept in the full model (including variables in the TESTPREDICTOR= and COVARIATES= options). See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NBINS=(*"name"* **=** *number* **<...** *"name"* **=** *number* **>)**

specifies the number of categories (or "bins") into which the distribution for each predictor variable (identified by its *name* from the VARDIST= option) is divided in internal calculations. Higher values increase computational time and memory requirements but generally lead to more accurate results. Each predictor variable that is absent from the NBINS= option derives its bin number from the DEFAULTNBINS= option.

There are two variable distributions for which the NBINS= value can be overridden internally:

- For an ordinal distribution, the number of ordinal values is always used as the number of bins.
- For a binomial distribution, if the requested number of bins is larger than $n + 1$, where *n* is the sample size parameter of the binomial distribution, then exactly $n + 1$ bins are used.

NFRACTIONAL

NFRAC

enables fractional input and output for sample sizes. See the section "Sample Size Adjustment Options" on page 5837 for information about the ramifications of the presence (and absence) of the NFRACTIONAL option.

NTOTAL=*number-list*

specifies the sample size or requests a solution for the sample size with a missing value (NTOTAL=.). Values must be at least one. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

OUTPUTORDER=INTERNAL

OUTPUTORDER=REVERSE

OUTPUTORDER=SYNTAX

controls how the input and default analysis parameters are ordered in the output. OUTPUTORDER=INTERNAL (the default) arranges the parameters in the output according to the following order of their corresponding options:

- DEFAULTNBINS=
- NBINS=
- ALPHA=

- RESPONSEPROB=
- INTERCEPT=
- TESTPREDICTOR=
- TESTODDSRATIO=
- TESTREGCOEFF=
- COVARIATES=
- COVODDSRATIOS=
- COVREGCOEFFS=
- NTOTAL=
- POWER=

The OUTPUTORDER=SYNTAX option arranges the parameters in the output in the same order in which their corresponding options are specified in the LOGISTIC statement. The OUTPUTORDER=REVERSE option arranges the parameters in the output in the reverse of the order in which their corresponding options are specified in the LOGISTIC statement.

POWER=*number-list*

specifies the desired power of the test or requests a solution for the power with a missing value (POWER=.). The power is expressed as a probability, a number between 0 and 1, rather than as a percentage. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

RESPONSEPROB=*number-list*

specifies the response probability in the full model when all predictor variables (including variables in the TESTPREDICTOR= and COVARIATES= options) are equal to their means. The log odds of this probability are equal to the intercept in the full model where all predictor are centered at their means. If the response variable is coded as $Y = 1$ for success and $Y = 0$ for failure, then this probability is equal to the mean of Y in the full model when all Xs are equal to their means. Values must be strictly between zero and one. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

TEST=LRCHI

specifies the likelihood ratio chi-square test of a single model parameter in binary logistic regression. This is the default test option.

TESTODDSRATIO=*number-list*

specifies the odds ratio for the predictor variable being tested in the full model (including variables in the TESTPREDICTOR= and COVARIATES= options). If the response variable is coded as $Y = 1$ for success and $Y = 0$ for failure, then the odds ratio for the X being tested is the odds of $Y = 1$ when $X = a$ divided by the odds of $Y = 1$ when $X = b$, where a and b are determined from the DEFAULTUNIT= and UNITS= options. Values must be greater than zero. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

TESTPREDICTOR=*name-list*

specifies the distribution of the predictor variable being tested, using labels specified with the

VARDIST= option. This distribution is assumed to be independent of the distributions of the covariates as defined in the COVARIATES= option. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *name-list*.

TESTREGCOEFF=*number-list*

specifies the regression coefficient for the predictor variable being tested in the full model including the covariates specified by the COVARIATES= option. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

UNITS=(*"name"* **=** *change-spec* **<...** *"name"* **=** *change-spec* **>)**

specifies the changes in the predictor variables assumed for odds ratios specified with the COVODDSRATIOS= and TESTODDSRATIO= options. Each predictor variable whose *name* (from the VARDIST= option) is absent from the UNITS option derives its change value from the DEFAULTUNIT= option. This option can be used only if at least one of the COVODDSRATIOS= and TESTODDSRATIO= options is used.

Valid specifications for *change-spec* are as follows:

number defines the odds ratio as the ratio of the response variable odds when $X = a$ to the odds when $X = a - number$ for any constant a.

<+ | ->SD defines the odds ratio as the ratio of the odds when $X = a$ to the odds when $X = a - \sigma$ (or $X = a + \sigma$, if SD is preceded by a minus sign (–)) for any constant a, where σ is the standard deviation of X (as determined from the VARDIST= option).

*multiple**SD defines the odds ratio as the ratio of the odds when $X = a$ to the odds when $X = a - multiple * \sigma$ for any constant a, where σ is the standard deviation of X (as determined from the VARDIST= option).

PERCENTILES(*p1*, *p2*) defines the odds ratio as the ratio of the odds when X is equal to its $p2 *$ 100th percentile to the odds when X is equal to its $p1 *$ 100th percentile (where the percentiles are determined from the distribution specified in the VARDIST= option). Values for *p1* and *p2* must be strictly between 0 and 1.

Each unit value must be nonzero.

VARDIST("label")=*distribution* **(***parameters***)**

defines a distribution for a predictor variable.

For the VARDIST= option,

label identifies the variable distribution in the output and with the COVARIATES= and TESTPREDICTOR= options.

distribution specifies the distributional form of the variable.

parameters specifies one or more parameters associated with the distribution.

Choices for distributional forms and their parameters are as follows:

ORDINAL ((*values*) : (*probabilities*)) is an ordered categorical distribution. The *values* are any numbers separated by spaces. The *probabilities* are numbers between 0 and 1 (inclusive) separated by spaces. Their sum must be exactly 1. The number of *probabilities* must match the number of *values*.

BETA (*a*, *b* <, *l*, *r* >) is a beta distribution with shape parameters a and b and optional location parameters l and r. The values of a and b must be greater than 0, and l must be less than r. The default values for l and r are 0 and 1, respectively.

BINOMIAL (*p*, *n*) is a binomial distribution with probability of success p and number of independent Bernoulli trials n. The value of p must be greater than 0 and less than 1, and n must be an integer greater than 0.

EXPONENTIAL (λ) is an exponential distribution with scale λ, which must be greater than 0.

GAMMA (*a*, λ) is a gamma distribution with shape a and scale λ. The values of a and λ must be greater than 0.

LAPLACE (θ, λ) is a Laplace distribution with location θ and scale λ. The value of λ must be greater than 0.

LOGISTIC (θ, λ) is a logistic distribution with location θ and scale λ. The value of λ must be greater than 0.

LOGNORMAL (θ, λ) is a lognormal distribution with location θ and scale λ. The value of λ must be greater than 0.

NORMAL (θ, λ) is a normal distribution with mean θ and standard deviation λ. The value of λ must be greater than 0.

POISSON (*m*) is a Poisson distribution with mean m. The value of m must be greater than 0.

UNIFORM (*l*, *r*) is a uniform distribution on the interval $[l, r]$, where $l < r$.

Restrictions on Option Combinations

To specify the intercept in the full model, choose one of the following two parameterizations:

- intercept (using the INTERCEPT= options)
- Prob($Y = 1$) when all predictors are equal to their means (using the RESPONSEPROB= option)

To specify the effect associated with the predictor variable being tested, choose one of the following two parameterizations:

- odds ratio (using the TESTODDSRATIO= options)
- regression coefficient (using the TESTREGCOEFFS= option)

To describe the effects of the covariates in the full model, choose one of the following two parameterizations:

- odds ratios (using the COVODDSRATIOS= options)
- regression coefficients (using the COVREGCOEFFS= options)

Option Groups for Common Analyses

This section summarizes the syntax for the common analyses supported in the LOGISTIC statement.

Likelihood Ratio Chi-Square Test for One Predictor

You can express effects in terms of response probability and odds ratios, as in the following statements:

```
proc power;
   logistic
      vardist("x1a") = normal(0, 2)
      vardist("x1b") = normal(0, 3)
      vardist("x2") = poisson(7)
      vardist("x3a") = ordinal((-5 0 5) : (.3 .4 .3))
      vardist("x3b") = ordinal((-5 0 5) : (.4 .3 .3))
      testpredictor = "x1a" "x1b"
      covariates = "x2" | "x3a" "x3b"
      responseprob = 0.15
      testoddsratio = 1.75
      covoddsratios = (2.1 1.4)
      ntotal = 100
      power = .;
run;
```

The VARDIST= options define the distributions of the predictor variables. The TESTPREDICTOR= option specifies two scenarios for the test predictor distribution, Normal(10,2) and Normal(10,3). The COVARIATES= option specifies two covariates, the first with a Poisson(7) distribution. The second covariate has an ordinal distribution on the values –5, 0, and 5 with two scenarios for the associated probabilities: (.3, .4, .3) and (.4, .3, .3). The response probability in the full model with all variables equal to zero is specified by the RESPONSEPROB= option as 0.15. The odds ratio for a unit decrease in the tested predictor is specified by the TESTODDSRATIO= option to be 1.75. Corresponding odds ratios for the two covariates in the full model are specified by the COVODDSRATIOS= option to be 2.1 and 1.4. The POWER=. option requests a solution for the power at a sample size of 100 as specified by the NTOTAL= option.

Default values of the TEST= and ALPHA= options specify a likelihood ratio test of the first predictor with a significance level of 0.05. The default of DEFAULTUNIT=1 specifies that all odds ratios are defined in terms of unit changes in predictors. The default of DEFAULTNBINS=10 specifies that each of the three predictor variables is discretized into a distribution with 10 categories in internal calculations.

You can also express effects in terms of regression coefficients, as in the following statements:

```
proc power;
   logistic
      vardist("x1a") = normal(0, 2)
      vardist("x1b") = normal(0, 3)
      vardist("x2") = poisson(7)
      vardist("x3a") = ordinal((-5 0 5) : (.3 .4 .3))
      vardist("x3b") = ordinal((-5 0 5) : (.4 .3 .3))
      testpredictor = "x1a" "x1b"
      covariates = "x2" | "x3a" "x3b"
      intercept = -6.928162
      testregcoeff = 0.5596158
      covregcoeffs = (0.7419373 0.3364722)
      ntotal = 100
      power = .;
run;
```

The regression coefficients for the tested predictor (TESTREGCOEFF=0.5596158) and covariates (COVREGCOEFFS=(0.7419373 0.3364722)) are determined by taking the logarithm of the corresponding odds ratios. The intercept in the full model is specified as –6.928162 by the INTERCEPT= option. This number is calculated according to the forumula at the end of "Analyses in the LOGISTIC Statement" on page 5842, which expresses the intercept in terms of the response probability, regression coefficients, and predictor means:

$$\text{Intercept} = \log\left(\frac{0.15}{1-0.15}\right) - (0.5596158(0) + 0.7419373(7) + 0.3364722(0))$$

MULTREG Statement

MULTREG < *options* > **;**

The MULTREG statement performs power and sample size analyses for Type III F tests of sets of predictors in multiple linear regression, assuming either fixed or normally distributed predictors.

Summary of Options

Table 70.4 summarizes categories of options available in the MULTREG statement.

Table 70.4 Summary of Options in the MULTREG Statement

Task	Options
Define analysis	TEST=
Specify analysis information	ALPHA= MODEL= NFULLPREDICTORS= NOINT NREDUCEDPREDICTORS= NTESTPREDICTORS=
Specify effects	PARTIALCORR= RSQUAREDIFF= RSQUAREFULL= RSQUAREREDUCED=
Specify sample size	NTOTAL=
Specify power	POWER=
Control sample size rounding	NFRACTIONAL
Control ordering in output	OUTPUTORDER=

Table 70.5 summarizes the valid result parameters in the MULTREG statement.

Table 70.5 Summary of Result Parameters in the MULTREG Statement

Analyses	Solve For	Syntax
TEST=TYPE3	Power	POWER=.
	Sample size	NTOTAL=.

Dictionary of Options

ALPHA=*number-list*

specifies the level of significance of the statistical test. The default is 0.05, corresponding to the usual $0.05 \times 100\% = 5\%$ level of significance. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

MODEL=*keyword-list*

specifies the assumed distribution of the tested predictors. MODEL=FIXED indicates a fixed predictor distribution. MODEL=RANDOM (the default) indicates a joint multivariate normal distribution for the response and tested predictors. You can use the aliases CONDITIONAL for FIXED and UNCONDITIONAL for RANDOM. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *keyword-list*.

FIXED fixed predictors

RANDOM random (multivariate normal) predictors

NFRACTIONAL

NFRAC

enables fractional input and output for sample sizes. See the section "Sample Size Adjustment Options" on page 5837 for information about the ramifications of the presence (and absence) of the NFRACTIONAL option.

NFULLPREDICTORS=*number-list*

NFULLPRED=*number-list*

specifies the number of predictors in the full model, not counting the intercept. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NOINT

specifies a no-intercept model (for both full and reduced models). By default, the intercept is included in the model. If you want to test the intercept, you can specify the NOINT option and simply consider the intercept to be one of the predictors being tested. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NREDUCEDPREDICTORS=*number-list*

NREDUCEDPRED=*number-list*

NREDPRED=*number-list*

specifies the number of predictors in the reduced model, not counting the intercept. This is the same

as the difference between values of the NFULLPREDICTORS= and NTESTPREDICTORS= options. Note that supplying a value of 0 is the same as specifying an F test of a Pearson correlation. This option cannot be used at the same time as the NTESTPREDICTORS= option. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NTESTPREDICTORS=*number-list*

NTESTPRED=*number-list*

specifies the number of predictors being tested. This is the same as the difference between values of the NFULLPREDICTORS= and NREDUCEDPREDICTORS= options. Note that supplying identical values for the NTESTPREDICTORS= and NFULLPREDICTORS= options is the same as specifying an F test of a Pearson correlation. This option cannot be used at the same time as the NREDUCEDPREDICTORS= option. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NTOTAL=*number-list*

specifies the sample size or requests a solution for the sample size with a missing value (NTOTAL=.). The minimum acceptable value for the sample size depends on the MODEL=, NOINT, NFULLPREDICTORS=, NTESTPREDICTORS=, and NREDUCEDPREDICTORS= options. It ranges from $p+1$ to $p+3$, where p is the value of the NFULLPREDICTORS option. See Table 70.30 for further information about minimum NTOTAL values, and see the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

OUTPUTORDER=INTERNAL

OUTPUTORDER=REVERSE

OUTPUTORDER=SYNTAX

controls how the input and default analysis parameters are ordered in the output. OUTPUTORDER=INTERNAL (the default) arranges the parameters in the output according to the following order of their corresponding options:

- MODEL=
- NFULLPREDICTORS=
- NTESTPREDICTORS=
- NREDUCEDPREDICTORS=
- ALPHA=
- PARTIALCORR=
- RSQUAREFULL=
- RSQUAREREDUCED=
- RSQUAREDIFF=
- NTOTAL=
- POWER=

The OUTPUTORDER=SYNTAX option arranges the parameters in the output in the same order in which their corresponding options are specified in the MULTREG statement. The OUTPUTORDER=REVERSE option arranges the parameters in the output in the reverse of the order in which their corresponding options are specified in the MULTREG statement.

PARTIALCORR=*number-list*

PCORR=*number-list*

specifies the partial correlation between the tested predictors and the response, adjusting for any other predictors in the model. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

POWER=*number-list*

specifies the desired power of the test or requests a solution for the power with a missing value (POWER=.). The power is expressed as a probability, a number between 0 and 1, rather than as a percentage. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

RSQUAREDIFF=*number-list*

RSQDIFF=*number-list*

specifies the difference in R^2 between the full and reduced models. This is equivalent to the proportion of variation explained by the predictors you are testing. It is also equivalent to the squared semipartial correlation of the tested predictors with the response. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

RSQUAREFULL=*number-list*

RSQFULL=*number-list*

specifies the R^2 of the full model, where R^2 is the proportion of variation explained by the model. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

RSQUAREREDUCED=*number-list*

RSQREDUCED=*number-list*

RSQRED=*number-list*

specifies the R^2 of the reduced model, where R^2 is the proportion of variation explained by the model. If the reduced model is an empty or intercept-only model (in other words, if NREDUCEDPREDICTORS=0 or NTESTPREDICTORS=NFULLPREDICTORS), then RSQUAREREDUCED=0 is assumed. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

TEST=TYPE3

specifies a Type III F test of a set of predictors adjusting for any other predictors in the model. This is the default test option.

Restrictions on Option Combinations

To specify the number of predictors, use any two of these three options:

- the number of predictors in the full model (NFULLPREDICTORS=)
- the number of predictors in the reduced model (NREDUCEDPREDICTORS=)
- the number of predictors being tested (NTESTPREDICTORS=)

To specify the effect, choose one of the following parameterizations:

- partial correlation (by using the PARTIALCORR= option)
- R^2 for the full and reduced models (by using any two of RSQUAREDIFF=, RSQUAREFULL=, and RSQUAREREDUCED=)

Option Groups for Common Analyses

This section summarizes the syntax for the common analyses supported in the MULTREG statement.

Type III F Test of a Set of Predictors

You can express effects in terms of partial correlation, as in the following statements. Default values of the TEST=, MODEL=, and ALPHA= options specify a Type III F test with a significance level of 0.05, assuming normally distributed predictors.

```
proc power;
   multreg
      model = random
      nfullpredictors = 7
      ntestpredictors = 3
      partialcorr = 0.35
      ntotal = 100
      power = .;
run;
```

You can also express effects in terms of R^2:

```
proc power;
   multreg
      model = fixed
      nfullpredictors = 7
      ntestpredictors = 3
      rsquarefull = 0.9
      rsquarediff = 0.1
      ntotal = .
      power = 0.9;
run;
```

ONECORR Statement

ONECORR < *options* > **;**

The ONECORR statement performs power and sample size analyses for tests of simple and partial Pearson correlation between two variables. Both Fisher's z test and the t test are supported.

Summary of Options

Table 70.6 summarizes categories of options available in the ONECORR statement.

Table 70.6 Summary of Options in the ONECORR Statement

Task	Options
Define analysis	DIST= TEST=
Specify analysis information	ALPHA= MODEL= NPARTIALVARS= NULLCORR= SIDES=
Specify effects	CORR=
Specify sample size	NTOTAL=
Specify power	POWER=
Control sample size rounding	NFRACTIONAL
Control ordering in output	OUTPUTORDER=

Table 70.7 summarizes the valid result parameters in the ONECORR statement.

Table 70.7 Summary of Result Parameters in the ONECORR Statement

Analyses	Solve For	Syntax
TEST=PEARSON	Power	POWER=.
	Sample size	NTOTAL=.

Dictionary of Options

ALPHA=*number-list*

specifies the level of significance of the statistical test. The default is 0.05, corresponding to the usual $0.05 \times 100\% = 5\%$ level of significance. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

CORR=*number-list*

specifies the correlation between two variables, possibly adjusting for other variables as determined by the NPARTIALVARS= option. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

DIST=FISHERZ

DIST=T

specifies the underlying distribution assumed for the test statistic. FISHERZ corresponds to Fisher's z normalizing transformation of the correlation coefficient. T corresponds to the t transformation of

the correlation coefficient. Note that DIST=T is equivalent to analyses in the MULTREG statement with NTESTPREDICTORS=1. The default value is FISHERZ.

MODEL=*keyword-list*

specifies the assumed distribution of the first variable when DIST=T. The second variable is assumed to have a normal distribution. MODEL=FIXED indicates a fixed distribution. MODEL=RANDOM (the default) indicates a joint bivariate normal distribution with the second variable. You can use the aliases CONDITIONAL for FIXED and UNCONDITIONAL for RANDOM. This option can be used only for DIST=T. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *keyword-list*.

FIXED fixed variables

RANDOM random (bivariate normal) variables

NFRACTIONAL

NFRAC

enables fractional input and output for sample sizes. See the section "Sample Size Adjustment Options" on page 5837 for information about the ramifications of the presence (and absence) of the NFRACTIONAL option.

NPARTIALVARS=*number-list*

NPVARS=*number-list*

specifies the number of variables adjusted for in the correlation between the two primary variables. The default value is 0, corresponding to a simple correlation. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NTOTAL=*number-list*

specifies the sample size or requests a solution for the sample size with a missing value (NTOTAL=.). Values for the sample size must be at least $p+3$ when DIST=T and MODEL=CONDITIONAL, and at least $p+4$ when either DIST=FISHER or when DIST=T and MODEL=UNCONDITIONAL, where p is the value of the NPARTIALVARS option. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NULLCORR=*number-list*

NULLC=*number-list*

specifies the null value of the correlation. The default value is 0. This option can be used only with the DIST=FISHERZ analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

OUTPUTORDER=INTERNAL

OUTPUTORDER=REVERSE

OUTPUTORDER=SYNTAX

controls how the input and default analysis parameters are ordered in the output. OUTPUTORDER=INTERNAL (the default) arranges the parameters in the output according to the following order of their corresponding options:

- MODEL=

- SIDES=
- NULL=
- ALPHA=
- NPARTIALVARS=
- CORR=
- NTOTAL=
- POWER=

The OUTPUTORDER=SYNTAX option arranges the parameters in the output in the same order in which their corresponding options are specified in the ONECORR statement. The OUTPUTORDER=REVERSE option arranges the parameters in the output in the reverse of the order in which their corresponding options are specified in the ONECORR statement.

POWER=*number-list*
specifies the desired power of the test or requests a solution for the power with a missing value (POWER=.). The power is expressed as a probability, a number between 0 and 1, rather than as a percentage. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

SIDES=*keyword-list*
specifies the number of sides (or tails) and the direction of the statistical test. Valid keywords are

1	one-sided with alternative hypothesis in same direction as effect
2	two-sided
U	upper one-sided with alternative greater than null value
L	lower one-sided with alternative less than null value

The default value is 2.

TEST=PEARSON
specifies a test of the Pearson correlation coefficient between two variables, possibly adjusting for other variables. This is the default test option.

Option Groups for Common Analyses

This section summarizes the syntax for the common analyses supported in the ONECORR statement.

Fisher's z Test for Pearson Correlation

The following statements demonstrate a power computation for Fisher's z test for correlation. Default values of TEST=PEARSON, ALPHA=0.05, SIDES=2, and NPARTIALVARS=0 are assumed.

```
proc power;
   onecorr dist=fisherz
      nullcorr = 0.15
```

```
      corr = 0.35
      ntotal = 180
      power = .;
run;
```

t *Test for Pearson Correlation*

The following statements demonstrate a sample size computation for the *t* test for correlation. Default values of TEST=PEARSON, MODEL=RANDOM, ALPHA=0.05, and SIDES=2 are assumed.

```
proc power;
   onecorr dist=t
      npartialvars = 4
      corr = 0.45
      ntotal = .
      power = 0.85;
run;
```

ONESAMPLEFREQ Statement

ONESAMPLEFREQ < *options* > **;**

The ONESAMPLEFREQ statement performs power and sample size analyses for exact and approximate tests (including equivalence, noninferiority, and superiority) and confidence interval precision for a single binomial proportion.

Summary of Options

Table 70.8 summarizes categories of options available in the ONESAMPLEFREQ statement.

Table 70.8 Summary of Options in the ONESAMPLEFREQ Statement

TEST=EXACT	Power	POWER=.
TEST=Z METHOD=EXACT	Power	POWER=.
TEST=Z METHOD=NORMAL	Power Sample size	POWER=. NTOTAL=.

Dictionary of Options

ALPHA=*number-list*

specifies the level of significance of the statistical test. The default is 0.05, corresponding to the usual $0.05 \times 100\% = 5\%$ level of significance. If the CI= and SIDES=1 options are used, then the value must be less than 0.5. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

CI

CI=AGRESTICOULL | AC

CI=JEFFREYS

CI=EXACT | CLOPPERPEARSON | CP

CI=WALD

CI=WALD_CORRECT

CI=WILSON | SCORE

specifies an analysis of precision of a confidence interval for the sample binomial proportion.

The value of the CI= option specifies the type of confidence interval. The CI=AGRESTICOULL option is a generalization of the "Adjusted Wald / add 2 successes and 2 failures" interval of Agresti and Coull (1998) and is presented in Brown, Cai, and DasGupta (2001). It corresponds to the TABLES / BINOMIAL (AGRESTICOULL) option in PROC FREQ. The CI=JEFFREYS option specifies the equal-tailed Jeffreys prior Bayesian interval, corresponding to the TABLES / BINOMIAL (JEFFREYS) option in PROC FREQ. The CI=EXACT option specifies the exact Clopper-Pearson confidence interval based on enumeration, corresponding to the TABLES / BINOMIAL (EXACT) option in PROC FREQ. The CI=WALD option specifies the confidence interval based on the Wald test (also commonly called the z test or normal-approximation test), corresponding to the TABLES / BINOMIAL (WALD) option in PROC FREQ. The CI=WALD_CORRECT option specifies the confidence interval based on the Wald test with continuity correction, corresponding to the TABLES / BINOMIAL (CORRECT WALD) option in PROC FREQ. The CI=WILSON option (the default) specifies the confidence interval based on the score statistic, corresponding to the TABLES / BINOMIAL (WILSON) option in PROC FREQ.

Instead of power, the relevant probability for this analysis is the probability of achieving a desired precision. Specifically, it is the probability that the half-width of the confidence interval will be at most the value specified by the HALFWIDTH= option.

EQUIVBOUNDS=*grouped-number-list*

specifies the lower and upper equivalence bounds, representing the same information as the combination of the LOWER= and UPPER= options but grouping them together. The EQUIVBOUNDS= option can be used only with equivalence analyses (TEST=EQUIV_ADJZ | EQUIV_EXACT | EQUIV_Z). Values must be strictly between 0 and 1. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

HALFWIDTH=*number-list*

specifies the desired confidence interval half-width. The half-width for a two-sided interval is the length of the confidence interval divided by two. This option can be used only with the CI= analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

LOWER=*number-list*

specifies the lower equivalence bound for the binomial proportion. The LOWER= option can be used only with equivalence analyses (TEST=EQUIV_ADJZ | EQUIV_EXACT | EQUIV_Z). Values must be strictly between 0 and 1. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

MARGIN=*number-list*

specifies the equivalence or noninferiority or superiority margin, depending on the analysis.

The MARGIN= option can be used with one-sided analyses (SIDES = 1 | U | L), in which case it specifies the margin added to the null proportion value in the hypothesis test, resulting in a noninferiority or superiority test (depending on the agreement between the effect and hypothesis directions and the sign of the margin). A test with a null proportion p_0 and a margin m is the same as a test with null proportion $p_0 + m$ and no margin.

The MARGIN= option can also be used with equivalence analyses (TEST=EQUIV_ADJZ | EQUIV_EXACT | EQUIV_Z) when the NULLPROPORTION= option is used, in which case it specifies the lower and upper equivalence bounds as $p_0 - m$ and $p_0 + m$, where p_0 is the value of the NULLPROPORTION= option and m is the value of the MARGIN= option.

The MARGIN= option cannot be used in conjunction with the SIDES=2 option. (Instead, specify an equivalence analysis by using TEST=EQUIV_ADJZ or TEST=EQUIV_EXACT or TEST=EQUIV_Z). Also, the MARGIN= option cannot be used with the CI= option.

Values must be strictly between –1 and 1. In addition, the sum of NULLPROPORTION and MARGIN must be strictly between 0 and 1 for one-sided analyses, and the derived lower equivalence bound (2 * NULLPROPORTION – MARGIN) must be strictly between 0 and 1 for equivalence analyses.

See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

METHOD=EXACT

METHOD=NORMAL

specifies the computational method. METHOD=EXACT (the default) computes exact results by using the binomial distribution. METHOD=NORMAL computes approximate results by using the normal approximation to the binomial distribution.

NFRACTIONAL

NFRAC

enables fractional input and output for sample sizes. This option is invalid when the METHOD=EXACT option is specified. See the section "Sample Size Adjustment Options" on page 5837 for information about the ramifications of the presence (and absence) of the NFRACTIONAL option.

NTOTAL=*number-list*

specifies the sample size or requests a solution for the sample size with a missing value (NTOTAL=.). See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NULLPROPORTION=*number-list*

NULLP=*number-list*

specifies the null proportion. A value of 0.5 corresponds to the sign test. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

OUTPUTORDER=INTERNAL

OUTPUTORDER=REVERSE

OUTPUTORDER=SYNTAX

controls how the input and default analysis parameters are ordered in the output. OUTPUTORDER=INTERNAL (the default) arranges the parameters in the output according to the following order of their corresponding options:

- SIDES=
- NULLPROPORTION=
- ALPHA=
- PROPORTION=
- NTOTAL=
- POWER=

The OUTPUTORDER=SYNTAX option arranges the parameters in the output in the same order in which their corresponding options are specified in the ONESAMPLEFREQ statement. The OUTPUTORDER=REVERSE option arranges the parameters in the output in the reverse of the order in which their corresponding options are specified in the ONESAMPLEFREQ statement.

POWER=*number-list*

specifies the desired power of the test or requests a solution for the power with a missing value (POWER=.). The power is expressed as a probability, a number between 0 and 1, rather than as a percentage. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

PROBWIDTH=*number-list*

specifies the desired probability of obtaining a confidence interval half-width less than or equal to the value specified by the HALFWIDTH= option. A missing value (PROBWIDTH=.) requests a solution for this probability. Values are expressed as probabilities (for example, 0.9) rather than percentages. This option can be used only with the CI= analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

PROPORTION=*number-list*

P=*number-list*

specifies the binomial proportion—that is, the expected proportion of successes in the hypothetical binomial trial. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

SIDES=*keyword-list*

specifies the number of sides (or tails) and the direction of the statistical test. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *keyword-list*. Valid keywords are as follows:

1 one-sided with alternative hypothesis in same direction as effect

2 two-sided

U upper one-sided with alternative greater than null value

L lower one-sided with alternative less than null value

If the effect size is zero, then SIDES=1 is not permitted; instead, specify the direction of the test explicitly in this case with either SIDES=L or SIDES=U. The default value is 2.

TEST

TEST= ADJZ

TEST= EQUIV_ADJZ

TEST= EQUIV_EXACT

TEST= EQUIV_Z

TEST= EXACT

TEST= Z

specifies the statistical analysis. TEST=ADJZ specifies a normal-approximate z test with continuity adjustment. TEST=EQUIV_ADJZ specifies a normal-approximate two-sided equivalence test based on the z statistic with continuity adjustment and a TOST (two one-sided tests) procedure. TEST=EQUIV_EXACT specifies the exact binomial two-sided equivalence test based on a TOST (two one-sided tests) procedure. TEST=EQUIV_Z specifies a normal-approximate two-sided equivalence test based on the z statistic without any continuity adjustment, which is the same as the chi-square statistic, and a TOST (two one-sided tests) procedure. TEST or TEST=EXACT (the default) specifies the exact binomial test. TEST=Z specifies a normal-approximate z test without any continuity adjustment, which is the same as the chi-square test when SIDES=2.

UPPER=*number-list*

specifies the upper equivalence bound for the binomial proportion. The UPPER= option can be used only with equivalence analyses (TEST=EQUIV_ADJZ | EQUIV_EXACT | EQUIV_Z). Values must be strictly between 0 and 1. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

VAREST=*keyword-list*

specifies how the variance is computed in the test statistic for the TEST=Z, TEST=ADJZ, TEST=EQUIV_Z, and TEST=EQUIV_ADJZ analyses. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *keyword-list*. Valid keywords are as follows:

NULL (the default) estimates the variance by using the null proportion(s) (specified by some combination of the NULLPROPORTION=, MARGIN=, LOWER=, and UPPER= options). For TEST=Z and TEST=ADJZ, the null proportion is the value of the NULLPROPORTION= option plus the value of the MARGIN= option (if it is used). For TEST=EQUIV_Z and TEST=EQUIV_ADJZ, there are two null proportions, corresponding to the lower and upper equivalence bounds, one for each test in the TOST (two one-sided tests) procedure.

SAMPLE estimates the variance by using the observed sample proportion.

This option is ignored if the analysis is one other than TEST=Z, TEST=ADJZ, TEST=EQUIV_Z, or TEST=EQUIV_ADJZ.

Option Groups for Common Analyses

This section summarizes the syntax for the common analyses supported in the ONESAMPLEFREQ statement.

Exact Test of a Binomial Proportion

The following statements demonstrate a power computation for the exact test of a binomial proportion. Defaults for the SIDES= and ALPHA= options specify a two-sided test with a 0.05 significance level.

```
proc power;
   onesamplefreq test=exact
      nullproportion = 0.2
      proportion = 0.3
      ntotal = 100
      power = .;
run;
```

z Test

The following statements demonstrate a sample size computation for the z test of a binomial proportion. Defaults for the SIDES=, ALPHA=, and VAREST= options specify a two-sided test with a 0.05 significance level that uses the null variance estimate.

```
proc power;
   onesamplefreq test=z method=normal
      nullproportion = 0.8
      proportion = 0.85
      sides = u
      ntotal = .
      power = .9;
run;
```

z Test with Continuity Adjustment

The following statements demonstrate a sample size computation for the z test of a binomial proportion with a continuity adjustment. Defaults for the SIDES=, ALPHA=, and VAREST= options specify a two-sided test with a 0.05 significance level that uses the null variance estimate.

```
proc power;
   onesamplefreq test=adjz method=normal
      nullproportion = 0.15
      proportion = 0.1
      sides = 1
      ntotal = .
      power = .9;
run;
```

Exact Equivalence Test for a Binomial Proportion

You can specify equivalence bounds by using the EQUIVBOUNDS= option, as in the following statements:

```
proc power;
   onesamplefreq test=equiv_exact
      proportion = 0.35
      equivbounds = (0.2 0.4)
      ntotal = 50
      power = .;
run;
```

You can also specify the combination of NULLPROPORTION= and MARGIN= options:

```
proc power;
   onesamplefreq test=equiv_exact
      proportion = 0.35
      nullproportion = 0.3
      margin = 0.1
      ntotal = 50
      power = .;
run;
```

Finally, you can specify the combination of LOWER= and UPPER= options:

```
proc power;
   onesamplefreq test=equiv_exact
      proportion = 0.35
      lower = 0.2
      upper = 0.4
      ntotal = 50
      power = .;
run;
```

Note that the three preceding analyses are identical.

Exact Noninferiority Test for a Binomial Proportion

A noninferiority test corresponds to an upper one-sided test with a negative-valued margin, as demonstrated in the following statements:

```
proc power;
   onesamplefreq test=exact
      sides = U
      proportion = 0.15
      nullproportion = 0.1
      margin = -0.02
      ntotal = 130
      power = .;
run;
```

Exact Superiority Test for a Binomial Proportion

A superiority test corresponds to an upper one-sided test with a positive-valued margin, as demonstrated in the following statements:

```
proc power;
   onesamplefreq test=exact
      sides = U
      proportion = 0.15
      nullproportion = 0.1
      margin = 0.02
      ntotal = 130
      power = .;
run;
```

Confidence Interval Precision

The following statements performs a confidence interval precision analysis for the Wilson score-based confidence interval for a binomial proportion. The default value of the ALPHA= option specifies a confidence level of 0.95.

```
proc power;
   onesamplefreq ci=wilson
      halfwidth = 0.1
      proportion = 0.3
      ntotal = 70
      probwidth = .;
run;
```

Restrictions on Option Combinations

To specify the equivalence bounds for TEST=EQUIV_ADJZ, TEST=EQUIV_EXACT, and TEST=EQUIV_Z, use any of these three option sets:

- lower and upper equivalence bounds, using the EQUIVBOUNDS= option
- lower and upper equivalence bounds, using the LOWER= and UPPER= options
- null proportion (NULLPROPORTION=) and margin (MARGIN=)

ONESAMPLEMEANS Statement

ONESAMPLEMEANS < *options* > **;**

The ONESAMPLEMEANS statement performs power and sample size analyses for *t* tests, equivalence tests, and confidence interval precision involving one sample.

Summary of Options

Table 70.10 summarizes categories of options available in the ONESAMPLEMEANS statement.

Table 70.10 Summary of Options in the ONESAMPLEMEANS Statement

TEST=EQUIV	Power	POWER=.
	Sample size	NTOTAL=.
CI=T	Prob(width)	PROBWIDTH=.
	Sample size	NTOTAL=.

Dictionary of Options

ALPHA=*number-list*

specifies the level of significance of the statistical test or requests a solution for alpha with a missing value (ALPHA=.). The default is 0.05, corresponding to the usual $0.05 \times 100\% = 5\%$ level of significance. If the CI= and SIDES=1 options are used, then the value must be less than 0.5. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

CI

CI=T

specifies an analysis of precision of the confidence interval for the mean. Instead of power, the relevant probability for this analysis is the probability of achieving a desired precision. Specifically, it is the probability that the half-width of the confidence interval will be at most the value specified by the HALFWIDTH= option. If neither the CI= option nor the TEST= option is used, the default is TEST=T.

CV=*number-list*

specifies the coefficient of variation, defined as the ratio of the standard deviation to the mean. You can use this option only with DIST=LOGNORMAL. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

DIST=LOGNORMAL

DIST=NORMAL

specifies the underlying distribution assumed for the test statistic. NORMAL corresponds the normal distribution, and LOGNORMAL corresponds to the lognormal distribution. The default value is NORMAL.

HALFWIDTH=*number-list*

specifies the desired confidence interval half-width. The half-width is defined as the distance between the point estimate and a finite endpoint. This option can be used only with the CI=T analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

LOWER=*number-list*

specifies the lower equivalence bound for the mean. This option can be used only with the TEST=EQUIV analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

MEAN=*number-list*

specifies the mean, in the original scale, or requests a solution for the mean with a missing value (MEAN=.). The mean is arithmetic if DIST=NORMAL and geometric if DIST=LOGNORMAL. This option can be used only with the TEST=T and TEST=EQUIV analyses. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NFRACTIONAL

NFRAC

enables fractional input and output for sample sizes. See the section "Sample Size Adjustment Options" on page 5837 for information about the ramifications of the presence (and absence) of the NFRACTIONAL option.

NTOTAL=*number-list*

specifies the sample size or requests a solution for the sample size with a missing value (NTOTAL=.). See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NULLMEAN=*number-list*

NULLM=*number-list*

specifies the null mean, in the original scale (whether DIST=NORMAL or DIST=LOGNORMAL). The default value is 0 when DIST=NORMAL and 1 when DIST=LOGNORMAL. This option can be used only with the TEST=T analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

OUTPUTORDER=INTERNAL

OUTPUTORDER=REVERSE

OUTPUTORDER=SYNTAX

controls how the input and default analysis parameters are ordered in the output. OUTPUTORDER=INTERNAL (the default) arranges the parameters in the output according to the following order of their corresponding options:

- SIDES=
- NULLMEAN=
- LOWER=
- UPPER=
- ALPHA=
- MEAN=
- HALFWIDTH=
- STDDEV=
- CV=
- NTOTAL=
- POWER=
- PROBTYPE=
- PROBWIDTH=

The OUTPUTORDER=SYNTAX option arranges the parameters in the output in the same order in which their corresponding options are specified in the ONESAMPLEMEANS statement. The OUTPUTORDER=REVERSE option arranges the parameters in the output in the reverse of the order in which their corresponding options are specified in the ONESAMPLEMEANS statement.

POWER=*number-list*

specifies the desired power of the test or requests a solution for the power with a missing value (POWER=.). The power is expressed as a probability, a number between 0 and 1, rather than as a percentage. This option can be used only with the TEST=T and TEST=EQUIV analyses. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

PROBTYPE=*keyword-list*

specifies the type of probability for the PROBWIDTH= option. A value of CONDITIONAL (the default) indicates the conditional probability that the confidence interval half-width is at most the value specified by the HALFWIDTH= option, given that the true mean is captured by the confidence interval. A value of UNCONDITIONAL indicates the unconditional probability that the confidence interval half-width is at most the value specified by the HALFWIDTH= option. You can use the alias GIVENVALIDITY for CONDITIONAL. The PROBTYPE= option can be used only with the CI=T analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *keyword-list*.

CONDITIONAL width probability conditional on interval containing the mean

UNCONDITIONAL unconditional width probability

PROBWIDTH=*number-list*

specifies the desired probability of obtaining a confidence interval half-width less than or equal to the value specified by the HALFWIDTH= option. A missing value (PROBWIDTH=.) requests a solution for this probability. The type of probability is controlled with the PROBTYPE= option. Values are expressed as probabilities (for example, 0.9) rather than percentages. This option can be used only with the CI=T analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

SIDES=*keyword-list*

specifies the number of sides (or tails) and the direction of the statistical test or confidence interval. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *keyword-list*. Valid keywords and their interpretation for the TEST= analyses are as follows:

1 one-sided with alternative hypothesis in same direction as effect

2 two-sided

U upper one-sided with alternative greater than null value

L lower one-sided with alternative less than null value

For confidence intervals, SIDES=U refers to an interval between the lower confidence limit and infinity, and SIDES=L refers to an interval between minus infinity and the upper confidence limit. For both of these cases and SIDES=1, the confidence interval computations are equivalent. The SIDES= option can be used only with the TEST=T and CI=T analyses. The default value is 2.

STDDEV=*number-list*

STD=*number-list*

specifies the standard deviation, or requests a solution for the standard deviation with a missing value (STDDEV=.). You can use this option only with DIST=NORMAL. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

TEST

TEST=EQUIV

TEST=T

specifies the statistical analysis. TEST=EQUIV specifies an equivalence test of the mean by using a

two one-sided tests (TOST) analysis (Schuirmann 1987). TEST or TEST=T (the default) specifies a *t* test on the mean. If neither the TEST= option nor the CI= option is used, the default is TEST=T.

UPPER=*number-list*
specifies the upper equivalence bound for the mean, in the original scale (whether DIST=NORMAL or DIST=LOGNORMAL). This option can be used only with the TEST=EQUIV analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

Restrictions on Option Combinations

To define the analysis, choose one of the following parameterizations:

- a statistical test (by using the TEST= option)
- confidence interval precision (by using the CI= option)

Option Groups for Common Analyses

This section summarizes the syntax for the common analyses supported in the ONESAMPLEMEANS statement.

One-Sample t *Test*

The following statements demonstrate a power computation for the one-sample *t* test. Default values for the DIST=, SIDES=, NULLMEAN=, and ALPHA= options specify a two-sided test for zero mean with a normal distribution and a significance level of 0.05.

```
proc power;
   onesamplemeans test=t
      mean = 7
      stddev = 3
      ntotal = 50
      power = .;
run;
```

One-Sample t *Test with Lognormal Data*

The following statements demonstrate a sample size computation for the one-sample *t* test for lognormal data. Default values for the SIDES=, NULLMEAN=, and ALPHA= options specify a two-sided test for unit mean with a significance level of 0.05.

```
proc power;
   onesamplemeans test=t dist=lognormal
      mean = 7
      cv = 0.8
      ntotal = .
      power = 0.9;
run;
```

Equivalence Test for Mean of Normal Data

The following statements demonstrate a power computation for the TOST equivalence test for a normal mean. Default values for the DIST= and ALPHA= options specify a normal distribution and a significance level of 0.05.

```
proc power;
   onesamplemeans test=equiv
      lower = 2
      upper = 7
      mean = 4
      stddev = 3
      ntotal = 100
      power = .;
run;
```

Equivalence Test for Mean of Lognormal Data

The following statements demonstrate a sample size computation for the TOST equivalence test for a lognormal mean. The default of ALPHA=0.05 specifies a significance level of 0.05.

```
proc power;
   onesamplemeans test=equiv dist=lognormal
      lower = 1
      upper = 5
      mean = 3
      cv = 0.6
      ntotal = .
      power = 0.85;
run;
```

Confidence Interval for Mean

By default CI=T analyzes the conditional probability of obtaining the desired precision, given that the interval contains the true mean, as in the following statements. The defaults of SIDES=2 and ALPHA=0.05 specify a two-sided interval with a confidence level of 0.95.

```
proc power;
   onesamplemeans ci = t
      halfwidth = 14
      stddev = 8
      ntotal = 50
      probwidth = .;
run;
```

ONEWAYANOVA Statement

ONEWAYANOVA < *options* > **;**

The ONEWAYANOVA statement performs power and sample size analyses for one-degree-of-freedom contrasts and the overall F test in one-way analysis of variance.

Summary of Options

Table 70.12 summarizes categories of options available in the ONEWAYANOVA statement.

Table 70.12 Summary of Options in the ONEWAYANOVA Statement

Task	Options
Define analysis	TEST=
Specify analysis information	ALPHA= CONTRAST= SIDES= NULLCONTRAST=
Specify effects	GROUPMEANS=
Specify variability	STDDEV=
Specify sample size and allocation	GROUPNS= GROUPWEIGHTS= NPERGROUP== NTOTAL=
Specify power	POWER=
Control sample size rounding	NFRACTIONAL
Control ordering in output	OUTPUTORDER=

Table 70.13 summarizes the valid result parameters for different analyses in the ONEWAYANOVA statement.

Table 70.13 Summary of Result Parameters in the ONEWAYANOVA Statement

Analyses	Solve For	Syntax
TEST=CONTRAST	Power Sample size	POWER=. NTOTAL=. NPERGROUP==.
TEST=OVERALL	Power Sample size	POWER=. NTOTAL=. NPERGROUP==.

Dictionary of Options

ALPHA=*number-list*

specifies the level of significance of the statistical test. The default is 0.05, corresponding to the usual $0.05 \times 100\% = 5\%$ level of significance. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

CONTRAST= (*values*) < (... *values*) >

specifies coefficients for single-degree-of-freedom hypothesis tests. You must provide a coefficient for every mean appearing in the GROUPMEANS= option. Specify multiple contrasts either with additional sets of coefficients or with additional CONTRAST= options. For example, you can specify two different contrasts of five means by using the following:

```
CONTRAST = (1 -1 0 0 0) (1 0 -1 0 0)
```

GROUPMEANS=*grouped-number-list*

GMEANS=*grouped-number-list*

specifies the group means. This option is used to implicitly set the number of groups. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

GROUPNS=*grouped-number-list*

GNS=*grouped-number-list*

specifies the group sample sizes. The number of groups represented must be the same as with the GROUPMEANS= option. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

GROUPWEIGHTS=*grouped-number-list*

GWEIGHTS=*grouped-number-list*

specifies the sample size allocation weights for the groups. This option controls how the total sample size is divided between the groups. Each set of values across all groups represents relative allocation weights. Additionally, if the NFRACTIONAL option is not used, the total sample size is restricted to be equal to a multiple of the sum of the group weights (so that the resulting design has an integer sample size for each group while adhering exactly to the group allocation weights). The number of groups represented must be the same as with the GROUPMEANS= option. Values must be integers unless the NFRACTIONAL option is used. The default value is 1 for each group, amounting to a balanced design. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

NFRACTIONAL

NFRAC

enables fractional input and output for sample sizes. See the section "Sample Size Adjustment Options" on page 5837 for information about the ramifications of the presence (and absence) of the NFRACTIONAL option.

NPERGROUP=*number-list*

NPERG=*number-list*

specifies the common sample size per group or requests a solution for the common sample size per group with a missing value (NPERGROUP==.). Use of this option implicitly specifies a balanced design. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NTOTAL=*number-list*

specifies the sample size or requests a solution for the sample size with a missing value (NTOTAL=.). See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NULLCONTRAST=*number-list*

NULLC=*number-list*

specifies the null value of the contrast. The default value is 0. This option can be used only with the TEST=CONTRAST analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

OUTPUTORDER=INTERNAL

OUTPUTORDER=REVERSE

OUTPUTORDER=SYNTAX

controls how the input and default analysis parameters are ordered in the output. OUTPUTORDER=INTERNAL (the default) arranges the parameters in the output according to the following order of their corresponding options:

- CONTRAST=
- SIDES=
- NULLCONTRAST=
- ALPHA=
- GROUPMEANS=
- STDDEV=
- GROUPWEIGHTS=
- NTOTAL=
- NPERGROUP==
- GROUPNS=
- POWER=

The OUTPUTORDER=SYNTAX option arranges the parameters in the output in the same order in which their corresponding options are specified in the ONEWAYANOVA statement. The OUTPUTORDER=REVERSE option arranges the parameters in the output in the reverse of the order in which their corresponding options are specified in the ONEWAYANOVA statement.

POWER=*number-list*

specifies the desired power of the test or requests a solution for the power with a missing value (POWER=.). The power is expressed as a probability, a number between 0 and 1, rather than as

a percentage. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

SIDES=*keyword-list*
specifies the number of sides (or tails) and the direction of the statistical test. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *keyword-list*. Valid keywords are as follows:

1	one-sided with alternative hypothesis in same direction as effect
2	two-sided
U	upper one-sided with alternative greater than null value
L	lower one-sided with alternative less than null value

This option can be used only with the TEST=CONTRAST analysis. The default value is 2.

STDDEV=*number-list*
STD=*number-list*
specifies the error standard deviation. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

TEST=CONTRAST
TEST=OVERALL
specifies the statistical analysis. TEST=CONTRAST specifies a one-degree-of-freedom test of a contrast of means. The test is the usual F test for the two-sided case and the usual t test for the one-sided case. TEST=OVERALL specifies the overall F test of equality of all means. The default is TEST=CONTRAST if the CONTRAST= option is used, and TEST=OVERALL otherwise.

Restrictions on Option Combinations

To specify the sample size and allocation, choose one of the following parameterizations:

- sample size per group in a balanced design (by using the NPERGROUP== option)
- total sample size and allocation weights (by using the NTOTAL= and GROUPWEIGHTS= options)
- individual group sample sizes (by using the GROUPNS= option)

Option Groups for Common Analyses

This section summarizes the syntax for the common analyses supported in the ONEWAYANOVA statement.

One-Degree-of-Freedom Contrast

You can use the NPERGROUP== option in a balanced design, as in the following statements. Default values for the SIDES=, NULLCONTRAST=, and ALPHA= options specify a two-sided test for a contrast value of 0 with a significance level of 0.05.

```
proc power;
   onewayanova test=contrast
      contrast = (1 0 -1)
      groupmeans = 3 | 7 | 8
      stddev = 4
      npergroup = 50
      power = .;
run;
```

You can also specify an unbalanced design with the NTOTAL= and GROUPWEIGHTS= options:

```
proc power;
   onewayanova test=contrast
      contrast = (1 0 -1)
      groupmeans = 3 | 7 | 8
      stddev = 4
      groupweights = (1 2 2)
      ntotal = .
      power = 0.9;
run;
```

Another way to specify the sample sizes is with the GROUPNS= option:

```
proc power;
   onewayanova test=contrast
      contrast = (1 0 -1)
      groupmeans = 3 | 7 | 8
      stddev = 4
      groupns = (20 40 40)
      power = .;
run;
```

Overall F Test

The following statements demonstrate a power computation for the overall F test in a one-way ANOVA. The default of ALPHA=0.05 specifies a significance level of 0.05.

```
proc power;
   onewayanova test=overall
      groupmeans = 3 | 7 | 8
      stddev = 4
      npergroup = 50
      power = .;
run;
```

PAIREDFREQ Statement

PAIREDFREQ < *options* > **;**

The PAIREDFREQ statement performs power and sample size analyses for McNemar's test for paired proportions.

Summary of Options

Table 70.14 summarizes categories of options available in the PAIREDFREQ statement.

Table 70.14 Summary of Options in the PAIREDFREQ Statement

Task	Options
Define analysis	DIST= TEST=
Specify analysis information	ALPHA= NULLDISCPROPRATIO= SIDES=

Dictionary of Options

ALPHA=*number-list*

specifies the level of significance of the statistical test. The default is 0.05, corresponding to the usual $0.05 \times 100\% = 5\%$ level of significance. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

CORR=*number-list*

specifies the correlation ϕ between members of a pair. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

DISCPROPORTIONS=*grouped-number-list*

DISCPS=*grouped-number-list*

specifies the two discordant proportions, p_{10} and p_{01}. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

DISCPROPDIFF=*number-list*

DISCPDIFF=*number-list*

specifies the difference $p_{01} - p_{10}$ between discordant proportions. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

DISCPROPRATIO=*number-list*

DISCPRATIO=*number-list*

specifies the ratio p_{01}/p_{10} of discordant proportions. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

DIST=EXACT_COND

DIST=NORMAL

specifies the underlying distribution assumed for the test statistic. EXACT_COND corresponds to the exact conditional test, based on the exact binomial distribution of the two types of discordant pairs given the total number of discordant pairs. NORMAL corresponds to the conditional test based on the normal approximation to the binomial distribution of the two types of discordant pairs given the total number of discordant pairs. The default value is EXACT_COND.

METHOD=CONNOR

METHOD=EXACT

METHOD=MIETTINEN

specifies the computational method. METHOD=EXACT (the default) uses the exact binomial distributions of the total number of discordant pairs and the two types of discordant pairs. METHOD=CONNOR uses an approximation from Connor (1987), and METHOD=MIETTINEN uses an approximation from Miettinen (1968). The CONNOR and MIETTINEN methods are valid only for DIST=NORMAL.

NFRACTIONAL

NFRAC

enables fractional input and output for sample sizes. See the section "Sample Size Adjustment Options" on page 5837 for information about the ramifications of the presence (and absence) of the NFRACTIONAL option. This option cannot be used with METHOD=EXACT.

NPAIRS=*number-list*

specifies the total number of proportion pairs (concordant and discordant) or requests a solution for the number of pairs with a missing value (NPAIRS=.). See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NULLDISCPROPRATIO=*number-list*

NULLDISCPRATIO=*number-list*

NULLRATIO=*number-list*

NULLR=*number-list*

specifies the null value of the ratio of discordant proportions. The default value is 1. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

ODDSRATIO=*number-list*

OR=*number-list*

specifies the odds ratio $[p_{.1}/(1-p_{.1})]\,/\,[p_{1.}/(1-p_{1.})]$. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

OUTPUTORDER=INTERNAL

OUTPUTORDER=REVERSE

OUTPUTORDER=SYNTAX

controls how the input and default analysis parameters are ordered in the output. OUTPUTORDER=INTERNAL (the default) arranges the parameters in the output according to the following order of their corresponding options:

- SIDES=
- NULLDISCPROPRATIO=
- ALPHA=
- PAIREDPROPORTIONS=
- PROPORTIONDIFF=
- ODDSRATIO=
- RELATIVERISK=
- CORR=
- DISCPROPORTIONS=
- DISCPROPDIFF=
- TOTALPROPDISC=
- REFPROPORTION=
- DISCPROPRATIO=
- NPAIRS=
- POWER=

The OUTPUTORDER=SYNTAX option arranges the parameters in the output in the same order in which their corresponding options are specified in the PAIREDFREQ statement. The OUTPUTORDER=REVERSE option arranges the parameters in the output in the reverse of the order in which their corresponding options are specified in the PAIREDFREQ statement.

PAIREDPROPORTIONS=*grouped-number-list*

PPROPORTIONS=*grouped-number-list*

PAIREDPS=*grouped-number-list*

PPS=*grouped-number-list*

specifies the two paired proportions, $p_{1\cdot}$ and $p_{\cdot 1}$. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

POWER=*number-list*

specifies the desired power of the test or requests a solution for the power with a missing value (POWER=.). The power is expressed as a probability, a number between 0 and 1, rather than as a percentage. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

PROPORTIONDIFF=*number-list*

PDIFF=*number-list*

specifies the proportion difference $p_{\cdot 1} - p_{1\cdot}$. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

REFPROPORTION=*number-list*

REFP=*number-list*

specifies either the reference first proportion $p_{1\cdot}$ (when used in conjunction with the PROPORTIONDIFF=, ODDSRATIO=, or RELATIVERISK= option) or the reference discordant proportion p_{10} (when used in conjunction with the DISCPROPDIFF= or DISCPROPRATIO= option). See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

RELATIVERISK=*number-list*

RR=*number-list*

specifies the relative risk $p_{\cdot 1}/p_{1\cdot}$. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

SIDES=*keyword-list*

specifies the number of sides (or tails) and the direction of the statistical test or confidence interval. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *keyword-list*. Valid keywords and their interpretation are as follows:

1	one-sided with alternative hypothesis in same direction as effect
2	two-sided
U	upper one-sided with alternative greater than null value
L	lower one-sided with alternative less than null value

If the effect size is zero, then SIDES=1 is not permitted; instead, specify the direction of the test explicitly in this case with either SIDES=L or SIDES=U. The default value is 2.

TEST=MCNEMAR
specifies the McNemar test of paired proportions. This is the default test option.

TOTALPROPDISC=*number-list*
TOTALPDISC=*number-list*
PDISC=*number-list*
specifies the sum of the two discordant proportions, $p_{10} + p_{01}$. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

Restrictions on Option Combinations

To specify the proportions, choose one of the following parameterizations:

- discordant proportions (using the DISCPROPORTIONS= option)
- difference and sum of discordant proportions (using the DISCPROPDIFF= and TOTALPROPDISC=options)
- difference of discordant proportions and reference discordant proportion (using the DISCPROPDIFF= and REFPROPORTION= options)
- ratio of discordant proportions and reference discordant proportion (using the DISCPROPRATIO= and REFPROPORTION= options)
- ratio and sum of discordant proportions (using the DISCPROPRATIO= and TOTALPROPDISC=options)
- paired proportions and correlation (using the PAIREDPROPORTIONS= and CORR= options)
- proportion difference, reference proportion, and correlation (using the PROPORTIONDIFF=, REFPROPORTION=, and CORR= options)
- odds ratio, reference proportion, and correlation (using the ODDSRATIO=, REFPROPORTION=, and CORR= options)
- relative risk, reference proportion, and correlation (using the RELATIVERISK=, REFPROPORTION=, and CORR= options)

Option Groups for Common Analyses

This section summarizes the syntax for the common analyses supported in the PAIREDFREQ statement.

McNemar Exact Conditional Test

You can express effects in terms of the individual discordant proportions, as in the following statements. Default values for the TEST=, SIDES=, ALPHA=, and NULLDISCPROPRATIO= options specify a two-sided McNemar test for no effect with a significance level of 0.05.

```
proc power;
   pairedfreq dist=exact_cond
      discproportions = 0.15 | 0.45
      npairs = 80
      power = .;
run;
```

You can also express effects in terms of the difference and sum of discordant proportions:

```
proc power;
   pairedfreq dist=exact_cond
      discpropdiff = 0.3
      totalpropdisc = 0.6
      npairs = 80
      power = .;
run;
```

You can also express effects in terms of the difference of discordant proportions and the reference discordant proportion:

```
proc power;
   pairedfreq dist=exact_cond
      discpropdiff = 0.3
      refproportion = 0.15
      npairs = 80
      power = .;
run;
```

You can also express effects in terms of the ratio of discordant proportions and the denominator of the ratio:

```
proc power;
   pairedfreq dist=exact_cond
      discpropratio = 3
      refproportion = 0.15
      npairs = 80
      power = .;
run;
```

You can also express effects in terms of the ratio and sum of discordant proportions:

```
proc power;
   pairedfreq dist=exact_cond
      discpropratio = 3
      totalpropdisc = 0.6
      npairs = 80
      power = .;
run;
```

You can also express effects in terms of the paired proportions and correlation:

```
proc power;
   pairedfreq dist=exact_cond
      pairedproportions = 0.6 | 0.8
      corr = 0.4
```

```
      npairs = 45
      power = .;
run;
```

You can also express effects in terms of the proportion difference, reference proportion, and correlation:

```
proc power;
   pairedfreq dist=exact_cond
      proportiondiff = 0.2
      refproportion = 0.6
      corr = 0.4
      npairs = 45
      power = .;
run;
```

You can also express effects in terms of the odds ratio, reference proportion, and correlation:

```
proc power;
   pairedfreq dist=exact_cond
      oddsratio = 2.66667
      refproportion = 0.6
      corr = 0.4
      npairs = 45
      power = .;
run;
```

You can also express effects in terms of the relative risk, reference proportion, and correlation:

```
proc power;
   pairedfreq dist=exact_cond
      relativerisk = 1.33333
      refproportion = 0.6
      corr = 0.4
      npairs = 45
      power = .;
run;
```

McNemar Normal Approximation Test

The following statements demonstrate a sample size computation for the normal-approximate McNemar test. The default value for the METHOD= option specifies an exact sample size computation. Default values for the TEST=, SIDES=, ALPHA=, and NULLDISCPROPRATIO= options specify a two-sided McNemar test for no effect with a significance level of 0.05.

```
proc power;
   pairedfreq dist=normal method=connor
      discproportions = 0.15 | 0.45
      npairs = .
      power = .9;
run;
```

PAIREDMEANS Statement

PAIREDMEANS < *options* > **;**

The PAIREDMEANS statement performs power and sample size analyses for *t* tests, equivalence tests, and confidence interval precision involving paired samples.

Summary of Options

Table 70.16 summarizes categories of options available in the PAIREDMEANS statement.

Table 70.16 Summary of Options in the PAIREDMEANS Statement

Task	Options
Define analysis	CI= DIST= TEST=

	Sample size	NPAIRS=.
CI=DIFF	Prob(width)	PROBWIDTH=.
	Sample size	NPAIRS=.

Dictionary of Options

ALPHA=*number-list*

specifies the level of significance of the statistical test. The default is 0.05, corresponding to the usual $0.05 \times 100\% = 5\%$ level of significance. If the CI= and SIDES=1 options are used, then the value must be less than 0.5. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

CI

CI=DIFF

specifies an analysis of precision of the confidence interval for the mean difference. Instead of power, the relevant probability for this analysis is the probability of achieving a desired precision. Specifically, it is the probability that the half-width of the observed confidence interval will be at most the value specified by the HALFWIDTH= option. If neither the CI= option nor the TEST= option is used, the default is TEST=DIFF.

CORR=*number-list*

specifies the correlation between members of a pair. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

CV=*number-list*

specifies the coefficient of variation assumed to be common to both members of a pair. The coefficient of variation is defined as the ratio of the standard deviation to the mean. You can use this option only with DIST=LOGNORMAL. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

DIST=LOGNORMAL

DIST=NORMAL

specifies the underlying distribution assumed for the test statistic. NORMAL corresponds the normal distribution, and LOGNORMAL corresponds to the lognormal distribution. The default value (also

the only acceptable value in each case) is NORMAL for TEST=DIFF, TEST=EQUIV_DIFF, and CI=DIFF; and LOGNORMAL for TEST=RATIO and TEST=EQUIV_RATIO.

HALFWIDTH=*number-list*
specifies the desired confidence interval half-width. The half-width is defined as the distance between the point estimate and a finite endpoint. This option can be used only with the CI=DIFF analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

LOWER=*number-list*
specifies the lower equivalence bound for the mean difference or mean ratio, in the original scale (whether DIST=NORMAL or DIST=LOGNORMAL). This option can be used only with the TEST=EQUIV_DIFF and TEST=EQUIV_RATIO analyses. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

MEANDIFF=*number-list*
specifies the mean difference, defined as the mean of the difference between the second and first members of a pair, $\mu_2 - \mu_1$. This option can be used only with the TEST=DIFF and TEST=EQUIV_DIFF analyses. When TEST=EQUIV_DIFF, the mean difference is interpreted as the treatment mean minus the reference mean. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

MEANRATIO=*number-list*
specifies the geometric mean ratio, defined as γ_2/γ_1. This option can be used only with the TEST=RATIO and TEST=EQUIV_RATIO analyses. When TEST=EQUIV_RATIO, the mean ratio is interpreted as the treatment mean divided by the reference mean. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NFRACTIONAL
NFRAC
enables fractional input and output for sample sizes. See the section "Sample Size Adjustment Options" on page 5837 for information about the ramifications of the presence (and absence) of the NFRACTIONAL option.

NPAIRS=*number-list*
specifies the number of pairs or requests a solution for the number of pairs with a missing value (NPAIRS=.). See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NULLDIFF=*number-list*
NULLD=*number-list*
specifies the null mean difference. The default value is 0. This option can be used only with the TEST=DIFF analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NULLRATIO=*number-list*
NULLR=*number-list*
specifies the null mean ratio. The default value is 1. This option can be used only with the TEST=RATIO analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

OUTPUTORDER=INTERNAL

OUTPUTORDER=REVERSE

OUTPUTORDER=SYNTAX

controls how the input and default analysis parameters are ordered in the output. OUTPUTORDER=INTERNAL (the default) arranges the parameters in the output according to the following order of their corresponding options:

- SIDES=
- NULLDIFF=
- NULLRATIO=
- LOWER=
- UPPER=
- ALPHA=
- PAIREDMEANS=
- MEANDIFF=
- MEANRATIO=
- HALFWIDTH=
- STDDEV=
- PAIREDSTDDEVS=
- CV=
- PAIREDCVS=
- CORR=
- NPAIRS=
- POWER=
- PROBTYPE=
- PROBWIDTH=

The OUTPUTORDER=SYNTAX option arranges the parameters in the output in the same order in which their corresponding options are specified in the PAIREDMEANS statement. The OUTPUTORDER=REVERSE option arranges the parameters in the output in the reverse of the order in which their corresponding options are specified in the PAIREDMEANS statement.

PAIREDCVS=*grouped-number-list*

specifies the coefficient of variation for each member of a pair. Unlike the CV= option, the PAIREDCVS= option supports different values for each member of a pair. Values must be nonnegative (unless both are equal to zero, which is permitted). This option can be used only with DIST=LOGNORMAL. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

PAIREDMEANS=*grouped-number-list*

PMEANS=*grouped-number-list*

specifies the two paired means, in the original scale. The means are arithmetic if DIST=NORMAL and geometric if DIST=LOGNORMAL. This option cannot be used with the CI=DIFF analysis. When TEST=EQUIV_DIFF, the means are interpreted as the reference mean (first) and the treatment mean (second). See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

PAIREDSTDDEVS=*grouped-number-list*

PAIREDSTDS=*grouped-number-list*

PSTDDEVS=*grouped-number-list*

PSTDS=*grouped-number-list*

specifies the standard deviation of each member of a pair. Unlike the STDDEV= option, the PAIREDSTDDEVS= option supports different values for each member of a pair. This option can be used only with DIST=NORMAL. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

POWER=*number-list*

specifies the desired power of the test or requests a solution for the power with a missing value (POWER=.). The power is expressed as a probability, a number between 0 and 1, rather than as a percentage. This option cannot be used with the CI=DIFF analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

PROBTYPE=*keyword-list*

specifies the type of probability for the PROBWIDTH= option. A value of CONDITIONAL (the default) indicates the conditional probability that the confidence interval half-width is at most the value specified by the HALFWIDTH= option, given that the true mean difference is captured by the confidence interval. A value of UNCONDITIONAL indicates the unconditional probability that the confidence interval half-width is at most the value specified by the HALFWIDTH= option. you can use the alias GIVENVALIDITY for CONDITIONAL. The PROBTYPE= option can be used only with the CI=DIFF analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *keyword-list*.

CONDITIONAL width probability conditional on interval containing the mean

UNCONDITIONAL unconditional width probability

PROBWIDTH=*number-list*

specifies the desired probability of obtaining a confidence interval half-width less than or equal to the value specified by the HALFWIDTH= option. A missing value (PROBWIDTH=.) requests a solution for this probability. The type of probability is controlled with the PROBTYPE= option. Values are expressed as probabilities (for example, 0.9) rather than percentages. This option can be used only with the CI=DIFF analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

SIDES=*keyword-list*

specifies the number of sides (or tails) and the direction of the statistical test or confidence interval. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about

specifying the *keyword-list*. Valid keywords and their interpretation for the TEST= analyses are as follows:

1 one-sided with alternative hypothesis in same direction as effect

2 two-sided

U upper one-sided with alternative greater than null value

L lower one-sided with alternative less than null value

For confidence intervals, SIDES=U refers to an interval between the lower confidence limit and infinity, and SIDES=L refers to an interval between minus infinity and the upper confidence limit. For both of these cases and SIDES=1, the confidence interval computations are equivalent. The SIDES= option cannot be used with the TEST=EQUIV_DIFF and TEST=EQUIV_RATIO analyses. The default value is 2.

STDDEV=*number-list*

STD=*number-list*

specifies the standard deviation assumed to be common to both members of a pair. This option can be used only with DIST=NORMAL. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

TEST

TEST=DIFF

TEST=EQUIV_DIFF

TEST=EQUIV_RATIO

TEST=RATIO

specifies the statistical analysis. TEST or TEST=DIFF (the default) specifies a paired t test on the mean difference. TEST=EQUIV_DIFF specifies an additive equivalence test of the mean difference by using a two one-sided tests (TOST) analysis (Schuirmann 1987). TEST=EQUIV_RATIO specifies a multiplicative equivalence test of the mean ratio by using a TOST analysis. TEST=RATIO specifies a paired t test on the geometric mean ratio. If neither the TEST= option nor the CI= option is used, the default is TEST=DIFF.

UPPER=*number-list*

specifies the upper equivalence bound for the mean difference or mean ratio, in the original scale (whether DIST=NORMAL or DIST=LOGNORMAL). This option can be used only with the TEST=EQUIV_DIFF and TEST=EQUIV_RATIO analyses. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

Restrictions on Option Combinations

To define the analysis, choose one of the following parameterizations:

- a statistical test (by using the TEST= option)
- confidence interval precision (by using the CI= option)

To specify the means, choose one of the following parameterizations:

- individual means (by using the PAIREDMEANS= option)
- mean difference (by using the MEANDIFF= option)
- mean ratio (by using the MEANRATIO= option)

To specify the coefficient of variation, choose one of the following parameterizations:

- common coefficient of variation (by using the CV= option)
- individual coefficients of variation (by using the PAIREDCVS= option)

To specify the standard deviation, choose one of the following parameterizations:

- common standard deviation (by using the STDDEV= option)
- individual standard deviations (by using the PAIREDSTDDEVS= option)

Option Groups for Common Analyses

This section summarizes the syntax for the common analyses supported in the PAIREDMEANS statement.

Paired t *Test*

You can express effects in terms of the mean difference and variability in terms of a correlation and common standard deviation, as in the following statements. Default values for the DIST=, SIDES=, NULLDIFF=, and ALPHA= options specify a two-sided test for no difference with a normal distribution and a significance level of 0.05.

```
proc power;
   pairedmeans test=diff
      meandiff = 7
      corr = 0.4
      stddev = 12
      npairs = 50
      power = .;
run;
```

You can also express effects in terms of individual means and variability in terms of correlation and individual standard deviations:

```
proc power;
   pairedmeans test=diff
      pairedmeans = 8 | 15
      corr = 0.4
      pairedstddevs = (7 12)
      npairs = .
      power = 0.9;
run;
```

Paired t Test of Mean Ratio with Lognormal Data

You can express variability in terms of correlation and a common coefficient of variation, as in the following statements. Defaults for the DIST=, SIDES=, NULLRATIO= and ALPHA= options specify a two-sided test of mean ratio = 1 assuming a lognormal distribution and a significance level of 0.05.

```
proc power;
   pairedmeans test=ratio
      meanratio = 7
      corr = 0.3
      cv = 1.2
      npairs = 30
      power = .;
run;
```

You can also express variability in terms of correlation and individual coefficients of variation:

```
proc power;
   pairedmeans test=ratio
      meanratio = 7
      corr = 0.3
      pairedcvs = 0.8 | 0.9
      npairs = 30
      power = .;
run;
```

Additive Equivalence Test for Mean Difference with Normal Data

The following statements demonstrate a sample size computation for a TOST equivalence test for a normal mean difference. Default values for the DIST= and ALPHA= options specify a normal distribution and a significance level of 0.05.

```
proc power;
   pairedmeans test=equiv_diff
      lower = 2
      upper = 5
      meandiff = 4
      corr = 0.2
      stddev = 8
      npairs = .
      power = 0.9;
run;
```

Multiplicative Equivalence Test for Mean Ratio with Lognormal Data

The following statements demonstrate a power computation for a TOST equivalence test for a lognormal mean ratio. Default values for the DIST= and ALPHA= options specify a lognormal distribution and a significance level of 0.05.

```
proc power;
   pairedmeans test=equiv_ratio
      lower = 3
      upper = 7
      meanratio = 5
      corr = 0.2
      cv = 1.1
      npairs = 50
      power = .;
run;
```

Confidence Interval for Mean Difference

By default CI=DIFF analyzes the conditional probability of obtaining the desired precision, given that the interval contains the true mean difference, as in the following statements. The defaults of SIDES=2 and ALPHA=0.05 specify a two-sided interval with a confidence level of 0.95.

```
proc power;
   pairedmeans ci = diff
      halfwidth = 4
      corr = 0.35
      stddev = 8
      npairs = 30
      probwidth = .;
run;
```

PLOT Statement

PLOT < *plot-options* > < / *graph-options* > **;**

The PLOT statement produces a graph or set of graphs for the sample size analysis defined by the previous analysis statement. The *plot-options* define the plot characteristics, and the *graph-options* are SAS/GRAPH-style options. If ODS Graphics is enabled, then the PLOT statement uses ODS Graphics to create graphs. For example:

```
ods listing style=htmlbluecml;
ods graphics on;

proc power;
   onesamplemeans
      mean   = 5 10
      ntotal = 150
      stddev =  30 50
      power  = .;
   plot x=n min=100 max=200;
run;

ods graphics off;
```

Otherwise, traditional graphics are produced. For example:

```
ods graphics off;

proc power;
   onesamplemeans
      mean   = 5 10
      ntotal = 150
      stddev =  30 50
      power  = .;
   plot x=n min=100 max=200;
run;
```

For more information about enabling and disabling ODS Graphics, see the section "Enabling and Disabling ODS Graphics" on page 612 in Chapter 21, "Statistical Graphics Using ODS."

The ODS LISTING STYLE=HTMLBLUECML statement specifies the HTMLBLUECML style, which is suitable for use with PROC POWER because it allows both marker symbols and line styles to vary. See the section "ODS Styles Suitable for Use with PROC POWER" on page 5897 for more information.

Options

You can specify the following *plot-options* in the PLOT statement.

INTERPOL=JOIN | NONE
specifies the type of curve to draw through the computed points. The INTERPOL=JOIN option connects computed points by straight lines. The INTERPOL=NONE option leaves computed points unconnected.

KEY=BYCURVE <(*bycurve-options*)>
KEY=BYFEATURE <(*byfeature-options*)>
KEY=ONCURVES
specifies the style of key (or "legend") for the plot. The default is KEY=BYFEATURE, which specifies a key with a column of entries for each plot feature (line style, color, and/or symbol). Each entry shows the mapping between a value of the feature and the value(s) of the analysis parameter(s) linked to that feature. The KEY=BYCURVE option specifies a key with each row identifying a distinct curve in the plot. The KEY=ONCURVES option places a curve-specific label adjacent to each curve.

You can specify the following *byfeature-options* in parentheses after the KEY=BYCURVE option.

NUMBERS=OFF | ON
specifies how the key should identify curves. If NUMBERS=OFF, then the key includes symbol, color, and line style samples to identify the curves. If NUMBERS=ON, then the key includes numbers matching numeric labels placed adjacent to the curves. The default is NUMBERS=ON.

POS=BOTTOM | INSET
specifies the position of the key. The POS=BOTTOM option places the key below the X axis. The POS=INSET option places the key inside the plotting region and attempts to choose the least crowded corner. The default is POS=BOTTOM.

You can specify the following *byfeature-options* in parentheses after KEY=BYFEATURE option.

POS=BOTTOM | INSET
specifies the position of the key. The POS=BOTTOM option places the key below the X axis. The POS=INSET option places the key inside the plotting region and attempts to choose the least crowded corner. The default is POS=BOTTOM.

MARKERS=ANALYSIS | COMPUTED | NICE | NONE
specifies the locations for plotting symbols.

The MARKERS=ANALYSIS option places plotting symbols at locations corresponding to the values of the relevant input parameter from the analysis statement preceding the PLOT statement.

The MARKERS=COMPUTED option (the default) places plotting symbols at the locations of actual computed points from the sample size analysis.

The MARKERS=NICE option places plotting symbols at tick mark locations (corresponding to the argument axis).

The MARKERS=NONE option disables plotting symbols.

MAX=*number* | **DATAMAX**
specifies the maximum of the range of values for the parameter associated with the "argument" axis (the axis that is *not* representing the parameter being solved for). The default is DATAMAX, which specifies the maximum value that occurs for this parameter in the analysis statement that precedes the PLOT statement.

MIN=*number* | **DATAMIN**
specifies the minimum of the range of values for the parameter associated with the "argument" axis (the axis that is *not* representing the parameter being solved for). The default is DATAMIN, which specifies the minimum value that occurs for this parameter in the analysis statement that precedes the PLOT statement.

NPOINTS=*number*

NPTS=*number*
specifies the number of values for the parameter associated with the "argument" axis (the axis that is *not* representing the parameter being solved for). You cannot use the NPOINTS= and STEP= options simultaneously. The default value for typical situations is 20.

STEP=*number*
specifies the increment between values of the parameter associated with the "argument" axis (the axis that is *not* representing the parameter being solved for). You cannot use the STEP= and NPOINTS= options simultaneously. By default, the NPOINTS= option is used instead of the STEP= option.

VARY (*feature* **<BY** *parameter-list***> <, . . . ,** *feature* **<BY** *parameter-list***> >)**
specifies how plot features should be linked to varying analysis parameters. Available plot *features* are COLOR, LINESTYLE, PANEL, and SYMBOL. A "panel" refers to a separate plot with a heading identifying the subset of values represented in the plot.

The *parameter-list* is a list of one or more names separated by spaces. Each name must match the name of an analysis option used in the analysis statement preceding the PLOT statement. Also, the

name must be the *primary* name for the analysis option—that is, the one listed first in the syntax description.

If you omit the < BY *parameter-list* > portion for a feature, then one or more multivalued parameters from the analysis will be automatically selected for you.

X=EFFECT N POWER

specifies a plot with the requested type of parameter on the X axis and the parameter being solved for on the Y axis. When X=EFFECT, the parameter assigned to the X axis is the one most representative of "effect size." When X=N, the parameter assigned to the X axis is the sample size. When X=POWER, the parameter assigned to the X axis is the one most representative of "power" (either power itself or a similar probability, such as Prob(Width) for confidence interval analyses). You cannot use the X= and Y= options simultaneously. The default is X=POWER, unless the result parameter is power or Prob(Width), in which case the default is X=N.

You can use the X=N option only when a scalar sample size parameter is used as input in the analysis. For example, X=N can be used with total sample size or sample size per group, or with two group sample sizes when one is being solved for.

Table 70.18 summarizes the parameters representing effect size in different analyses.

Table 70.18 Effect Size Parameters for Different Analyses

Analysis Statement and Options	Effect Size Parameters
LOGISTIC	None
MULTREG	Partial correlation or R^2 difference
ONECORR	Correlation
ONESAMPLEFREQ TEST	Proportion
ONESAMPLEFREQ CI	CI half-width
ONESAMPLEMEANS TEST=T, ONESAMPLEMEANS TEST=EQUIV	Mean
ONESAMPLEMEANS CI=T	CI half-width
ONEWAYANOVA	None
PAIREDFREQ	Discordant proportion difference or ratio
PAIREDMEANS TEST=DIFF, PAIREDMEANS TEST=EQUIV_DIFF	Mean difference
PAIREDMEANS TEST=RATIO, PAIREDMEANS TEST=EQUIV_RATIO	Mean ratio
PAIREDMEANS CI=DIFF	CI half-width
TWOSAMPLEFREQ	Proportion difference, odds ratio, or relative risk
TWOSAMPLEMEANS TEST=DIFF, TWOSAMPLEMEANS TEST=DIFF_SATT,	

Table 70.18 *continued*

Analysis Statement and Options	Effect Size Parameters
TWOSAMPLEMEANS TEST=EQUIV_DIFF	Mean difference
TWOSAMPLEMEANS TEST=RATIO, TWOSAMPLEMEANS TEST=EQUIV_RATIO	Mean ratio
TWOSAMPLEMEANS CI=DIFF	CI half-width
TWOSAMPLESURVIVAL	Hazard ratio if used, else none
TWOSAMPLEWILCOXON	None

XOPTS=(*x-options* **)**
specifies plot characteristics pertaining to the X axis.

You can specify the following *x-options* in parentheses.

CROSSREF=NO | YES
specifies whether the reference lines defined by the REF= *x-option* should be crossed with a reference line on the Y axis that indicates the solution point on the curve.

REF=*number-list*
specifies locations for reference lines extending from the X axis across the entire plotting region. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

Y=EFFECT N POWER
specifies a plot with the requested type of parameter on the Y axis and the parameter being solved for on the X axis. When Y=EFFECT, the parameter assigned to the Y axis is the one most representative of "effect size." When Y=N, the parameter assigned to the Y axis is the sample size. When Y=POWER, the parameter assigned to the Y axis is the one most representative of "power" (either power itself or a similar probability, such as Prob(Width) for confidence interval analyses). You cannot use the Y= and X= options simultaneously. By default, the X= option is used instead of the Y= option.

YOPTS=(*y-options* **)**
specifies plot characteristics pertaining to the Y axis.

You can specify the following *y-options* in parentheses.

CROSSREF=NO | YES
specifies whether the reference lines defined by the REF= *y-option* should be crossed with a reference line on the X axis that indicates the solution point on the curve.

REF=*number-list*
specifies locations for reference lines extending from the Y axis across the entire plotting region. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

You can specify the following *graph-options* in the PLOT statement after a slash (/).

DESCRIPTION='*string* **'**
specifies a descriptive string of up to 40 characters that appears in the "Description" field of the graphics catalog. The description does not appear on the plots. By default, PROC POWER assigns a description either of the form "*Y* versus *X*" (for a single-panel plot) or of the form "*Y* versus *X* (*S*)," where *Y* is the parameter on the Y axis, *X* is the parameter on the X axis, and *S* is a description of the subset represented on the current panel of a multipanel plot.

NAME='*string* **'**
specifies a name of up to eight characters for the catalog entry for the plot. The default name is PLOT*n*, where *n* is the number of the plot statement within the current invocation of PROC POWER. If the name duplicates the name of an existing entry, SAS/GRAPH software adds a number to the duplicate name to create a unique entry—for example, PLOT11 and PLOT12 for the second and third panels of a multipanel plot generated in the first PLOT statement in an invocation of PROC POWER.

TWOSAMPLEFREQ Statement

TWOSAMPLEFREQ < *options* > **;**

The TWOSAMPLEFREQ statement performs power and sample size analyses for tests of two independent proportions. Pearson's chi-square, Fisher's exact, and likelihood ratio chi-square tests are supported.

Summary of Options

Table 70.19 summarizes categories of options available in the TWOSAMPLEFREQ statement.

Dictionary of Options

ALPHA=*number-list*

specifies the level of significance of the statistical test. The default is 0.05, corresponding to the usual $0.05 \times 100\% = 5\%$ level of significance. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

GROUPPROPORTIONS=*grouped-number-list*

GPROPORTIONS=*grouped-number-list*

GROUPPS=*grouped-number-list*

GPS=*grouped-number-list*

specifies the two independent proportions, p_1 and p_2. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

GROUPNS=*grouped-number-list*

GNS=*grouped-number-list*

specifies the two group sample sizes. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

GROUPWEIGHTS=*grouped-number-list*

GWEIGHTS=*grouped-number-list*

specifies the sample size allocation weights for the two groups. This option controls how the total sample size is divided between the two groups. Each pair of values for the two groups represents

relative allocation weights. Additionally, if the NFRACTIONAL option is not used, the total sample size is restricted to be equal to a multiple of the sum of the two group weights (so that the resulting design has an integer sample size for each group while adhering exactly to the group allocation weights). Values must be integers unless the NFRACTIONAL option is used. The default value is (1 1), a balanced design with a weight of 1 for each group. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

NFRACTIONAL

NFRAC

enables fractional input and output for sample sizes. See the section "Sample Size Adjustment Options" on page 5837 for information about the ramifications of the presence (and absence) of the NFRACTIONAL option.

NPERGROUP=*number-list*

NPERG=*number-list*

specifies the common sample size per group or requests a solution for the common sample size per group with a missing value (NPERGROUP=.). Use of this option implicitly specifies a balanced design. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NTOTAL=*number-list*

specifies the sample size or requests a solution for the sample size with a missing value (NTOTAL=.). See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NULLODDSRATIO=*number-list*

NULLOR=*number-list*

specifies the null odds ratio. The default value is 1. This option can be used only with the ODDSRATIO= option in the TEST=PCHI analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NULLPROPORTIONDIFF=*number-list*

NULLPDIFF=*number-list*

specifies the null proportion difference. The default value is 0. This option can be used only with the GROUPPROPORTIONS= or PROPORTIONDIFF= option in the TEST=PCHI analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NULLRELATIVERISK=*number-list*

NULLRR=*number-list*

specifies the null relative risk. The default value is 1. This option can be used only with the RELATIVERISK= option in the TEST=PCHI analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

ODDSRATIO=*number-list*

OR=*number-list*

specifies the odds ratio $[p_2/(1-p_2)]\,/\,[p_1/(1-p_1)]$. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

OUTPUTORDER=INTERNAL

OUTPUTORDER=REVERSE

OUTPUTORDER=SYNTAX

controls how the input and default analysis parameters are ordered in the output. OUTPUTORDER=INTERNAL (the default) arranges the parameters in the output according to the following order of their corresponding options:

- SIDES=
- NULLPROPORTIONDIFF=
- NULLODDSRATIO=
- NULLRELATIVERISK=
- ALPHA=
- GROUPPROPORTIONS=
- REFPROPORTION=
- PROPORTIONDIFF=
- ODDSRATIO=
- RELATIVERISK=
- GROUPWEIGHTS=
- NTOTAL=
- NPERGROUP=
- GROUPNS=
- POWER=

The OUTPUTORDER=SYNTAX option arranges the parameters in the output in the same order in which their corresponding options are specified in the TWOSAMPLEFREQ statement. The OUTPUTORDER=REVERSE option arranges the parameters in the output in the reverse of the order in which their corresponding options are specified in the TWOSAMPLEFREQ statement.

POWER=*number-list*

specifies the desired power of the test or requests a solution for the power with a missing value (POWER=.). The power is expressed as a probability, a number between 0 and 1, rather than as a percentage. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

PROPORTIONDIFF=*number-list*

PDIFF=*number-list*

specifies the proportion difference $p_2 - p_1$. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

REFPROPORTION=*number-list*

REFP=*number-list*

specifies the reference proportion p_1. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

RELATIVERISK=*number-list*

RR=*number-list*

specifies the relative risk p_2/p_1. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

SIDES=*keyword-list*

specifies the number of sides (or tails) and the direction of the statistical test or confidence interval. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *keyword-list*. Valid keywords and their interpretation are as follows:

1	one-sided with alternative hypothesis in same direction as effect
2	two-sided
U	upper one-sided with alternative greater than null value
L	lower one-sided with alternative less than null value

If the effect size is zero, then SIDES=1 is not permitted; instead, specify the direction of the test explicitly in this case with either SIDES=L or SIDES=U. The default value is 2.

TEST=FISHER

TEST=LRCHI

TEST=PCHI

specifies the statistical analysis. TEST=FISHER specifies Fisher's exact test. TEST=LRCHI specifies the likelihood ratio chi-square test. TEST=PCHI (the default) specifies Pearson's chi-square test.

Restrictions on Option Combinations

To specify the proportions, choose one of the following parameterizations:

- individual proportions (by using the GROUPPROPORTIONS= option)
- difference between proportions and reference proportion (by using the PROPORTIONDIFF= and REFPROPORTION= options)
- odds ratio and reference proportion (by using the ODDSRATIO= and REFPROPORTION= options)
- relative risk and reference proportion (by using the RELATIVERISK= and REFPROPORTION= options)

To specify the sample size and allocation, choose one of the following parameterizations:

- sample size per group in a balanced design (by using the NPERGROUP= option)
- total sample size and allocation weights (by using the NTOTAL= and GROUPWEIGHTS= options)
- individual group sample sizes (by using the GROUPNS= option)

Option Groups for Common Analyses

This section summarizes the syntax for the common analyses supported in the TWOSAMPLEFREQ statement.

Pearson Chi-Square Test for Two Proportions

You can use the NPERGROUP= option in a balanced design and express effects in terms of the individual proportions, as in the following statements. Default values for the SIDES= and ALPHA= options specify a two-sided test with a significance level of 0.05.

```
proc power;
   twosamplefreq test=pchi
      grouppproportions = (.15 .25)
      nullproportiondiff = .03
      npergroup = 50
      power = .;
run;
```

You can also specify an unbalanced design by using the NTOTAL= and GROUPWEIGHTS= options and express effects in terms of the odds ratio. The default value of the NULLODDSRATIO= option specifies a test of no effect.

```
proc power;
   twosamplefreq test=pchi
      oddsratio = 2.5
      refproportion = 0.3
      groupweights = (1 2)
      ntotal = .
      power = 0.8;
run;
```

You can also specify sample sizes with the GROUPNS= option and express effects in terms of relative risks. The default value of the NULLRELATIVERISK= option specifies a test of no effect.

```
proc power;
   twosamplefreq test=pchi
      relativerisk = 1.5
      refproportion = 0.2
      groupns = 40 | 60
      power = .;
run;
```

You can also express effects in terms of the proportion difference. The default value of the NULLPROPORTIONDIFF= option specifies a test of no effect, and the default value of the GROUPWEIGHTS= option specifies a balanced design.

```
proc power;
   twosamplefreq test=pchi
      proportiondiff = 0.15
      refproportion = 0.4
      ntotal = 100
      power = .;
run;
```

Fisher's Exact Conditional Test for Two Proportions

The following statements demonstrate a power computation for Fisher's exact conditional test for two proportions. Default values for the SIDES= and ALPHA= options specify a two-sided test with a significance level of 0.05.

```
proc power;
   twosamplefreq test=fisher
      grouppproportions = (.35 .15)
      npergroup = 50
      power = .;
run;
```

Likelihood Ratio Chi-Square Test for Two Proportions

The following statements demonstrate a sample size computation for the likelihood ratio chi-square test for two proportions. Default values for the SIDES= and ALPHA= options specify a two-sided test with a significance level of 0.05.

```
proc power;
   twosamplefreq test=lrchi
      oddsratio = 2
      refproportion = 0.4
      npergroup = .
      power = 0.9;
run;
```

TWOSAMPLEMEANS Statement

TWOSAMPLEMEANS < *options* > **;**

The TWOSAMPLEMEANS statement performs power and sample size analyses for pooled and unpooled t tests, equivalence tests, and confidence interval precision involving two independent samples.

Summary of Options

Table 70.21 summarizes categories of options available in the TWOSAMPLEMEANS statement.

Dictionary of Options

ALPHA=*number-list*

specifies the level of significance of the statistical test or requests a solution for alpha with a missing value (ALPHA=.). The default is 0.05, corresponding to the usual $0.05 \times 100\% = 5\%$ level of significance. If the CI= and SIDES=1 options are used, then the value must be less than 0.5. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

CI

CI=DIFF

specifies an analysis of precision of the confidence interval for the mean difference, assuming equal variances. Instead of power, the relevant probability for this analysis is the probability that the interval half-width is at most the value specified by the HALFWIDTH= option. If neither the TEST= option nor the CI= option is used, the default is TEST=DIFF.

CV=*number-list*

specifies the coefficient of variation assumed to be common to both groups. The coefficient of variation is defined as the ratio of the standard deviation to the mean. You can use this option only with DIST=LOGNORMAL. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

DIST=LOGNORMAL

DIST=NORMAL

specifies the underlying distribution assumed for the test statistic. NORMAL corresponds the normal distribution, and LOGNORMAL corresponds to the lognormal distribution. The default value (also the only acceptable value in each case) is NORMAL for TEST=DIFF, TEST=DIFF_SATT, TEST=EQUIV_DIFF, and CI=DIFF; and LOGNORMAL for TEST=RATIO and TEST=EQUIV_RATIO.

GROUPMEANS=*grouped-number-list*

GMEANS=*grouped-number-list*

specifies the two group means or requests a solution for one group mean given the other. Means are in the original scale. They are arithmetic if DIST=NORMAL and geometric if DIST=LOGNORMAL. This option cannot be used with the CI=DIFF analysis. When TEST=EQUIV_DIFF, the means are interpreted as the reference mean (first) and the treatment mean (second). See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

GROUPNS=*grouped-number-list*

GNS=*grouped-number-list*

specifies the two group sample sizes or requests a solution for one group sample size given the other. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

GROUPSTDDEVS=*grouped-number-list*

GSTDDEVS=*grouped-number-list*

GROUPSTDS=*grouped-number-list*

GSTDS=*grouped-number-list*

specifies the standard deviation of each group. Unlike the STDDEV= option, the GROUPSTDDEVS== option supports different values for each group. It is valid only for the Satterthwaite *t* test (TEST=DIFF_SATT DIST=NORMAL). See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

GROUPWEIGHTS=*grouped-number-list*

GWEIGHTS=*grouped-number-list*

specifies the sample size allocation weights for the two groups, or requests a solution for one group weight given the other. This option controls how the total sample size is divided between the two groups. Each pair of values for the two groups represents relative allocation weights. Additionally, if the NFRACTIONAL option is not used, the total sample size is restricted to be equal to a multiple of the sum of the two group weights (so that the resulting design has an integer sample size for each group while adhering exactly to the group allocation weights). Values must be integers unless the NFRACTIONAL option is used. The default value is (1 1), a balanced design with a weight of 1 for each group. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

HALFWIDTH=*number-list*

specifies the desired confidence interval half-width. The half-width is defined as the distance between the point estimate and a finite endpoint. This option can be used only with the CI=DIFF analysis.

See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

LOWER=*number-list*

specifies the lower equivalence bound for the mean difference or mean ratio, in the original scale (whether DIST=NORMAL or DIST=LOGNORMAL). Values must be greater than 0 when DIST=LOGNORMAL. This option can be used only with the TEST=EQUIV_DIFF and TEST=EQUIV_RATIO analyses. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

MEANDIFF=*number-list*

specifies the mean difference, defined as $\mu_2 - \mu_1$, or requests a solution for the mean difference with a missing value (MEANDIFF=.). This option can be used only with the TEST=DIFF, TEST=DIFF_SATT, and TEST=EQUIV_DIFF analyses. When TEST=EQUIV_DIFF, the mean difference is interpreted as the treatment mean minus the reference mean. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

MEANRATIO=*number-list*

specifies the geometric mean ratio, defined as γ_2/γ_1. This option can be used only with the TEST=RATIO and TEST=EQUIV_RATIO analyses. When TEST=EQUIV_RATIO, the mean ratio is interpreted as the treatment mean divided by the reference mean. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NFRACTIONAL

NFRAC

enables fractional input and output for sample sizes. See the section "Sample Size Adjustment Options" on page 5837 for information about the ramifications of the presence (and absence) of the NFRACTIONAL option.

NPERGROUP=*number-list*

NPERG=*number-list*

specifies the common sample size per group or requests a solution for the common sample size per group with a missing value (NPERGROUP=.). Use of this option implicitly specifies a balanced design. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NTOTAL=*number-list*

specifies the sample size or requests a solution for the sample size with a missing value (NTOTAL=.). See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NULLDIFF=*number-list*

NULLD=*number-list*

specifies the null mean difference. The default value is 0. This option can be used only with the TEST=DIFF and TEST=DIFF_SATT analyses. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NULLRATIO=*number-list*

NULLR=*number-list*

specifies the null mean ratio. The default value is 1. This option can be used only with the TEST=RATIO analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

OUTPUTORDER=INTERNAL

OUTPUTORDER=REVERSE

OUTPUTORDER=SYNTAX

controls how the input and default analysis parameters are ordered in the output. OUTPUTORDER=INTERNAL (the default) arranges the parameters in the output according to the following order of their corresponding options:

- SIDES=
- NULLDIFF=
- NULLRATIO=
- LOWER=
- UPPER=
- ALPHA=
- GROUPMEANS=
- MEANDIFF=
- MEANRATIO=
- HALFWIDTH=
- STDDEV=
- GROUPSTDDEVS==
- CV=
- GROUPWEIGHTS=
- NTOTAL=
- NPERGROUP=
- GROUPNS=
- POWER=
- PROBTYPE=
- PROBWIDTH=

The OUTPUTORDER=SYNTAX option arranges the parameters in the output in the same order in which their corresponding options are specified in the TWOSAMPLEMEANS statement. The OUTPUTORDER=REVERSE option arranges the parameters in the output in the reverse of the order in which their corresponding options are specified in the TWOSAMPLEMEANS statement.

POWER=*number-list*

specifies the desired power of the test or requests a solution for the power with a missing value (POWER=.). The power is expressed as a probability, a number between 0 and 1, rather than as a percentage. This option cannot be used with the CI=DIFF analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

PROBTYPE=*keyword-list*

specifies the type of probability for the PROBWIDTH= option. A value of CONDITIONAL (the default) indicates the conditional probability that the confidence interval half-width is at most the value specified by the HALFWIDTH= option, given that the true mean difference is captured by the confidence interval. A value of UNCONDITIONAL indicates the unconditional probability that the confidence interval half-width is at most the value specified by the HALFWIDTH= option. you can use the alias GIVENVALIDITY for CONDITIONAL. The PROBTYPE= option can be used only with the CI=DIFF analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *keyword-list*.

CONDITIONAL width probability conditional on interval containing the mean

UNCONDITIONAL unconditional width probability

PROBWIDTH=*number-list*

specifies the desired probability of obtaining a confidence interval half-width less than or equal to the value specified by the HALFWIDTH= option. A missing value (PROBWIDTH=.) requests a solution for this probability. The type of probability is controlled with the PROBTYPE= option. Values are expressed as probabilities (for example, 0.9) rather than percentages. This option can be used only with the CI=DIFF analysis. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

SIDES=*keyword-list*

specifies the number of sides (or tails) and the direction of the statistical test or confidence interval. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *keyword-list*. Valid keywords and their interpretation for the TEST= analyses are as follows:

1 one-sided with alternative hypothesis in same direction as effect

2 two-sided

U upper one-sided with alternative greater than null value

L lower one-sided with alternative less than null value

For confidence intervals, SIDES=U refers to an interval between the lower confidence limit and infinity, and SIDES=L refers to an interval between minus infinity and the upper confidence limit. For both of these cases and SIDES=1, the confidence interval computations are equivalent. The SIDES= option cannot be used with the TEST=EQUIV_DIFF and TEST=EQUIV_RATIO analyses. The default value is 2.

STDDEV=*number-list*

STD=*number-list*

specifies the standard deviation assumed to be common to both groups, or requests a solution for the common standard deviation with a missing value (STDDEV=.). This option can be used only with DIST=NORMAL. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

TEST
TEST=DIFF
TEST=DIFF_SATT
TEST=EQUIV_DIFF
TEST=EQUIV_RATIO
TEST=RATIO

specifies the statistical analysis. TEST or TEST=DIFF (the default) specifies a pooled *t* test on the mean difference, assuming equal variances. TEST=DIFF_SATT specifies a Satterthwaite unpooled *t* test on the mean difference, assuming unequal variances. TEST=EQUIV_DIFF specifies an additive equivalence test of the mean difference by using a two one-sided tests (TOST) analysis (Schuirman 1987). TEST=EQUIV_RATIO specifies a multiplicative equivalence test of the mean ratio by using a TOST analysis. TEST=RATIO specifies a pooled *t* test on the mean ratio, assuming equal coefficients of variation. If neither the TEST= option nor the CI= option is used, the default is TEST=DIFF.

UPPER=*number-list*

specifies the upper equivalence bound for the mean difference or mean ratio, in the original scale (whether DIST=NORMAL or DIST=LOGNORMAL). This option can be used only with the TEST=EQUIV_DIFF and TEST=EQUIV_RATIO analyses. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

Restrictions on Option Combinations

To define the analysis, choose one of the following parameterizations:

- a statistical test (by using the TEST= option)
- confidence interval precision (by using the CI= option)

To specify the means, choose one of the following parameterizations:

- individual group means (by using the GROUPMEANS= option)
- mean difference (by using the MEANDIFF= option)
- mean ratio (by using the MEANRATIO= option)

To specify standard deviations in the Satterthwaite *t* test (TEST=DIFF_SATT), choose one of the following parameterizations:

- common standard deviation (by using the STDDEV= option)
- individual group standard deviations (by using the GROUPSTDDEVS== option)

To specify the sample sizes and allocation, choose one of the following parameterizations:

- sample size per group in a balanced design (by using the NPERGROUP= option)

- total sample size and allocation weights (by using the NTOTAL= and GROUPWEIGHTS= options)
- individual group sample sizes (by using the GROUPNS= option)

Option Groups for Common Analyses

This section summarizes the syntax for the common analyses supported in the TWOSAMPLEMEANS statement.

Two-Sample t *Test Assuming Equal Variances*

You can use the NPERGROUP= option in a balanced design and express effects in terms of the mean difference, as in the following statements. Default values for the DIST=, SIDES=, NULLDIFF=, and ALPHA= options specify a two-sided test for no difference with a normal distribution and a significance level of 0.05.

```
proc power;
   twosamplemeans test=diff
      meandiff = 7
      stddev = 12
      npergroup = 50
      power = .;
run;
```

You can also specify an unbalanced design by using the NTOTAL= and GROUPWEIGHTS= options and express effects in terms of individual group means:

```
proc power;
   twosamplemeans test=diff
      groupmeans = 8 | 15
      stddev = 4
      groupweights = (2 3)
      ntotal = .
      power = 0.9;
run;
```

Another way to specify the sample sizes is with the GROUPNS= option:

```
proc power;
   twosamplemeans test=diff
      groupmeans = 8 | 15
      stddev = 4
      groupns = (25 40)
      power = .;
run;
```

Two-Sample Satterthwaite t *Test Assuming Unequal Variances*

The following statements demonstrate a power computation for the two-sample Satterthwaite *t* test allowing unequal variances. Default values for the DIST=, SIDES=, NULLDIFF=, and ALPHA= options specify a two-sided test for no difference with a normal distribution and a significance level of 0.05.

```
proc power;
   twosamplemeans test=diff_satt
      meandiff = 3
      groupstddevs = 5 | 8
      groupweights = (1 2)
      ntotal = 60
      power = .;
run;
```

Two-Sample Pooled t Test of Mean Ratio with Lognormal Data

The following statements demonstrate a power computation for the pooled *t* test of a lognormal mean ratio. Default values for the DIST=, SIDES=, NULLRATIO=, and ALPHA= options specify a two-sided test of mean ratio = 1 assuming a lognormal distribution and a significance level of 0.05.

```
proc power;
   twosamplemeans test=ratio
      meanratio = 7
      cv = 0.8
      groupns = 50 | 70
      power = .;
run;
```

Additive Equivalence Test for Mean Difference with Normal Data

The following statements demonstrate a sample size computation for the TOST equivalence test for a normal mean difference. A default value of GROUPWEIGHTS=(1 1) specifies a balanced design. Default values for the DIST= and ALPHA= options specify a significance level of 0.05 and an assumption of normally distributed data.

```
proc power;
   twosamplemeans test=equiv_diff
      lower = 2
      upper = 5
      meandiff = 4
      stddev = 8
      ntotal = .
      power = 0.9;
run;
```

Multiplicative Equivalence Test for Mean Ratio with Lognormal Data

The following statements demonstrate a power computation for the TOST equivalence test for a lognormal mean ratio. Default values for the DIST= and ALPHA= options specify a significance level of 0.05 and an assumption of lognormally distributed data.

```
proc power;
   twosamplemeans test=equiv_ratio
      lower = 3
      upper = 7
      meanratio = 5
      cv = 0.75
```

```
      npergroup = 50
      power = .;
run;
```

Confidence Interval for Mean Difference

By default CI=DIFF analyzes the conditional probability of obtaining the desired precision, given that the interval contains the true mean difference, as in the following statements. The defaults of SIDES=2 and ALPHA=0.05 specify a two-sided interval with a confidence level of 0.95.

```
proc power;
   twosamplemeans ci = diff
      halfwidth = 4
      stddev = 8
      groupns = (30 35)
      probwidth = .;
run;
```

TWOSAMPLESURVIVAL Statement

TWOSAMPLESURVIVAL < *options* > **;**

The TWOSAMPLESURVIVAL statement performs power and sample size analyses for comparing two survival curves. The log-rank, Gehan, and Tarone-Ware rank tests are supported.

Summary of Options

Table 70.23 summarizes categories of options available in the TWOSAMPLESURVIVAL statement.

Dictionary of Options

ACCRUALRATEPERGROUP=*number-list*

ACCRUALRATEPERG=*number-list*

ARPERGROUP=*number-list*

ARPERG=*number-list*

specifies the common accrual rate per group or requests a solution for the common accrual rate per group with a missing value (ACCRUALRATEPERGROUP=.). The accrual rate per group is the number of subjects in each group that enters the study per time unit during the accrual period. Use of this option implicitly specifies a balanced design. The NFRACTIONAL option is automatically enabled when the ACCRUALRATEPERGROUP= option is used. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

ACCRUALRATETOTAL=*number-list*

ARTOTAL=*number-list*

specifies the total accrual rate or requests a solution for the accrual rate with a missing value (ACCRUALRATETOTAL=.). The total accrual rate is the total number of subjects that enter the study per time unit during the accrual period. The NFRACTIONAL option is automatically enabled when the ACCRUALRATETOTAL= option is used. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

ACCRUALTIME=*number-list* | **MAX**

ACCTIME=*number-list* | **MAX**

ACCRUALT=*number-list* | **MAX**

ACCT=*number-list* | **MAX**

specifies the accrual time. Accrual is assumed to occur uniformly from time 0 to the time specified by the ACCRUALTIME= option. If the GROUPSURVIVAL= or REFSURVIVAL= option is used, then the value of the total time (the sum of accrual and follow-up times) must be less than or equal to the largest time in *each* multipoint (piecewise linear) survival curve. If the ACCRUALRATEPERGROUP=, ACCRUALRATETOTAL=, or GROUPACCRUALRATES= option is used, then the accrual time must be greater than 0. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

ACCRUALTIME=MAX can be used when each scenario in the analysis contains at least one piecewise linear survival curve (in the GROUPSURVIVAL= or REFSURVIVAL= option). It causes the accrual time to be automatically set, separately for each scenario, to the maximum possible time supported by the piecewise linear survival curve(s) in that scenario. It is not compatible with the FOLLOWUPTIME=MAX option or the TOTALTIME= option.

ALPHA=*number-list*

specifies the level of significance of the statistical test. The default is 0.05, corresponding to the

usual 0.05 × 100% = 5% level of significance. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

CURVE("label")=points

defines a survival curve.

For the CURVE= option,

label identifies the curve in the output and with the GROUPLOSS=, GROUPSURVIVAL=, and REFSURVIVAL= options.

points specifies one or more (time, survival) pairs on the curve, where the survival value denotes the probability of surviving until at least the specified time.

A single-point curve is interpreted as exponential, and a multipoint curve is interpreted as piecewise linear. Points can be expressed in either of two forms:

- a series of time:survival pairs separated by spaces. For example:

```
1:0.9 2:0.7 3:0.6
```

- a DOLIST of times enclosed in parentheses, followed by a colon (:), followed by a DOLIST of survival values enclosed in parentheses. For example:

```
(1 to 3 by 1):(0.9 0.7 0.6)
```

  The DOLIST format is the same as in the DATA step.

Points can also be expressed as combinations of the two forms. For example:

```
1:0.9 2:0.8 (3 to 6 by 1):(0.7 0.65 0.6 0.55)
```

The points have the following restrictions:

- The time values must be nonnegative and strictly increasing.
- The survival values must be strictly decreasing.
- The survival value at a time of 0 must be equal to 1.
- If there is only one point, then the time must be greater than 0, and the survival value cannot be 0 or 1.

EVENTSPERGROUP=*number-list*

EEPERGROUP=*number-list*

EVENTSPERG=*number-list*

EEPERG=*number-list*

specifies the expected number of events per group—that is, deaths, whether observed or censored—during the entire study period, or requests a solution for this parameter with a missing value (EVENTSPERGROUP=.). Use of this option implicitly specifies a balanced design. The NFRACTIONAL option is automatically enabled when the EVENTSPERGROUP= option is used. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

EVENTSTOTAL=*number-list*

EVENTTOTAL=*number-list*

EETOTAL=*number-list*

specifies the expected total number of events—that is, deaths, whether observed or censored—during the entire study period, or requests a solution for this parameter with a missing value (EVENTSTOTAL=.). The NFRACTIONAL option is automatically enabled when the EVENTSTOTAL= option is used. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

FOLLOWUPTIME=*number-list* | **MAX**

FUTIME=*number-list* | **MAX**

FOLLOWUPT=*number-list* | **MAX**

FUT=*number-list* | **MAX**

specifies the follow-up time, the amount of time in the study past the accrual time. If the GROUPSURVIVAL= or REFSURVIVAL= option is used, then the value of the total time (the sum of accrual and follow-up times) must be less than or equal to the largest time in *each* multipoint (piecewise linear) survival curve. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

FOLLOWUPTIME=MAX can be used when each scenario in the analysis contains at least one piecewise linear survival curve (in the GROUPSURVIVAL= or REFSURVIVAL= option). It causes the follow-up time to be automatically set, separately for each scenario, to the maximum possible time supported by the piecewise linear survival curve(s) in that scenario. It is not compatible with the ACCRUALTIME=MAX option or the TOTALTIME= option.

GROUPACCRUALRATES=*grouped-number-list*

GACCRUALRATES=*grouped-number-list*

GROUPARS=*grouped-number-list*

GARS=*grouped-number-list*

specifies the accrual rate for each group. The groupwise accrual rates are the numbers of subjects in each group that enters the study per time unit during the accrual period. The NFRACTIONAL option is automatically enabled when the GROUPACCRUALRATES= option is used. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

GROUPEVENTS=*grouped-number-list*

GEVENTS=*grouped-number-list*

GROUPEES=*grouped-number-list*

GEES=*grouped-number-list*

specifies the expected number of events in each group—that is, deaths, whether observed or censored—during the entire study period. The NFRACTIONAL option is automatically enabled when the GROUPEVENTS= option is used. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

GROUPLOSS=*grouped-name-list*

GLOSS=*grouped-name-list*

specifies the exponential loss survival curve for each group, by using labels specified with the

CURVE= option. Loss is assumed to follow an exponential curve, indicating the expected rate of censoring (in other words, loss to follow-up) over time. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-name-list*.

GROUPLOSSEXPHAZARDS=*grouped-number-list*

GLOSSEXPHAZARDS=*grouped-number-list*

GROUPLOSSEXPHS=*grouped-number-list*

GLOSSEXPHS=*grouped-number-list*

specifies the exponential hazards of the loss in each group. Loss is assumed to follow an exponential curve, indicating the expected rate of censoring (in other words, loss to follow-up) over time. If none of the GROUPLOSSEXPHAZARDS=, GROUPLOSS=, and GROUPMEDLOSSTIMES= options are used, the default of GROUPLOSSEXPHAZARDS=(0 0) indicates no loss to follow-up. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

GROUPMEDLOSSTIMES=*grouped-number-list*

GMEDLOSSTIMES=*grouped-number-list*

GROUPMEDLOSSTS=*grouped-number-list*

GMEDLOSSTS=*grouped-number-list*

specifies the median times of the loss in each group. Loss is assumed to follow an exponential curve, indicating the expected rate of censoring (in other words, loss to follow-up) over time. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

GROUPMEDSURVTIMES=*grouped-number-list*

GMEDSURVTIMES=*grouped-number-list*

GROUPMEDSURVTS=*grouped-number-list*

GMEDSURVTS=*grouped-number-list*

specifies the median survival times in each group. When the GROUPMEDSURVTIMES= option is used, the survival curve in each group is assumed to be exponential. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

GROUPNS=*grouped-number-list*

GNS=*grouped-number-list*

specifies the two group sample sizes. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

GROUPSURVEXPHAZARDS=*grouped-number-list*

GSURVEXPHAZARDS=*grouped-number-list*

GROUPSURVEXPHS=*grouped-number-list*

GEXPHS=*grouped-number-list*

specifies exponential hazard rates of the survival curve for each group. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

GROUPSURVIVAL=*grouped-name-list*

GSURVIVAL=*grouped-name-list*

GROUPSURV=*grouped-name-list*

GSURV=*grouped-name-list*

specifies the survival curve for each group, by using labels specified with the CURVE= option. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-name-list*.

GROUPWEIGHTS=*grouped-number-list*

GWEIGHTS=*grouped-number-list*

specifies the sample size allocation weights for the two groups. This option controls how the total sample size is divided between the two groups. Each pair of values for the two groups represents relative allocation weights. Additionally, if the NFRACTIONAL option is not used, the total sample size is restricted to be equal to a multiple of the sum of the two group weights (so that the resulting design has an integer sample size for each group while adhering exactly to the group allocation weights). Values must be integers unless the NFRACTIONAL option is used. The default value is (1 1), a balanced design with a weight of 1 for each group. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

HAZARDRATIO=*number-list*

HR=*number-list*

specifies the hazard ratio of the second group's survival curve to the first group's survival curve. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NFRACTIONAL

NFRAC

enables fractional input and output for sample sizes. This option is automatically enabled when any of the following options are used: ACCRUALRATEPERGROUP=, ACCRUALRATETOTAL=, EVENTSPERGROUP=, EVENTSTOTAL=, GROUPACCRUALRATES=, and GROUPEVENTS=. See the section "Sample Size Adjustment Options" on page 5837 for information about the ramifications of the presence (and absence) of the NFRACTIONAL option.

NPERGROUP=*number-list*

NPERG=*number-list*

specifies the common sample size per group or requests a solution for the common sample size per group with a missing value (NPERGROUP=.). Use of this option implicitly specifies a balanced design. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NSUBINTERVAL=*number-list*

NSUBINTERVALS=*number-list*

NSUB=*number-list*

NSUBS=*number-list*

specifies the number of subintervals per unit time to use in internal calculations. Higher values increase computational time and memory requirements but generally lead to more accurate results. The default value is 12. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NTOTAL=*number-list*

specifies the sample size or requests a solution for the sample size with a missing value (NTOTAL=.). See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

OUTPUTORDER=INTERNAL

OUTPUTORDER=REVERSE

OUTPUTORDER=SYNTAX

controls how the input and default analysis parameters are ordered in the output. OUTPUTORDER=INTERNAL (the default) arranges the parameters in the output according to the following order of their corresponding options:

- SIDES=
- ACCRUALTIME=
- FOLLOWUPTIME=
- TOTALTIME=
- NSUBINTERVAL=
- ALPHA=
- REFSURVIVAL=
- GROUPSURVIVAL=
- REFSURVEXPHAZARD=
- HAZARDRATIO=
- GROUPSURVEXPHAZARDS=
- GROUPMEDSURVTIMES=
- GROUPLOSSEXPHAZARDS=
- GROUPLOSS=
- GROUPMEDLOSSTIMES=
- GROUPWEIGHTS=
- NTOTAL=
- ACCRUALRATETOTAL=
- EVENTSTOTAL=
- NPERGROUP=
- ACCRUALRATEPERGROUP=
- EVENTSPERGROUP=
- GROUPNS=
- GROUPACCRUALRATES=
- GROUPEVENTS=
- POWER=

The OUTPUTORDER=SYNTAX option arranges the parameters in the output in the same order in which their corresponding options are specified in the TWOSAMPLESURVIVAL statement. The OUTPUTORDER=REVERSE option arranges the parameters in the output in the reverse of the order in which their corresponding options are specified in the TWOSAMPLESURVIVAL statement.

POWER=*number-list*

specifies the desired power of the test or requests a solution for the power with a missing value (POWER=.). The power is expressed as a probability, a number between 0 and 1, rather than as a percentage. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

REFSURVEXPHAZARD=*number-list*

REFSURVEXPH=*number-list*

specifies the exponential hazard rate of the survival curve for the first (reference) group. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

REFSURVIVAL=*name-list*

REFSURV=*name-list*

specifies the survival curve for the first (reference) group, by using labels specified with the CURVE= option. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *name-list*.

SIDES=*keyword-list*

specifies the number of sides (or tails) and the direction of the statistical test or confidence interval. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *keyword-list*. Valid keywords and their interpretation are as follows:

1 one-sided with alternative hypothesis in same direction as effect

2 two-sided

U upper one-sided with the alternative hypothesis favoring better survival in the second group

L lower one-sided with the alternative hypothesis favoring better survival in the first (reference) group

The default value is 2.

TEST=GEHAN

TEST=LOGRANK

TEST=TARONEWARE

specifies the statistical analysis. TEST=GEHAN specifies the Gehan rank test. TEST=LOGRANK (the default) specifies the log-rank test. TEST=TARONEWARE specifies the Tarone-Ware rank test.

TOTALTIME=*number-list* | **MAX**

TOTALT=*number-list* | **MAX**

specifies the total time, which is equal to the sum of accrual and follow-up times. If the GROUPSURVIVAL= or REFSURVIVAL= option is used, then the value of the total time must be less than or equal

to the largest time in *each* multipoint (piecewise linear) survival curve. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

TOTALTIME=MAX can be used when each scenario in the analysis contains at least one piecewise linear survival curve (in the GROUPSURVIVAL= or REFSURVIVAL= option). It causes the total time to be automatically set, separately for each scenario, to the maximum possible time supported by the piecewise linear survival curve(s) in that scenario. It is not compatible with the ACCRUALTIME=MAX option or the FOLLOWUPTIME=MAX option.

Restrictions on Option Combinations

To specify the survival curves, choose one of the following parameterizations:

- arbitrary piecewise linear or exponential curves (by using the CURVE= and GROUPSURVIVAL= options)
- curves with proportional hazards (by using the CURVE=, REFSURVIVAL=, and HAZARDRATIO= options)
- exponential curves, by using one of the following parameterizations:
  - median survival times (by using the GROUPMEDSURVTIMES= option)
  - the hazard ratio and the hazard of the reference curve (by using the HAZARDRATIO= and REFSURVEXPHAZARD= options)
  - the individual hazards (by using the GROUPSURVEXPHAZARDS= option)

To specify the study time, use any two of the following three options:

- accrual time (by using the ACCRUALTIME= option)
- follow-up time (by using the FOLLOWUPTIME= option)
- total time, the sum of accrual and follow-up times (by using the TOTALTIME= option)

To specify the sample size and allocation, choose one of the following parameterizations:

- sample size per group in a balanced design (by using the NPERGROUP= option)
- accrual rate per group in a balanced design (by using the ACCRUALRATEPERGROUP= option)
- expected number of events per group in a balanced design (by using the EVENTSPERGROUP= option)
- total sample size and allocation weights (by using the NTOTAL= and GROUPWEIGHTS= options)
- total accrual rate and allocation weights (by using the ACCRUALRATETOTAL= and GROUPWEIGHTS= options)

- expected total number of events and allocation weights (by using the EVENTSTOTAL= and GROUPWEIGHTS= options)
- individual group sample sizes (by using the GROUPNS= option)
- individual group accrual rates (by using the GROUPACCRUALRATES= option)
- expected numbers of events in each group (by using the GROUPEVENTS= option)

The values of parameters that involve expected number of events or accrual rate are converted internally to the analogous sample size parameterization (that is, the NPERGROUP=, NTOTAL=, or GROUPNS= option) for the purpose of sample size adjustments according to the presence or absence of the NFRACTIONAL option.

To specify the exponential loss curves, choose one of the following parameterizations:

- a point on the loss curve of each group (by using the CURVE= and GROUPLOSS= options)
- median loss times (by using the GROUPMEDLOSSTIMES= option)
- the individual loss hazards (by using the GROUPLOSSEXPHAZARDS= option)

Option Groups for Common Analyses

This section summarizes the syntax for the common analyses supported in the TWOSAMPLESURVIVAL statement.

Log-Rank Test for Two Survival Curves

You can use the NPERGROUP= option in a balanced design and specify piecewise linear or exponential survival curves by using the CURVE= and GROUPSURVIVAL= options, as in the following statements. Default values for the SIDES=, ALPHA=, NSUBINTERVAL=, and GROUPLOSSEXPHAZARDS= options specify a two-sided test with a significance level of 0.05, an assumption of no loss to follow-up, and the use of 12 subintervals per unit time in computations.

```
proc power;
   twosamplesurvival test=logrank
      curve("Control")   = (1 2 3):(0.8 0.7 0.6)
      curve("Treatment") = (5):(.6)
      groupsurvival = "Control" | "Treatment"
      accrualtime = 2
      followuptime = 1
      npergroup = 50
      power = .;
run;
```

In the preceding example, the “Control” curve is piecewise linear (since it has more than one point), and the “Treatment” curve is exponential (since it has only one point).

You can also specify an unbalanced design by using the NTOTAL= and GROUPWEIGHTS= options and specify piecewise linear or exponential survival curves with proportional hazards by using the CURVE=, REFSURVIVAL=, and HAZARDRATIO= options:

```
proc power;
   twosamplesurvival test=logrank
      curve("Control")   = (1 2 3):(0.8 0.7 0.6)
      refsurvival = "Control"
      hazardratio = 1.5
      accrualtime = 2
      followuptime = 1
      groupweights = (1 2)
      ntotal = .
      power = 0.8;
run;
```

Instead of computing sample size, you can compute the accrual rate by using the ACCRUALRATETOTAL= option:

```
proc power;
   twosamplesurvival test=logrank
      curve("Control")   = (1 2 3):(0.8 0.7 0.6)
      refsurvival = "Control"
      hazardratio = 1.5
      accrualtime = 2
      followuptime = 1
      groupweights = (1 2)
      accrualratetotal = .
      power = 0.8;
run;
```

or the expected number of events by using the EVENTSTOTAL= option:

```
proc power;
   twosamplesurvival test=logrank
      curve("Control")   = (1 2 3):(0.8 0.7 0.6)
      refsurvival = "Control"
      hazardratio = 1.5
      accrualtime = 2
      followuptime = 1
      groupweights = (1 2)
      eventstotal = .
      power = 0.8;
run;
```

You can also specify sample sizes with the GROUPNS= option and specify exponential survival curves in terms of median survival times:

```
proc power;
   twosamplesurvival test=logrank
      groupmedsurvtimes = (16 22)
      accrualtime = 6
      totaltime = 18
      groupns = 40 | 60
      power = .;
run;
```

You can also specify exponential survival curves in terms of the hazard ratio and reference hazard. The default value of the GROUPWEIGHTS= option specifies a balanced design.

```
proc power;
   twosamplesurvival test=logrank
      hazardratio = 1.2
      refsurvexphazard = 0.7
      accrualtime = 2
      totaltime = 4
      ntotal = 100
      power = .;
run;
```

You can also specify exponential survival curves in terms of the individual hazards, as in the following statements:

```
proc power;
   twosamplesurvival test=logrank
      groupsurvexphazards = 0.7 | 0.84
      accrualtime = 2
      totaltime = 4
      ntotal = .
      power = 0.9;
run;
```

Gehan Rank Test for Two Survival Curves

In addition to the logrank test, you can also specify the Gehan tank test, as in the following statements. Default values for the SIDES=, ALPHA=, NSUBINTERVAL=, and GROUPLOSSEXPHAZARDS= options specify a two-sided test with a significance level of 0.05, an assumption of no loss to follow-up, and the use of 12 subintervals per unit time in computations.

```
proc power;
   twosamplesurvival test=gehan
      groupmedsurvtimes = 5 | 7
      accrualtime = 3
      totaltime = 6
      npergroup = .
      power = 0.8;
run;
```

Tarone-Ware Rank Test for Two Survival Curves

You can also specify the Tarone-Ware tank test, as in the following statements. Default values for the SIDES=, ALPHA=, NSUBINTERVAL=, and GROUPLOSSEXPHAZARDS= options specify a two-sided test with a significance level of 0.05, an assumption of no loss to follow-up, and the use of 12 subintervals per unit time in computations.

```
proc power;
   twosamplesurvival test=taroneware
      groupmedsurvtimes = 5 | 7
      accrualtime = 3
      totaltime = 6
      npergroup = 100
      power = .;
run;
```

TWOSAMPLEWILCOXON Statement

TWOSAMPLEWILCOXON < *options* > **;**

The TWOSAMPLEWILCOXON statement performs power and sample size analyses for the Wilcoxon-Mann-Whitney test (also called the Wilcoxon rank-sum test, Mann-Whitney-Wilcoxon test, or Mann-Whitney U test) for two independent groups.

Note that the O'Brien-Castelloe approach to computing power for the Wilcoxon test is approximate, based on asymptotic behavior as the total sample size gets large. The quality of the power approximation degrades for small sample sizes; conversely, the quality of the sample size approximation degrades if the two distributions are far apart, so that only a small sample is needed to detect a significant difference. But this degradation is rarely a problem in practical situations, in which experiments are usually performed for relatively close distributions.

Summary of Options

Table 70.25 summarizes categories of options available in the TWOSAMPLEWILCOXON statement.

Table 70.25 Summary of Options in the TWOSAMPLEWILCOXON Statement

Dictionary of Options

ALPHA=*number-list*

specifies the level of significance of the statistical test. The default is 0.05, corresponding to the usual $0.05 \times 100\% = 5\%$ level of significance. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

GROUPNS=*grouped-number-list*

GNS=*grouped-number-list*

specifies the two group sample sizes. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

GROUPWEIGHTS=*grouped-number-list*

GWEIGHTS=*grouped-number-list*

specifies the sample size allocation weights for the two groups. This option controls how the total sample size is divided between the two groups. Each pair of values for the two groups represents relative allocation weights. Additionally, if the NFRACTIONAL option is not used, the total sample size is restricted to be equal to a multiple of the sum of the two group weights (so that the resulting design has an integer sample size for each group while adhering exactly to the group allocation weights). Values must be integers unless the NFRACTIONAL option is used. The default value is (1 1), a balanced design with a weight of 1 for each group. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-number-list*.

NBINS=*number-list*

specifies the number of categories (or "bins") each variable's distribution is divided into (unless it is ordinal, in which case the categories remain intact) in internal calculations. Higher values increase computational time and memory requirements but generally lead to more accurate results. However, if the value is too high, then numerical instability can occur. The default value is 1000. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NFRACTIONAL

NFRAC

enables fractional input and output for sample sizes. See the section "Sample Size Adjustment Options" on page 5837 for information about the ramifications of the presence (and absence) of the NFRACTIONAL option.

NPERGROUP=*number-list*

NPERG=*number-list*

specifies the common sample size per group or requests a solution for the common sample size per group with a missing value (NPERGROUP=.). Use of this option implicitly specifies a balanced design. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

NTOTAL=*number-list*

specifies the sample size or requests a solution for the sample size with a missing value (NTOTAL=.). See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

OUTPUTORDER=INTERNAL

OUTPUTORDER=REVERSE

OUTPUTORDER=SYNTAX

controls how the input and default analysis parameters are ordered in the output. OUTPUTORDER=INTERNAL (the default) arranges the parameters in the output according to the following order of their corresponding options:

- SIDES
- NBINS=
- ALPHA=
- VARIABLES=
- GROUPWEIGHTS=
- NTOTAL=
- NPERGROUP=
- GROUPNS=
- POWER=

The OUTPUTORDER=SYNTAX option arranges the parameters in the output in the same order in which their corresponding options are specified in the TWOSAMPLEWILCOXON statement. The OUTPUTORDER=REVERSE option arranges the parameters in the output in the reverse of the order in which their corresponding options are specified in the TWOSAMPLEWILCOXON statement.

POWER=*number-list*

specifies the desired power of the test or requests a solution for the power with a missing value (POWER=.). The power is expressed as a probability, a number between 0 and 1, rather than as a percentage. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *number-list*.

SIDES=*keyword-list*
specifies the number of sides (or tails) and the direction of the statistical test. Valid keywords are as follows:

1	one-sided with alternative hypothesis in same direction as effect
2	two-sided
U	upper one-sided with alternative greater than null value
L	lower one-sided with alternative less than null value

The default value is 2.

TEST=WMW
specifies the Wilcoxon-Mann-Whitney test for two independent groups This is the default test option.

VARDIST("label")=*distribution* **(***parameters***)**
defines a distribution for a variable.

For the VARDIST= option,

label	identifies the variable distribution in the output and with the VARIABLES= option.
distribution	specifies the distributional form of the variable.
parameters	specifies one or more parameters associated with the distribution.

Choices for distributional forms and their parameters are as follows:

ORDINAL ((*values*) : (*probabilities*)) is an ordered categorical distribution. The *values* are any numbers separated by spaces. The *probabilities* are numbers between 0 and 1 (inclusive) separated by spaces. Their sum must be exactly 1. The number of *probabilities* must match the number of *values*.

BETA (*a*, *b* <, *l*, *r* >) is a beta distribution with shape parameters a and b and optional location parameters l and r. The values of a and b must be greater than 0, and l must be less than r. The default values for l and r are 0 and 1, respectively.

BINOMIAL (*p*, *n*) is a binomial distribution with probability of success p and number of independent Bernoulli trials n. The value of p must be greater than 0 and less than 1, and n must be an integer greater than 0.

EXPONENTIAL (λ) is an exponential distribution with scale λ, which must be greater than 0.

GAMMA (*a*, λ) is a gamma distribution with shape a and scale λ. The values of a and λ must be greater than 0.

LAPLACE (θ, λ) is a Laplace distribution with location θ and scale λ. The value of λ must be greater than 0.

LOGISTIC (θ, λ) is a logistic distribution with location θ and scale λ. The value of λ must be greater than 0.

LOGNORMAL (θ, λ) is a lognormal distribution with location θ and scale λ. The value of λ must be greater than 0.

NORMAL (θ, λ) is a normal distribution with mean θ and standard deviation λ. The value of λ must be greater than 0.

POISSON (m) is a Poisson distribution with mean m. The value of m must be greater than 0.

UNIFORM (l, r) is a uniform distribution on the interval $[l, r]$, where $l < r$.

VARIABLES=*grouped-name-list*

VARS=*grouped-name-list*

specifies the distributions of two or more variables, using labels specified with the VARDIST= option. See the section "Specifying Value Lists in Analysis Statements" on page 5834 for information about specifying the *grouped-name-list*.

Restrictions on Option Combinations

To specify the sample size and allocation, choose one of the following parameterizations:

- sample size per group in a balanced design (using the NPERGROUP= option)
- total sample size and allocation weights (using the NTOTAL= and GROUPWEIGHTS= options)
- individual group sample sizes (using the GROUPNS= option)

Option Groups for Common Analyses

This section summarizes the syntax for the common analyses supported in the TWOSAMPLEWILCOXON statement.

Wilcoxon-Mann-Whitney Test for Comparing Two Distributions

The following statements performs a power analysis for Wilcoxon-Mann-Whitney tests comparing an ordinal variable with each other type of distribution. Default values for the ALPHA=, NBINS=, SIDES=, and TEST= options specify a two-sided test with a significance level of 0.05 and the use of 1000 categories per distribution when discretization is needed.

```
proc power;
   twosamplewilcoxon
      vardist("myordinal") = ordinal ((0 1 2) : (.2 .3 .5))
      vardist("mybeta1") = beta (1, 2)
      vardist("mybeta2") = beta (1, 2, 0, 2)
      vardist("mybinomial") = binomial (.3, 3)
      vardist("myexponential") = exponential (2)
      vardist("mygamma") = gamma (1.5, 2)
      vardist("mylaplace") = laplace (1, 2)
      vardist("mylogistic") = logistic (1, 2)
      vardist("mylognormal") = lognormal (1, 2)
      vardist("mynormal") = normal (3, 2)
      vardist("mypoisson") = poisson (2)
      vardist("myuniform") = uniform (0, 2)
```

```
      variables = "myordinal" | "mybeta1" "mybeta2" "mybinomial"
                                "myexponential" "mygamma" "mylaplace"
                                "mylogistic" "mylognormal" "mynormal"
                                "mypoisson" "myuniform"
      ntotal = 40
      power = .;
run;
```

Details: POWER Procedure

Overview of Power Concepts

In statistical hypothesis testing, you typically express the belief that some effect exists in a population by specifying an alternative hypothesis H_1. You state a null hypothesis H_0 as the assertion that the effect does *not* exist and attempt to gather evidence to reject H_0 in favor of H_1. Evidence is gathered in the form of sample data, and a statistical test is used to assess H_0. If H_0 is rejected but there really is *no* effect, this is called a *Type I error*. The probability of a Type I error is usually designated "alpha" or α, and statistical tests are designed to ensure that α is suitably small (for example, less than 0.05).

If there really is an effect in the population but H_0 is *not* rejected in the statistical test, then a *Type II error* has been made. The probability of a Type II error is usually designated "beta" or β. The probability $1-\beta$ of avoiding a Type II error—that is, correctly rejecting H_0 and achieving statistical significance—is called the *power*. (**NOTE:** Another more general definition of power is the probability of rejecting H_0 for any given set of circumstances, even those corresponding to H_0 being true. The POWER procedure uses this more general definition.)

An important goal in study planning is to ensure an acceptably high level of power. Sample size plays a prominent role in power computations because the focus is often on determining a sufficient sample size to achieve a certain power, or assessing the power for a range of different sample sizes.

Some of the analyses in the POWER procedure focus on *precision* rather than power. An analysis of confidence interval precision is analogous to a traditional power analysis, with "CI Half-Width" taking the place of effect size and "Prob(Width)" taking the place of power. The *CI Half-Width* is the margin of error associated with the confidence interval, the distance between the point estimate and an endpoint. The *Prob(Width)* is the probability of obtaining a confidence interval with *at most* a target half-width.

Summary of Analyses

Table 70.27 gives a summary of the analyses supported in the POWER procedure. The name of the analysis statement reflects the type of data and design. The TEST=, CI=, and DIST= options specify the focus of the statistical hypothesis (in other words, the criterion on which the research question is based) and the test statistic to be used in data analysis.

Specifying Value Lists in Analysis Statements

To specify one or more scenarios for an analysis parameter (or set of parameters), you provide a list of values for the statement option that corresponds to the parameter(s). To identify the parameter you want to solve for, you place missing values in the appropriate list.

There are five basic types of such lists: *keyword-lists*, *number-lists*, *grouped-number-lists*, *name-lists*, and *grouped-name-lists*. Some parameters, such as the direction of a test, have values represented by one or more keywords in a *keyword-list*. Scenarios for scalar-valued parameters, such as power, are represented by a *number-list*. Scenarios for groups of scalar-valued parameters, such as group sample sizes in a multi-group design, are represented by a *grouped-number-list*. Scenarios for named parameters, such as reference survival curves, are represented by a *name-list*. Scenarios for groups of named parameters, such as group survival curves, are represented by a *grouped-name-list*.

The following subsections explain these five basic types of lists.

Keyword-Lists

A *keyword-list* is a list of one or more keywords separated by spaces. For example, you can specify both two-sided and upper-tailed versions of a one-sample t test:

```
SIDES = 2 U
```

Number-Lists

A *number-list* can be one of two things: a series of one or more numbers expressed in the form of one or more DOLISTs, or a missing value indicator (.).

The DOLIST format is the same as in the DATA step language. For example, for the one-sample t test you can specify four scenarios (30, 50, 70, and 100) for a total sample size in any of the following ways.

```
NTOTAL = 30 50 70 100
NTOTAL = 30 to 70 by 20 100
```

A missing value identifies a parameter as the result parameter; it is valid only with options representing parameters you can solve for in a given analysis. For example, you can request a solution for NTOTAL:

```
NTOTAL = .
```

Grouped-Number-Lists

A *grouped-number-list* specifies multiple scenarios for numeric values in two or more groups, possibly including missing value indicators to solve for a specific group. The list can assume one of two general forms, a "crossed" version and a "matched" version.

Crossed Grouped-Number-Lists

The crossed version of a grouped number list consists of a series of *number-lists* (see the section "Number-Lists" on page 5834), one representing each group, with groups separated by a vertical bar (|). The values for each group represent multiple scenarios for that group, and the scenarios for each individual group are crossed to produce the set of all scenarios for the analysis option. For example, you can specify the following six scenarios for the sizes (n_1, n_2) of two groups

$$(20, 30)(20, 40)(20, 50)$$
$$(25, 30)(25, 40)(25, 50)$$

as follows:

```
GROUPNS = 20 25 | 30 40 50
```

If the analysis can solve for a value in one group given the other groups, then one of the *number-lists* in a *crossed grouped-number-list* can be a missing value indicator (.). For example, in a two-sample t test you can posit three scenarios for the group 2 sample size while solving for the group 1 sample size:

```
GROUPNS = . | 30 40 50
```

Some analyses can involve more than two groups. For example, you can specify $2 \times 3 \times 1 = 6$ scenarios for the means of three groups in a one-way ANOVA as follows:

```
GROUPMEANS = 10 12 | 10 to 20 by 5 | 24
```

Matched Grouped-Number-Lists

The matched version of a grouped number list consists of a series of numeric lists, each enclosed in parentheses. Each list consists of a value for each group and represents a single scenario for the analysis option. Multiple scenarios for the analysis option are represented by multiple lists. For example, you can express the crossed grouped-number-list

```
GROUPNS = 20 25 | 30 40 50
```

alternatively in a matched format:

```
GROUPNS = (20 30) (20 40) (20 50) (25 30) (25 40) (25 50)
```

The matched version is particularly useful when you want to include only a subset of all combinations of individual group values. For example, you might want to pair 20 only with 50, and 25 only with 30 and 40:

```
GROUPNS = (20 50) (25 30) (25 40)
```

If the analysis can solve for a value in one group given the other groups, then you can replace the value for that group with a missing value indicator (.). If used, the missing value indicator must occur in the same group in every scenario. For example, you can solve for the group 1 sample size (as in the section "Crossed Grouped-Number-Lists" on page 5835) by using a matched format:

```
GROUPNS = (. 30) (. 40) (. 50)
```

Some analyses can involve more than two groups. For example, you can specify two scenarios for the means of three groups in a one-way ANOVA:

```
GROUPMEANS = (15 24 32) (12 25 36)
```

Name-Lists

A *name-list* is a list of one or more names in single or double quotes, separated by spaces. For example, you can specify two scenarios for the reference survival curve in a log-rank test:

```
REFSURVIVAL = "Curve A" "Curve B"
```

Grouped-Name-Lists

A *grouped-name-list* specifies multiple scenarios for names in two or more groups. The list can assume one of two general forms, a "crossed" version and a "matched" version.

Crossed Grouped-Name-Lists

The crossed version of a grouped name list consists of a series of *name-lists* (see the section "Name-Lists" on page 5836), one representing each group, with groups separated by a vertical bar (|). The values for each group represent multiple scenarios for that group, and the scenarios for each individual group are crossed to produce the set of all scenarios for the analysis option. For example, you can specify the following six scenarios for the survival curves (c_1, c_2) of two groups

("Curve A", "Curve C")("Curve A", "Curve D")("Curve A", "Curve E")
("Curve B", "Curve C")("Curve B", "Curve D")("Curve B", "Curve E")

as follows:

```
GROUPSURVIVAL = "Curve A" "Curve B" | "Curve C" "Curve D"
                                      "Curve E"
```

Matched Grouped-Name-Lists

The matched version of a grouped name list consists of a series of name lists, each enclosed in parentheses. Each list consists of a name for each group and represents a single scenario for the analysis option. Multiple scenarios for the analysis option are represented by multiple lists. For example, you can express the crossed grouped-name-list

```
GROUPSURVIVAL = "Curve A" "Curve B" | "Curve C" "Curve D"
                                           "Curve E"
```

alternatively in a matched format:

```
GROUPSURVIVAL = ("Curve A" "Curve C")
                ("Curve A" "Curve D")
                ("Curve A" "Curve E")
                ("Curve B" "Curve C")
                ("Curve B" "Curve D")
                ("Curve B" "Curve E")
```

The matched version is particularly useful when you want to include only a subset of all combinations of individual group values. For example, you might want to pair “Curve A” only with “Curve C”, and “Curve B” only with “Curve D” and “Curve E”:

```
GROUPSURVIVAL = ("Curve A" "Curve C")
                ("Curve B" "Curve D")
                ("Curve B" "Curve E")
```

Sample Size Adjustment Options

By default, PROC POWER rounds sample sizes conservatively (down in the input, up in the output) so that all total sizes (and individual group sample sizes, if a multigroup design) are integers. This is generally considered conservative because it selects the closest realistic design providing *at most* the power of the (possibly fractional) input or mathematically optimized design. In addition, in a multigroup design, all group sizes are adjusted to be multiples of the corresponding group weights. For example, if GROUPWEIGHTS = (2 6), then all group 1 sample sizes become multiples of 2, and all group 2 sample sizes become multiples of 6 (and all total sample sizes become multiples of 8).

With the NFRACTIONAL option, sample size input is not rounded, and sample size output (whether total or groupwise) are reported in two versions, a raw “fractional” version and a “ceiling” version rounded up to the nearest integer.

Whenever an input sample size is adjusted, both the original (“nominal”) and adjusted (“actual”) sample sizes are reported. Whenever computed output sample sizes are adjusted, both the original input (“nominal”) power and the achieved (“actual”) power at the adjusted sample size are reported.

Error and Information Output

The Error column in the main output table provides reasons for missing results and flags numerical results that are bounds rather than exact answers. For example, consider the sample size analysis implemented by the following statements:

```
proc power;
   twosamplefreq test=pchi
     method=normal
     oddsratio= 1.0001
     refproportion=.4
     nulloddsratio=1
     power=.9
     ntotal=.;
run;
```

Figure 70.6 Error Column

The POWER Procedure
Pearson Chi-square Test for Two Proportions

Fixed Scenario Elements

Distribution	Asymptotic normal
Method	Normal approximation
Null Odds Ratio	1
Reference (Group 1) Proportion	0.4
Odds Ratio	1.0001
Nominal Power	0.9
Number of Sides	2
Alpha	0.05
Group 1 Weight	1
Group 2 Weight	1

Computed N Total

Actual Power	N Total	Error
0.206	2.15E+09	Solution is a lower bound

The output in Figure 70.6 reveals that the sample size to achieve a power of 0.9 could not be computed, but that the sample size 2.15E+09 achieves a power of 0.206.

The Info column provides further details about Error column entries, warnings about any boundary conditions detected, and notes about any adjustments to input. Note that the Info column is hidden by default in the main output. You can view it by using the ODS OUTPUT statement to save the output as a data set and the PRINT procedure. For example, the following SAS statements print both the Error and Info columns for a power computation in a two-sample *t* test:

```
proc power;
   twosamplemeans
```

```
      meandiff= 0 7
      stddev=2
      ntotal=2 5
      power=.;
   ods output output=Power;
run;
proc print noobs data=Power;
   var MeanDiff NominalNTotal NTotal Power Error Info;
run;
```

The output is shown in Figure 70.7.

Figure 70.7 Error and Info Columns

Mean Diff	Nominal NTotal	NTotal	Power	Error	Info
0	2	2	.	Invalid input	N too small / No effect
0	5	4	0.050		Input N adjusted / No effect
7	2	2	.	Invalid input	N too small
7	5	4	0.477		Input N adjusted

The mean difference of 0 specified with the MEANDIFF= option leads to a "No effect" message to appear in the Info column. The sample size of 2 specified with the NTOTAL= option leads to an "Invalid input" message in the Error column and an "NTotal too small" message in the Info column. The sample size of 5 leads to an "Input N adjusted" message in the Info column because it is rounded down to 4 to produce integer group sizes of 2 per group.

Displayed Output

If you use the PLOTONLY option in the PROC POWER statement, the procedure displays only graphical output. Otherwise, the displayed output of the POWER procedure includes the following:

- the "Fixed Scenario Elements" table, which shows all applicable single-valued analysis parameters, in the following order: distribution, method, parameters input explicitly, and parameters supplied with defaults
- an output table showing the following when applicable (in order): the index of the scenario, all multivalued input, ancillary results, the primary computed result, and error descriptions
- plots (if requested)

For each input parameter, the order of the input values is preserved in the output.

Ancillary results include the following:

- Actual Power, the achieved power, if it differs from the input (Nominal) power value

- Actual Prob(Width), the achieved precision probability, if it differs from the input (Nominal) probability value
- Actual Alpha, the achieved significance level, if it differs from the input (Nominal) alpha value
- fractional sample size, if the NFRACTIONAL option is used in the analysis statement

If sample size is the result parameter and the NFRACTIONAL option is used in the analysis statement, then both "Fractional" and "Ceiling" sample size results are displayed. Fractional sample sizes correspond to the "Nominal" values of power or precision probability. Ceiling sample sizes are simply the fractional sample sizes rounded up to the nearest integer; they correspond to "Actual" values of power or precision probability.

ODS Table Names

PROC POWER assigns a name to each table that it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 70.28. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 70.28 ODS Tables Produced by PROC POWER

ODS Table Name	Description	Statement
FixedElements	Factoid with single-valued analysis parameters	Default*
Output	All input and computed analysis parameters, error messages, and information messages for each scenario	Default
PlotContent	Data contained in plots, including analysis parameters and indices identifying plot features. (**NOTE:** This table is saved as a data set and not displayed in PROC POWER output.)	PLOT

*Depends on input.

Computational Resources

Memory

In the TWOSAMPLESURVIVAL statement, the amount of required memory is roughly proportional to the product of the number of subintervals (specified by the NSUBINTERVAL= option) and the total time of the study (specified by the ACCRUALTIME=, FOLLOWUPTIME=, and TOTALTIME= options). If you run out of memory, then you can try either specifying a smaller number of subintervals, changing the time scale to a use a longer time unit (for example, years instead of months), or both.

CPU Time

In the Satterthwaite t test analysis (TWOSAMPLEMEANS TEST=DIFF_SATT), the required CPU time grows as the mean difference decreases relative to the standard deviations. In the PAIREDFREQ statement, the required CPU time for the exact power computation (METHOD=EXACT) grows with the sample size.

Computational Methods and Formulas

This section describes the approaches used in PROC POWER to compute power for each analysis. The first subsection defines some common notation. The following subsections describe the various power analyses, including discussions of the data, statistical test, and power formula for each analysis. Unless otherwise indicated, computed values for parameters besides power (for example, sample size) are obtained by solving power formulas for the desired parameters.

Common Notation

Table 70.29 displays notation for some of the more common parameters across analyses. The Associated Syntax column shows examples of relevant analysis statement options, where applicable.

Table 70.29 Common Notation

Symbol	Description	Associated Syntax
α	Significance level	ALPHA=
N	Total sample size	NTOTAL=, NPAIRS=
n_i	Sample size in ith group	NPERGROUP=, GROUPNS=
w_i	Allocation weight for ith group (standardized to sum to 1)	GROUPWEIGHTS=
μ	(Arithmetic) mean	MEAN=
μ_i	(Arithmetic) mean in ith group	GROUPMEANS=, PAIREDMEANS=
μ_{diff}	(Arithmetic) mean difference, $\mu_2 - \mu_1$ or $\mu_T - \mu_R$	MEANDIFF=
μ_0	Null mean or mean difference (arithmetic)	NULL=, NULLDIFF=
γ	Geometric mean	MEAN=
γ_i	Geometric mean in ith group	GROUPMEANS=, PAIREDMEANS=
γ_0	Null mean or mean ratio (geometric)	NULL=, NULLRATIO=
σ	Standard deviation (or common standard deviation per group)	STDDEV=
σ_i	Standard deviation in ith group	GROUPSTDDEVS=, PAIREDSTDDEVS=
σ_{diff}	Standard deviation of differences	

Table 70.29 *continued*

Symbol	Description	Associated Syntax
CV	Coefficient of variation, defined as the ratio of the standard deviation to the (arithmetic) mean	CV=, PAIREDCVS=
ρ	Correlation	CORR=
μ_T, μ_R	Treatment and reference (arithmetic) means for equivalence test	GROUPMEANS=, PAIREDMEANS=
γ_T, γ_R	Treatment and reference geometric means for equivalence test	GROUPMEANS=, PAIREDMEANS=
θ_L	Lower equivalence bound	LOWER=
θ_U	Upper equivalence bound	UPPER=
$t(\nu, \delta)$	t distribution with d.f. ν and noncentrality δ	
$F(\nu_1, \nu_2, \lambda)$	F distribution with numerator d.f. ν_1, denominator d.f. ν_2, and noncentrality λ	
$t_{p;\nu}$	pth percentile of t distribution with d.f. ν	
$F_{p;\nu_1,\nu_2}$	pth percentile of F distribution with numerator d.f. ν_1 and denominator d.f. ν_2	
Bin(N, p)	Binomial distribution with sample size N and proportion p	

A "lower one-sided" test is associated with SIDES=L (or SIDES=1 with the effect smaller than the null value), and an "upper one-sided" test is associated with SIDES=U (or SIDES=1 with the effect larger than the null value).

Owen (1965) defines a function, known as Owen's Q, that is convenient for representing terms in power formulas for confidence intervals and equivalence tests:

$$Q_\nu(t, \delta; a, b) = \frac{\sqrt{2\pi}}{\Gamma(\frac{\nu}{2})2^{\frac{\nu-2}{2}}} \int_a^b \Phi\left(\frac{tx}{\sqrt{\nu}} - \delta\right) x^{\nu-1}\phi(x)\mathrm{d}x$$

where $\phi(\cdot)$ and $\Phi(\cdot)$ are the density and cumulative distribution function of the standard normal distribution, respectively.

Analyses in the LOGISTIC Statement

Likelihood Ratio Chi-Square Test for One Predictor (TEST=LRCHI)

The power computing formula is based on Shieh and O'Brien (1998), Shieh (2000), and Self, Mauritsen, and Ohara (1992).

Define the following notation for a logistic regression analysis:

$$
\begin{aligned}
N &= \text{\# subjects} \quad \text{(NTOTAL)} \\
K &= \text{\# predictors (not counting intercept)} \\
\mathbf{x} &= (x_1, \ldots, x_K)' = \text{ random variables for predictor vector} \\
\boldsymbol{\mu} &= (\mu_1, \ldots, \mu_K)' = \mathrm{E}\mathbf{x} = \text{ mean predictor vector} \\
\mathbf{x}_i &= (x_{i1}, \ldots, x_{iK})' = \text{ predictor vector for subject } i \quad (i \in 1, \ldots, N) \\
Y &= \text{ random variable for response (0 or 1)} \\
Y_i &= \text{ response for subject } i \quad (i \in 1, \ldots, N) \\
p_i &= \mathrm{Prob}(Y_i = 1 | \mathbf{x}_i) \quad (i \in 1, \ldots, N) \\
\phi &= \mathrm{Prob}(Y_i = 1 | \mathbf{x}_i = \boldsymbol{\mu}) \quad \text{(RESPONSEPROB)} \\
U_j &= \text{ unit change for } j\text{th predictor} \quad \text{(UNITS)} \\
\mathrm{OR}_j &= \mathrm{Odds}(Y_i = 1 | x_{ij} = c)/\mathrm{Odds}(Y_i = 1 | x_{ij} = c - U_j) \quad (c \text{ arbitrary}, i \in 1, \ldots, N, \\
&\qquad j \in 1, \ldots, K) \quad \text{(TESTODDSRATIO if } j = 1, \text{ COVODDSRATIOS if } j > 1) \\
\Psi_0 &= \text{ intercept in full model} \quad \text{(INTERCEPT)} \\
\boldsymbol{\Psi} &= (\Psi_1, \ldots, \Psi_K)' = \text{ regression coefficients in full model} \\
&\qquad (\Psi_1 = \text{TESTREGCOEFF, others = COVREGCOEFFS}) \\
c_j &= \text{\# distinct possible values of } x_{ij} \quad (j \in 1, \ldots, K) \text{ (for any } i) \quad \text{(NBINS)} \\
x^{\star}_{gj} &= g\text{th possible value of } x_{ij} \quad (g \in 1, \ldots, c_j)\ (j \in 1, \ldots, K) \\
&\qquad \text{(for any } i) \quad \text{(VARDIST)} \\
\pi_{gj} &= \mathrm{Prob}\left(x_{ij} = x^{\star}_{gj}\right) \quad (g \in 1, \ldots, c_j)\ (j \in 1, \ldots, K) \\
&\qquad \text{(for any } i) \quad \text{(VARDIST)} \\
C &= \prod_{j=1}^{K} c_j = \text{ \# possible values of } \mathbf{x}_i \quad \text{(for any } i) \\
\mathbf{x}^{\star}_m &= m\text{th possible value of } \mathbf{x}_i \quad (m \in 1, \ldots, C) \\
\pi_m &= \mathrm{Prob}\left(\mathbf{x}_i = \mathbf{x}^{\star}_m\right) \quad (m \in 1, \ldots, C)
\end{aligned}
$$

The logistic regression model is

$$\log\left(\frac{p_i}{1 - p_i}\right) = \Psi_0 + \boldsymbol{\Psi}'\mathbf{x}_i$$

The hypothesis test of the first predictor variable is

$$
\begin{aligned}
H_0&: \Psi_1 = 0 \\
H_1&: \Psi_1 \neq 0
\end{aligned}
$$

Assuming independence among all predictor variables, π_m is defined as follows:

$$\pi_m = \prod_{j=1}^{K} \pi_{h(m,j)j} \quad (m \in 1, \ldots, C)$$

where $h(m, j)$ is calculated according to the following algorithm:

$z = m;$
do $j = K$ to 1;
  $h(m, j) = \text{mod}(z - 1, c_j) + 1;$
  $z = \text{floor}((z - 1)/c_j) + 1;$
end;

This algorithm causes the elements of the transposed vector $\{h(m, 1), \ldots, h(m, K)\}$ to vary fastest to slowest from right to left as m increases, as shown in the following table of $h(m, j)$ values:

		j				
$h(m, j)$	1	2	$\cdots$	$K-1$	K
1	1	1	$\cdots$	1	1
1	1	1	$\cdots$	1	2
$\vdots$			$\vdots$		
$\vdots$	1	1	$\cdots$	1	c_K
$\vdots$	1	1	$\cdots$	2	1
$\vdots$	1	1	$\cdots$	2	2
$\vdots$			$\vdots$		
m $\vdots$	1	1	$\cdots$	2	c_K
$\vdots$			$\vdots$		
$\vdots$	c_1	c_2	$\cdots$	c_{K-1}	1
$\vdots$	c_1	c_2	$\cdots$	c_{K-1}	2
$\vdots$			$\vdots$		
C	c_1	c_2	$\cdots$	c_{K-1}	c_K

The $\mathbf{x}^{\star}_m$ values are determined in a completely analogous manner.

The discretization is handled as follows (unless the distribution is ordinal, or binomial with sample size parameter at least as large as requested number of bins): for x_j, generate c_j quantiles at evenly spaced probability values such that each such quantile is at the midpoint of a bin with probability $\frac{1}{c_j}$. In other words,

$$x^{\star}_{gj} = \left(\frac{g - 0.5}{c_j}\right) \text{th quantile of relevant distribution,}$$
$$(g \in 1, \ldots, c_j)(j \in 1, \ldots, K)$$
$$\pi_{gj} = \frac{1}{c_j} \quad \text{(same for all } g\text{)}$$

The primary noncentrality for the power computation is

$$\Delta^{\star} = 2 \sum_{m=1}^{C} \pi_m \left[b'(\theta_m) \left(\theta_m - \theta^{\star}_m\right) - \left(b(\theta_m) - b(\theta^{\star}_m)\right)\right]$$

where

$$b'(\theta) = \frac{\exp(\theta)}{1+\exp(\theta)}$$
$$b(\theta) = \log\left(1+\exp(\theta)\right)$$
$$\theta_m = \Psi_0 + \boldsymbol{\Psi}'\mathbf{x}^{\star}_m$$
$$\theta^{\star}_m = \Psi^{\star}_0 + \boldsymbol{\Psi}^{\star\prime}\mathbf{x}^{\star}_m$$

where

$$\Psi^{\star}_0 = \Psi_0 + \Psi_1\mu_1 = \text{ intercept in reduced model, absorbing the tested predictor}$$
$$\boldsymbol{\Psi}^{\star} = (0, \Psi_2, \ldots, \Psi_K)' = \text{ coefficients in reduced model}$$

The power is

$$\text{power} = P\left(\chi^2(1, \Delta^{\star}N) \geq \chi^2_{1-\alpha}(1)\right)$$

Alternative input parameterizations are handled by the following transformations:

$$\Psi_0 = \log\left(\frac{\phi}{1-\phi}\right) - \boldsymbol{\Psi}'\boldsymbol{\mu}$$
$$\Psi_j = \frac{\log(\text{OR}_j)}{U_j} \quad (j \in 1, \ldots, K)$$

Analyses in the MULTREG Statement

Type III F Test in Multiple Regression (TEST=TYPE3)

Maxwell (2000) discusses a number of different ways to represent effect sizes (and to compute exact power based on them) in multiple regression. PROC POWER supports two of these, multiple partial correlation and R^2 in full and reduced models.

Let p denote the total number of predictors in the full model (excluding the intercept), and let Y denote the response variable. You are testing that the coefficients of $p_1 \geq 1$ predictors in a set X_1 are 0, controlling for all of the other predictors X_{-1}, which consists of $p - p_1 \geq 0$ variables.

The hypotheses can be expressed in two different ways. The first is in terms of $\rho_{YX_1|X_{-1}}$, the multiple partial correlation between the predictors in X_1 and the response Y adjusting for the predictors in X_{-1}:

$$H_0{:}\rho^2_{YX_1|X_{-1}} = 0$$
$$H_1{:}\rho^2_{YX_1|X_{-1}} > 0$$

The second is in terms of the multiple correlations in full ($\rho_{Y|(X_1,X_{-1})}$) and reduced ($\rho_{Y|X_{-1}}$) nested models:

$$H_0{:}\rho^2_{Y|(X_1,X_{-1})} - \rho^2_{Y|X_{-1}} = 0$$
$$H_1{:}\rho^2_{Y|(X_1,X_{-1})} - \rho^2_{Y|X_{-1}} > 0$$

Note that the squared values of $\rho_{Y|(X_1,X_{-1})}$ and $\rho_{Y|X_{-1}}$ are the population R^2 values for full and reduced models.

The test statistic can be written in terms of the sample multiple partial correlation $R_{YX_1|X_{-1}}$,

$$F = \begin{cases} (N-1-p)\frac{R^2_{YX_1|X_{-1}}}{1-R^2_{YX_1|X_{-1}}}, & \text{intercept} \\ (N-p)\frac{R^2_{YX_1|X_{-1}}}{1-R^2_{YX_1|X_{-1}}}, & \text{no intercept} \end{cases}$$

or the sample multiple correlations in full ($R_{Y|(X_1,X_{-1})}$) and reduced ($R_{Y|X_{-1}}$) models,

$$F = \begin{cases} (N-1-p)\frac{R^2_{Y|(X_1,X_{-1})}-R^2_{Y|X_{-1}}}{1-R^2_{Y|(X_1,X_{-1})}}, & \text{intercept} \\ (N-p)\frac{R^2_{Y|(X_1,X_{-1})}-R^2_{Y|X_{-1}}}{1-R^2_{Y|(X_1,X_{-1})}}, & \text{no intercept} \end{cases}$$

The test is the usual Type III F test in multiple regression:

$$\text{Reject} \quad H_0 \quad \text{if} \begin{cases} F \geq F_{1-\alpha}(p_1, N-1-p), & \text{intercept} \\ F \geq F_{1-\alpha}(p_1, N-p), & \text{no intercept} \end{cases}$$

Although the test is invariant to whether the predictors are assumed to be random or fixed, the power is affected by this assumption. If the response and predictors are assumed to have a joint multivariate normal distribution, then the exact power is given by the following formula:

$$\begin{aligned} \text{power} &= \begin{cases} P\left[\left(\frac{N-1-p}{p_1}\right)\left(\frac{R^2_{Y|(X_1,X_{-1})}}{1-R^2_{Y|(X_1,X_{-1})}}\right) \geq F_{1-\alpha}(p_1, N-1-p)\right], & \text{intercept} \\ P\left[\left(\frac{N-p}{p_1}\right)\left(\frac{R^2_{Y|(X_1,X_{-1})}}{1-R^2_{Y|(X_1,X_{-1})}}\right) \geq F_{1-\alpha}(p_1, N-p)\right], & \text{no intercept} \end{cases} \\ &= \begin{cases} P\left[R^2_{Y|(X_1,X_{-1})} \geq \frac{F_{1-\alpha}(p_1,N-1-p)}{F_{1-\alpha}(p_1,N-1-p)+\frac{N-1-p}{p_1}}\right], & \text{intercept} \\ P\left[R^2_{Y|(X_1,X_{-1})} \geq \frac{F_{1-\alpha}(p_1,N-p)}{F_{1-\alpha}(p_1,N-p)+\frac{N-p}{p_1}}\right], & \text{no intercept} \end{cases} \end{aligned}$$

The distribution of $R^2_{Y|(X_1,X_{-1})}$ (for any $\rho^2_{Y|(X_1,X_{-1})}$) is given in Chapter 32 of Johnson, Kotz, and Balakrishnan (1995). Sample size tables are presented in Gatsonis and Sampson (1989).

If the predictors are assumed to have fixed values, then the exact power is given by the noncentral F distribution. The noncentrality parameter is

$$\lambda = N\frac{\rho^2_{YX_1|X_{-1}}}{1-\rho^2_{YX_1|X_{-1}}}$$

or equivalently,

$$\lambda = N\frac{\rho^2_{Y|(X_1,X_{-1})}-\rho^2_{Y|X_{-1}}}{1-\rho^2_{Y|(X_1,X_{-1})}}$$

The power is

$$\text{power} = \begin{cases} P\left(F(p_1, N-1-p, \lambda) \geq F_{1-\alpha}(p_1, N-1-p)\right), & \text{intercept} \\ P\left(F(p_1, N-p, \lambda) \geq F_{1-\alpha}(p_1, N-p)\right), & \text{no intercept} \end{cases}$$

The minimum acceptable input value of N depends on several factors, as shown in Table 70.30.

Table 70.30 Minimum Acceptable Sample Size Values in the MULTREG Statement

Predictor Type	Intercept in Model?	$p_1 = 1$?	Minimum N
Random	Yes	Yes	$p+3$
Random	Yes	No	$p+2$
Random	No	Yes	$p+2$
Random	No	No	$p+1$
Fixed	Yes	Yes or No	$p+2$
Fixed	No	Yes or No	$p+1$

Analyses in the ONECORR Statement

Fisher's z Test for Pearson Correlation (TEST=PEARSON DIST=FISHERZ)

Fisher's z transformation (Fisher 1921) of the sample correlation $R_{Y|(X_1,X_{-1})}$ is defined as

$$z = \frac{1}{2}\log\left(\frac{1+R_{Y|(X_1,X_{-1})}}{1-R_{Y|(X_1,X_{-1})}}\right)$$

Fisher's z test assumes the approximate normal distribution $N(\mu, \sigma^2)$ for z, where

$$\mu = \frac{1}{2}\log\left(\frac{1+\rho_{Y|(X_1,X_{-1})}}{1-\rho_{Y|(X_1,X_{-1})}}\right) + \frac{\rho_{Y|(X_1,X_{-1})}}{2(N-1-p^\star)}$$

and

$$\sigma^2 = \frac{1}{N-3-p^\star}$$

where $p^\star$ is the number of variables partialed out (Anderson 1984, pp. 132–133) and $\rho_{Y|(X_1,X_{-1})}$ is the partial correlation between Y and X_1 adjusting for the set of zero or more variables X_{-1}.

The test statistic

$$z^\star = (N-3-p^\star)^{\frac{1}{2}}\left[z - \frac{1}{2}\log\left(\frac{1+\rho_0}{1-\rho_0}\right) - \frac{\rho_0}{2(N-1-p^\star)}\right]$$

is assumed to have a normal distribution $N(\delta, \nu)$, where ρ_0 is the null partial correlation and δ and ν are derived from Section 16.33 of Stuart and Ord (1994):

$$\delta = (N-3-p^\star)^{\frac{1}{2}}\left[\frac{1}{2}\log\left(\frac{1+\rho_{Y|(X_1,X_{-1})}}{1-\rho_{Y|(X_1,X_{-1})}}\right)+\frac{\rho_{Y|(X_1,X_{-1})}}{2(N-1-p^\star)}\left(1+\frac{5+\rho^2_{Y|(X_1,X_{-1})}}{4(N-1-p^\star)}+\frac{11+2\rho^2_{Y|(X_1,X_{-1})}+3\rho^4_{Y|(X_1,X_{-1})}}{8(N-1-p^\star)^2}\right)-\frac{1}{2}\log\left(\frac{1+\rho_0}{1-\rho_0}\right)-\frac{\rho_0}{2(N-1-p^\star)}\right]$$

$$\nu = \frac{N-3-p^\star}{N-1-p^\star}\left[1+\frac{4-\rho^2_{Y|(X_1,X_{-1})}}{2(N-1-p^\star)}+\frac{22-6\rho^2_{Y|(X_1,X_{-1})}-3\rho^4_{Y|(X_1,X_{-1})}}{6(N-1-p^\star)^2}\right]$$

The approximate power is computed as

$$\text{power} = \begin{cases} \Phi\left(\frac{\delta - z_{1-\alpha}}{\nu^{\frac{1}{2}}}\right), & \text{upper one-sided} \\ \Phi\left(\frac{-\delta - z_{1-\alpha}}{\nu^{\frac{1}{2}}}\right), & \text{lower one-sided} \\ \Phi\left(\frac{\delta - z_{1-\frac{\alpha}{2}}}{\nu^{\frac{1}{2}}}\right) + \Phi\left(\frac{-\delta - z_{1-\frac{\alpha}{2}}}{\nu^{\frac{1}{2}}}\right), & \text{two-sided} \end{cases}$$

Because the test is biased, the achieved significance level might differ from the nominal significance level. The actual alpha is computed in the same way as the power except with the correlation $\rho_{Y|(X_1,X_{-1})}$ replaced by the null correlation ρ_0.

t *Test for Pearson Correlation (TEST=PEARSON DIST=T)*

The two-sided case is identical to multiple regression with an intercept and $p_1 = 1$, which is discussed in the section "Analyses in the MULTREG Statement" on page 5845.

Let $p^\star$ denote the number of variables partialed out. For the one-sided cases, the test statistic is

$$t = (N-2-p^\star)^{\frac{1}{2}}\frac{R_{YX_1|X_{-1}}}{\left(1-R^2_{YX_1|X_{-1}}\right)^{\frac{1}{2}}}$$

which is assumed to have a null distribution of $t(N-2-p^\star)$.

If the X and Y variables are assumed to have a joint multivariate normal distribution, then the exact power is given by the following formula:

$$\text{power} = \begin{cases} P\left[\dfrac{(N-2-p^\star)^{\frac{1}{2}} R_{YX_1|X_{-1}}}{\left(1-R^2_{YX_1|X_{-1}}\right)^{\frac{1}{2}}} \geq t_{1-\alpha}(N-2-p^\star)\right], & \text{upper one-sided} \\ P\left[\dfrac{(N-2-p^\star)^{\frac{1}{2}} R_{YX_1|X_{-1}}}{\left(1-R^2_{YX_1|X_{-1}}\right)^{\frac{1}{2}}} \leq t_{\alpha}(N-2-p^\star)\right], & \text{lower one-sided} \end{cases}$$

$$= \begin{cases} P\left[R_{Y|(X_1,X_{-1})} \geq \dfrac{t_{1-\alpha}(N-2-p^\star)}{\left(t^2_{1-\alpha}(N-2-p^\star)+N-2-p^\star\right)^{\frac{1}{2}}}\right], & \text{upper one-sided} \\ P\left[R_{Y|(X_1,X_{-1})} \leq \dfrac{t_{\alpha}(N-2-p^\star)}{\left(t^2_{\alpha}(N-2-p^\star)+N-2-p^\star\right)^{\frac{1}{2}}}\right], & \text{lower one-sided} \end{cases}$$

The distribution of $R_{Y|(X_1,X_{-1})}$ (given the underlying true correlation $\rho_{Y|(X_1,X_{-1})}$) is given in Chapter 32 of Johnson, Kotz, and Balakrishnan (1995).

If the X variables are assumed to have fixed values, then the exact power is given by the noncentral t distribution $t(N-2-p^\star, \delta)$, where the noncentrality is

$$\delta = N^{\frac{1}{2}} \frac{\rho_{YX_1|X_{-1}}}{\left(1-\rho^2_{YX_1|X_{-1}}\right)^{\frac{1}{2}}}$$

The power is

$$\text{power} = \begin{cases} P\left(t(N-2-p^\star, \delta) \geq t_{1-\alpha}(N-2-p^\star)\right), & \text{upper one-sided} \\ P\left(t(N-2-p^\star, \delta) \leq t_{\alpha}(N-2-p^\star)\right), & \text{lower one-sided} \end{cases}$$

Analyses in the ONESAMPLEFREQ Statement

Exact Test of a Binomial Proportion (TEST=EXACT)

Let X be distributed as Bin(N, p). The hypotheses for the test of the proportion p are as follows:

$$H_0: p = p_0$$

$$H_1: \begin{cases} p \neq p_0, & \text{two-sided} \\ p > p_0, & \text{upper one-sided} \\ p < p_0, & \text{lower one-sided} \end{cases}$$

The exact test assumes binomially distributed data and requires $N \geq 1$ and $0 < p_0 < 1$. The test statistic is

$$X = \text{number of successes} \sim \text{Bin}(N, p)$$

The significance probability α is split symmetrically for two-sided tests, in the sense that each tail is filled with as much as possible up to $\alpha/2$.

Exact power computations are based on the binomial distribution and computing formulas such as the following from Johnson, Kotz, and Kemp (1992, equation 3.20):

$$P(X \geq C|N,p) = P\left(F_{\nu_1,\nu_2} \leq \frac{\nu_2 p}{\nu_1(1-p)}\right) \quad \text{where } \nu_1 = 2C \text{ and } \nu_2 = 2(N-C+1)$$

Let C_L and C_U denote lower and upper critical values, respectively. Let α_a denote the achieved (actual) significance level, which for two-sided tests is the sum of the favorable major tail (α_M) and the opposite minor tail (α_m).

For the upper one-sided case,

$$\begin{aligned} C_U &= \min\{C : P(X \geq C|p_0) \leq \alpha\} \\ \text{Reject } H_0 \text{ if } & X \geq C_U \\ \alpha_a &= P(X \geq C_U|p_0) \\ \text{power} &= P(X \geq C_U|p) \end{aligned}$$

For the lower one-sided case,

$$\begin{aligned} C_L &= \max\{C : P(X \leq C|p_0) \leq \alpha\} \\ \text{Reject } H_0 \text{ if } & X \leq C_L \\ \alpha_a &= P(X \leq C_L|p_0) \\ \text{power} &= P(X \leq C_L|p) \end{aligned}$$

For the two-sided case,

$$\begin{aligned} C_L &= \max\{C : P(X \leq C|p_0) \leq \frac{\alpha}{2}\} \\ C_U &= \min\{C : P(X \geq C|p_0) \leq \frac{\alpha}{2}\} \\ \text{Reject } H_0 \text{ if } & X \leq C_L \text{ or } X \geq C_U \\ \alpha_a &= P(X \leq C_L \text{ or } X \geq C_U|p_0) \\ \text{power} &= P(X \leq C_L \text{ or } X \geq C_U|p) \end{aligned}$$

z Test for Binomial Proportion Using Null Variance (TEST=Z VAREST=NULL)

For the normal approximation test, the test statistic is

$$Z(X) = \frac{X - Np_0}{[Np_0(1-p_0)]^{\frac{1}{2}}}$$

For the METHOD=EXACT option, the computations are the same as described in the section "Exact Test of a Binomial Proportion (TEST=EXACT)" on page 5849 except for the definitions of the critical values.

For the upper one-sided case,

$$C_U = \min\{C : Z(C) \geq z_{1-\alpha}\}$$

For the lower one-sided case,

$$C_L = \max\{C : Z(C) \leq z_\alpha\}$$

For the two-sided case,

$$C_L = \max\{C : Z(C) \leq z_{\frac{\alpha}{2}}\}$$
$$C_U = \min\{C : Z(C) \geq z_{1-\frac{\alpha}{2}}\}$$

For the METHOD=NORMAL option, the test statistic $Z(X)$ is assumed to have the normal distribution

$$\mathrm{N}\left(\frac{N^{\frac{1}{2}}(p-p_0)}{[p_0(1-p_0)]^{\frac{1}{2}}}, \frac{p(1-p)}{p_0(1-p_0)}\right)$$

The approximate power is computed as

$$\text{power} = \begin{cases} \Phi\left(\dfrac{z_\alpha + \sqrt{N}\frac{p-p_0}{\sqrt{p_0(1-p_0)}}}{\sqrt{\frac{p(1-p)}{p_0(1-p_0)}}}\right), & \text{upper one-sided} \\ \Phi\left(\dfrac{z_\alpha - \sqrt{N}\frac{p-p_0}{\sqrt{p_0(1-p_0)}}}{\sqrt{\frac{p(1-p)}{p_0(1-p_0)}}}\right), & \text{lower one-sided} \\ \Phi\left(\dfrac{z_{\frac{\alpha}{2}} + \sqrt{N}\frac{p-p_0}{\sqrt{p_0(1-p_0)}}}{\sqrt{\frac{p(1-p)}{p_0(1-p_0)}}}\right) + \Phi\left(\dfrac{z_{\frac{\alpha}{2}} - \sqrt{N}\frac{p-p_0}{\sqrt{p_0(1-p_0)}}}{\sqrt{\frac{p(1-p)}{p_0(1-p_0)}}}\right), & \text{two-sided} \end{cases}$$

The approximate sample size is computed in closed form for the one-sided cases by inverting the power equation,

$$N = \left(\frac{z_{\text{power}}\sqrt{p(1-p)} + z_{1-\alpha}\sqrt{p_0(1-p_0)}}{p-p_0}\right)^2$$

and by numerical inversion for the two-sided case.

z Test for Binomial Proportion Using Sample Variance (TEST=Z VAREST=SAMPLE)

For the normal approximation test using the sample variance, the test statistic is

$$Z_s(X) = \frac{X - Np_0}{[N\hat{p}(1-\hat{p})]^{\frac{1}{2}}}$$

where $\hat{p} = X/N$.

For the METHOD=EXACT option, the computations are the same as described in the section "Exact Test of a Binomial Proportion (TEST=EXACT)" on page 5849 except for the definitions of the critical values.

For the upper one-sided case,

$$C_U = \min\{C : Z_s(C) \geq z_{1-\alpha}\}$$

For the lower one-sided case,

$$C_L = \max\{C : Z_s(C) \leq z_{\alpha}\}$$

For the two-sided case,

$$C_L = \max\{C : Z_s(C) \leq z_{\frac{\alpha}{2}}\}$$
$$C_U = \min\{C : Z_s(C) \geq z_{1-\frac{\alpha}{2}}\}$$

For the METHOD=NORMAL option, the test statistic $Z_s(X)$ is assumed to have the normal distribution

$$\mathrm{N}\left(\frac{N^{\frac{1}{2}}(p-p_0)}{[p(1-p)]^{\frac{1}{2}}}, 1\right)$$

(see Chow, Shao, and Wang (2003), p. 82).

The approximate power is computed as

$$\text{power} = \begin{cases} \Phi\left(z_\alpha + \sqrt{N}\frac{p-p_0}{\sqrt{p(1-p)}}\right), & \text{upper one-sided} \\ \Phi\left(z_\alpha - \sqrt{N}\frac{p-p_0}{\sqrt{p(1-p)}}\right), & \text{lower one-sided} \\ \Phi\left(z_{\frac{\alpha}{2}} + \sqrt{N}\frac{p-p_0}{\sqrt{p(1-p)}}\right) + \Phi\left(z_{\frac{\alpha}{2}} - \sqrt{N}\frac{p-p_0}{\sqrt{p(1-p)}}\right), & \text{two-sided} \end{cases}$$

The approximate sample size is computed in closed form for the one-sided cases by inverting the power equation,

$$N = p(1-p)\left(\frac{z_{\text{power}} + z_{1-\alpha}}{p-p_0}\right)^2$$

and by numerical inversion for the two-sided case.

z Test for Binomial Proportion with Continuity Adjustment Using Null Variance (TEST=ADJZ VAREST=NULL)

For the normal approximation test with continuity adjustment, the test statistic is (Pagano and Gauvreau 1993 p. 295):

$$Z_c(X) = \frac{X - Np_0 + 0.5(1_{\{X<Np_0\}}) - 0.5(1_{\{X>Np_0\}})}{[Np_0(1-p_0)]^{\frac{1}{2}}}$$

For the METHOD=EXACT option, the computations are the same as described in the section "Exact Test of a Binomial Proportion (TEST=EXACT)" on page 5849 except for the definitions of the critical values.

For the upper one-sided case,

$$C_U = \min\{C : Z_c(C) \geq z_{1-\alpha}\}$$

For the lower one-sided case,

$$C_L = \max\{C : Z_c(C) \leq z_{\alpha}\}$$

For the two-sided case,

$$C_L = \max\{C : Z_c(C) \leq z_{\frac{\alpha}{2}}\}$$
$$C_U = \min\{C : Z_c(C) \geq z_{1-\frac{\alpha}{2}}\}$$

For the METHOD=NORMAL option, the test statistic $Z_c(X)$ is assumed to have the normal distribution $N(\mu, \sigma^2)$, where μ and σ^2 are derived as follows.

For convenience of notation, define

$$k = \frac{1}{2\sqrt{Np_0(1-p_0)}}$$

Then

$$E\left[Z_c(X)\right] = 2kNp - 2kNp_0 + kP(X < Np_0) - kP(X > Np_0)$$

and

$$\begin{aligned}\mathrm{Var}\left[Z_c(X)\right] = {} & 4k^2Np(1-p) + k^2\left[1 - P(X = Np_0)\right] - k^2\left[P(X < Np_0) - P(X > Np_0)\right]^2 \\ & + 4k^2\left[E\left(X1_{\{X<Np_0\}}\right) - E\left(X1_{\{X>Np_0\}}\right)\right] - 4k^2Np\left[P(X < Np_0) - P(X > Np_0)\right]\end{aligned}$$

The probabilities $P(X = Np_0)$, $P(X < Np_0)$, and $P(X > Np_0)$ and the truncated expectations $E\left(X1_{\{X<Np_0\}}\right)$ and $E\left(X1_{\{X>Np_0\}}\right)$ are approximated by assuming the normal-approximate distribution of X, $N(Np, Np(1-p))$. Letting $\phi(\cdot)$ and $\Phi(\cdot)$ denote the standard normal PDF and CDF, respectively, and defining d as

$$d = \frac{Np_0 - Np}{[Np(1-p)]^{\frac{1}{2}}}$$

the terms are computed as follows:

$$\begin{aligned}P(X = Np_0) &= 0 \\ P(X < Np_0) &= \Phi(d) \\ P(X > Np_0) &= 1 - \Phi(d) \\ E\left(X1_{\{X<Np_0\}}\right) &= Np\Phi(d) - [Np(1-p)]^{\frac{1}{2}}\phi(d) \\ E\left(X1_{\{X>Np_0\}}\right) &= Np\left[1 - \Phi(d)\right] + [Np(1-p)]^{\frac{1}{2}}\phi(d)\end{aligned}$$

The mean and variance of $Z_c(X)$ are thus approximated by

$$\mu = k\left[2Np - 2Np_0 + 2\Phi(d) - 1\right]$$

and

$$\sigma^2 = 4k^2\left[Np(1-p) + \Phi(d)\left(1-\Phi(d)\right) - 2\left(Np(1-p)\right)^{\frac{1}{2}}\phi(d)\right]$$

The approximate power is computed as

$$\text{power} = \begin{cases} \Phi\left(\frac{z_\alpha+\mu}{\sigma}\right), & \text{upper one-sided} \\ \Phi\left(\frac{z_\alpha-\mu}{\sigma}\right), & \text{lower one-sided} \\ \Phi\left(\frac{z_{\frac{\alpha}{2}}+\mu}{\sigma}\right) + \Phi\left(\frac{z_{\frac{\alpha}{2}}-\mu}{\sigma}\right), & \text{two-sided} \end{cases}$$

The approximate sample size is computed by numerical inversion.

z Test for Binomial Proportion with Continuity Adjustment Using Sample Variance (TEST=ADJZ VAREST=SAMPLE)

For the normal approximation test with continuity adjustment using the sample variance, the test statistic is

$$Z_{cs}(X) = \frac{X - Np_0 + 0.5(1_{\{X<Np_0\}}) - 0.5(1_{\{X>Np_0\}})}{\left[N\hat{p}(1-\hat{p})\right]^{\frac{1}{2}}}$$

where $\hat{p} = X/N$.

For the METHOD=EXACT option, the computations are the same as described in the section "Exact Test of a Binomial Proportion (TEST=EXACT)" on page 5849 except for the definitions of the critical values.

For the upper one-sided case,

$$C_U = \min\{C : Z_{cs}(C) \geq z_{1-\alpha}\}$$

For the lower one-sided case,

$$C_L = \max\{C : Z_{cs}(C) \leq z_\alpha\}$$

For the two-sided case,

$$C_L = \max\{C : Z_{cs}(C) \leq z_{\frac{\alpha}{2}}\}$$
$$C_U = \min\{C : Z_{cs}(C) \geq z_{1-\frac{\alpha}{2}}\}$$

For the METHOD=NORMAL option, the test statistic $Z_{cs}(X)$ is assumed to have the normal distribution $N(\mu, \sigma^2)$, where μ and σ^2 are derived as follows.

For convenience of notation, define

$$k = \frac{1}{2\sqrt{Np(1-p)}}$$

Then

$$E\left[Z_{cs}(X)\right] \approx 2kNp - 2kNp_0 + kP(X < Np_0) - kP(X > Np_0)$$

and

$$\begin{aligned}\mathrm{Var}\left[Z_{cs}(X)\right] \approx {} & 4k^2Np(1-p) + k^2\left[1 - P(X = Np_0)\right] - k^2\left[P(X < Np_0) - P(X > Np_0)\right]^2 \\ & + 4k^2\left[E\left(X1_{\{X<Np_0\}}\right) - E\left(X1_{\{X>Np_0\}}\right)\right] - 4k^2Np\left[P(X < Np_0) - P(X > Np_0)\right]\end{aligned}$$

The probabilities $P(X = Np_0)$, $P(X < Np_0)$, and $P(X > Np_0)$ and the truncated expectations $E\left(X1_{\{X<Np_0\}}\right)$ and $E\left(X1_{\{X>Np_0\}}\right)$ are approximated by assuming the normal-approximate distribution of X, $N(Np, Np(1-p))$. Letting $\phi(\cdot)$ and $\Phi(\cdot)$ denote the standard normal PDF and CDF, respectively, and defining d as

$$d = \frac{Np_0 - Np}{[Np(1-p)]^{\frac{1}{2}}}$$

the terms are computed as follows:

$$\begin{aligned}P(X = Np_0) &= 0 \\ P(X < Np_0) &= \Phi(d) \\ P(X > Np_0) &= 1 - \Phi(d) \\ E\left(X1_{\{X<Np_0\}}\right) &= Np\Phi(d) - [Np(1-p)]^{\frac{1}{2}}\phi(d) \\ E\left(X1_{\{X>Np_0\}}\right) &= Np\left[1 - \Phi(d)\right] + [Np(1-p)]^{\frac{1}{2}}\phi(d)\end{aligned}$$

The mean and variance of $Z_{cs}(X)$ are thus approximated by

$$\mu = k\left[2Np - 2Np_0 + 2\Phi(d) - 1\right]$$

and

$$\sigma^2 = 4k^2\left[Np(1-p) + \Phi(d)\left(1 - \Phi(d)\right) - 2\left(Np(1-p)\right)^{\frac{1}{2}}\phi(d)\right]$$

The approximate power is computed as

$$\text{power} = \begin{cases} \Phi\left(\frac{z_\alpha + \mu}{\sigma}\right), & \text{upper one-sided} \\ \Phi\left(\frac{z_\alpha - \mu}{\sigma}\right), & \text{lower one-sided} \\ \Phi\left(\frac{z_{\frac{\alpha}{2}} + \mu}{\sigma}\right) + \Phi\left(\frac{z_{\frac{\alpha}{2}} - \mu}{\sigma}\right), & \text{two-sided} \end{cases}$$

The approximate sample size is computed by numerical inversion.

Exact Equivalence Test of a Binomial Proportion (TEST=EQUIV_EXACT)

The hypotheses for the equivalence test are

$$H_0: p < \theta_L \quad \text{or} \quad p > \theta_U$$
$$H_1: \theta_L \leq p \leq \theta_U$$

where θ_L and θ_U are the lower and upper equivalence bounds, respectively.

The analysis is the two one-sided tests (TOST) procedure as described in Chow, Shao, and Wang (2003) on p. 84, but using exact critical values as on p. 116 instead of normal-based critical values.

Two different hypothesis tests are carried out:

$$H_{a0}: p < \theta_L$$
$$H_{a1}: p \geq \theta_L$$

and

$$H_{b0}: p > \theta_U$$
$$H_{b1}: p \leq \theta_U$$

If H_{a0} is rejected in favor of H_{a1} *and* H_{b0} is rejected in favor of H_{b1}, then H_0 is rejected in favor of H_1.

The test statistic for each of the two tests (H_{a0} versus H_{a1} and H_{b0} versus H_{b1}) is

$$X = \text{number of successes} \sim \text{Bin}(N, p)$$

Let C_U denote the critical value of the exact upper one-sided test of H_{a0} versus H_{a1}, and let C_L denote the critical value of the exact lower one-sided test of H_{b0} versus H_{b1}. These critical values are computed in the section "Exact Test of a Binomial Proportion (TEST=EXACT)" on page 5849. Both of these tests are rejected if and only if $C_U \leq X \leq C_L$. Thus, the exact power of the equivalence test is

$$\begin{aligned} \text{power} &= P\left(C_U \leq X \leq C_L\right) \\ &= P\left(X \geq C_U\right) - P\left(X \geq C_L + 1\right) \end{aligned}$$

The probabilities are computed using Johnson and Kotz (1970, equation 3.20).

z Equivalence Test for Binomial Proportion Using Null Variance (TEST=EQUIV_Z VAREST=NULL)

The hypotheses for the equivalence test are

$$H_0: p < \theta_L \quad \text{or} \quad p > \theta_U$$
$$H_1: \theta_L \leq p \leq \theta_U$$

where θ_L and θ_U are the lower and upper equivalence bounds, respectively.

The analysis is the two one-sided tests (TOST) procedure as described in Chow, Shao, and Wang (2003) on p. 84, but using the null variance instead of the sample variance.

Two different hypothesis tests are carried out:

$$H_{a0}: p < \theta_L$$
$$H_{a1}: p \geq \theta_L$$

and

$$H_{b0}: p > \theta_U$$
$$H_{b1}: p \leq \theta_U$$

If H_{a0} is rejected in favor of H_{a1} *and* H_{b0} is rejected in favor of H_{b1}, then H_0 is rejected in favor of H_1.

The test statistic for the test of H_{a0} versus H_{a1} is

$$Z_L(X) = \frac{X - N\theta_L}{[N\theta_L(1-\theta_L)]^{\frac{1}{2}}}$$

The test statistic for the test of H_{b0} versus H_{b1} is

$$Z_U(X) = \frac{X - N\theta_U}{[N\theta_U(1-\theta_U)]^{\frac{1}{2}}}$$

For the METHOD=EXACT option, let C_U denote the critical value of the exact upper one-sided test of H_{a0} versus H_{a1} using $Z_L(X)$. This critical value is computed in the section "z Test for Binomial Proportion Using Null Variance (TEST=Z VAREST=NULL)" on page 5850. Similarly, let C_L denote the critical value of the exact lower one-sided test of H_{b0} versus H_{b1} using $Z_U(X)$. Both of these tests are rejected if and only if $C_U \leq X \leq C_L$. Thus, the exact power of the equivalence test is

$$\begin{aligned}\text{power} &= P\left(C_U \leq X \leq C_L\right) \\ &= P\left(X \geq C_U\right) - P\left(X \geq C_L + 1\right)\end{aligned}$$

The probabilities are computed using Johnson and Kotz (1970, equation 3.20).

For the METHOD=NORMAL option, the test statistic $Z_L(X)$ is assumed to have the normal distribution

$$\mathrm{N}\left(\frac{N^{\frac{1}{2}}(p-\theta_L)}{[\theta_L(1-\theta_L)]^{\frac{1}{2}}}, \frac{p(1-p)}{\theta_L(1-\theta_L)}\right)$$

and the test statistic $Z_U(X)$ is assumed to have the normal distribution

$$\mathrm{N}\left(\frac{N^{\frac{1}{2}}(p-\theta_U)}{[\theta_U(1-\theta_U)]^{\frac{1}{2}}}, \frac{p(1-p)}{\theta_U(1-\theta_U)}\right)$$

(see Chow, Shao, and Wang (2003), p. 84).

The approximate power is computed as

$$\text{power} = \Phi\left(\frac{z_\alpha - \sqrt{N}\frac{p-\theta_U}{\sqrt{\theta_U(1-\theta_U)}}}{\sqrt{\frac{p(1-p)}{\theta_U(1-\theta_U)}}}\right) + \Phi\left(\frac{z_\alpha + \sqrt{N}\frac{p-\theta_L}{\sqrt{\theta_L(1-\theta_L)}}}{\sqrt{\frac{p(1-p)}{\theta_L(1-\theta_L)}}}\right) - 1$$

The approximate sample size is computed by numerically inverting the power formula, using the sample size estimate N_0 of Chow, Shao, and Wang (2003, p. 85) as an initial guess:

$$N_0 = p(1-p)\left(\frac{z_{1-\alpha} + z_{(1+\text{power})/2}}{0.5(\theta_U - \theta_L) - \mid p - 0.5(\theta_L + \theta_U) \mid}\right)^2$$

z Equivalence Test for Binomial Proportion Using Sample Variance (TEST=EQUIV_Z VAREST=SAMPLE)

The hypotheses for the equivalence test are

$$H_0: p < \theta_L \quad \text{or} \quad p > \theta_U$$
$$H_1: \theta_L \le p \le \theta_U$$

where θ_L and θ_U are the lower and upper equivalence bounds, respectively.

The analysis is the two one-sided tests (TOST) procedure as described in Chow, Shao, and Wang (2003) on p. 84.

Two different hypothesis tests are carried out:

$$H_{a0}: p < \theta_L$$
$$H_{a1}: p \ge \theta_L$$

and

$$H_{b0}: p > \theta_U$$
$$H_{b1}: p \le \theta_U$$

If H_{a0} is rejected in favor of H_{a1} *and* H_{b0} is rejected in favor of H_{b1}, then H_0 is rejected in favor of H_1.

The test statistic for the test of H_{a0} versus H_{a1} is

$$Z_{sL}(X) = \frac{X - N\theta_L}{[N\hat{p}(1-\hat{p})]^{\frac{1}{2}}}$$

where $\hat{p} = X/N$.

The test statistic for the test of H_{b0} versus H_{b1} is

$$Z_{sU}(X) = \frac{X - N\theta_U}{[N\hat{p}(1-\hat{p})]^{\frac{1}{2}}}$$

For the METHOD=EXACT option, let C_U denote the critical value of the exact upper one-sided test of H_{a0} versus H_{a1} using $Z_{sL}(X)$. This critical value is computed in the section "z Test for Binomial Proportion Using Sample Variance (TEST=Z VAREST=SAMPLE)" on page 5851. Similarly, let C_L denote the critical value of the exact lower one-sided test of H_{b0} versus H_{b1} using $Z_{sU}(X)$. Both of these tests are rejected if and only if $C_U \le X \le C_L$. Thus, the exact power of the equivalence test is

$$\begin{aligned}\text{power} &= P\left(C_U \le X \le C_L\right) \\ &= P\left(X \ge C_U\right) - P\left(X \ge C_L + 1\right)\end{aligned}$$

The probabilities are computed using Johnson and Kotz (1970, equation 3.20).

For the METHOD=NORMAL option, the test statistic $Z_{sL}(X)$ is assumed to have the normal distribution

$$\mathrm{N}\left(\frac{N^{\frac{1}{2}}(p-\theta_L)}{[p(1-p)]^{\frac{1}{2}}},1\right)$$

and the test statistic $Z_{sU}(X)$ is assumed to have the normal distribution

$$\mathrm{N}\left(\frac{N^{\frac{1}{2}}(p-\theta_U)}{[p(1-p)]^{\frac{1}{2}}},1\right)$$

(see Chow, Shao, and Wang (2003), p. 84).

The approximate power is computed as

$$\text{power} = \Phi\left(z_\alpha - \sqrt{N}\frac{p-\theta_U}{\sqrt{p(1-p)}}\right) + \Phi\left(z_\alpha + \sqrt{N}\frac{p-\theta_L}{\sqrt{p(1-p)}}\right) - 1$$

The approximate sample size is computed by numerically inverting the power formula, using the sample size estimate N_0 of Chow, Shao, and Wang (2003, p. 85) as an initial guess:

$$N_0 = p(1-p)\left(\frac{z_{1-\alpha} + z_{(1+\text{power})/2}}{0.5(\theta_U-\theta_L) - \mid p - 0.5(\theta_L+\theta_U)\mid}\right)^2$$

z Equivalence Test for Binomial Proportion with Continuity Adjustment Using Null Variance (TEST=EQUIV_ADJZ VAREST=NULL)

The hypotheses for the equivalence test are

$$H_0{:}p < \theta_L \quad \text{or} \quad p > \theta_U$$
$$H_1{:}\theta_L \le p \le \theta_U$$

where θ_L and θ_U are the lower and upper equivalence bounds, respectively.

The analysis is the two one-sided tests (TOST) procedure as described in Chow, Shao, and Wang (2003) on p. 84, but using the null variance instead of the sample variance.

Two different hypothesis tests are carried out:

$$H_{a0}{:}p < \theta_L$$
$$H_{a1}{:}p \ge \theta_L$$

and

$$H_{b0}{:}p > \theta_U$$
$$H_{b1}{:}p \le \theta_U$$

If H_{a0} is rejected in favor of H_{a1} *and* H_{b0} is rejected in favor of H_{b1}, then H_0 is rejected in favor of H_1.

The test statistic for the test of H_{a0} versus H_{a1} is

$$Z_{cL}(X) = \frac{X - N\theta_L + 0.5(1_{\{X<N\theta_L\}}) - 0.5(1_{\{X>N\theta_L\}})}{\left[N\hat{\theta_L}(1-\hat{\theta_L})\right]^{\frac{1}{2}}}$$

where $\hat{p} = X/N$.

The test statistic for the test of H_{b0} versus H_{b1} is

$$Z_{cU}(X) = \frac{X - N\theta_U + 0.5(1_{\{X<N\theta_U\}}) - 0.5(1_{\{X>N\theta_U\}})}{\left[N\hat{\theta_U}(1-\hat{\theta_U})\right]^{\frac{1}{2}}}$$

For the METHOD=EXACT option, let C_U denote the critical value of the exact upper one-sided test of H_{a0} versus H_{a1} using $Z_{cL}(X)$. This critical value is computed in the section "z Test for Binomial Proportion with Continuity Adjustment Using Null Variance (TEST=ADJZ VAREST=NULL)" on page 5852. Similarly, let C_L denote the critical value of the exact lower one-sided test of H_{b0} versus H_{b1} using $Z_{cU}(X)$. Both of these tests are rejected if and only if $C_U \le X \le C_L$. Thus, the exact power of the equivalence test is

$$\begin{aligned}\text{power} &= P\left(C_U \le X \le C_L\right) \\ &= P\left(X \ge C_U\right) - P\left(X \ge C_L + 1\right)\end{aligned}$$

The probabilities are computed using Johnson and Kotz (1970, equation 3.20).

For the METHOD=NORMAL option, the test statistic $Z_{cL}(X)$ is assumed to have the normal distribution $N(\mu_L, \sigma_L^2)$, and $Z_{cU}(X)$ is assumed to have the normal distribution $N(\mu_U, \sigma_U^2)$, where μ_L, μ_U, σ_L^2, and σ_U^2 are derived as follows.

For convenience of notation, define

$$k_L = \frac{1}{2\sqrt{N\theta_L(1-\theta_L)}}$$
$$k_U = \frac{1}{2\sqrt{N\theta_U(1-\theta_U)}}$$

Then

$$E\left[Z_{cL}(X)\right] \approx 2k_L Np - 2k_L N\theta_L + k_L P(X < N\theta_L) - k_L P(X > N\theta_L)$$
$$E\left[Z_{cU}(X)\right] \approx 2k_U Np - 2k_U N\theta_U + k_U P(X < N\theta_U) - k_U P(X > N\theta_U)$$

and

$$\begin{aligned}\text{Var}\left[Z_{cL}(X)\right] \approx\ & 4k_L^2 Np(1-p) + k_L^2\left[1 - P(X = N\theta_L)\right] - k_L^2\left[P(X < N\theta_L) - P(X > N\theta_L)\right]^2 \\ & + 4k_L^2\left[E\left(X1_{\{X<N\theta_L\}}\right) - E\left(X1_{\{X>N\theta_L\}}\right)\right] - 4k_L^2 Np\left[P(X < N\theta_L) - P(X > N\theta_L)\right] \\ \text{Var}\left[Z_{cU}(X)\right] \approx\ & 4k_U^2 Np(1-p) + k_U^2\left[1 - P(X = N\theta_U)\right] - k_U^2\left[P(X < N\theta_U) - P(X > N\theta_U)\right]^2 \\ & + 4k_U^2\left[E\left(X1_{\{X<N\theta_U\}}\right) - E\left(X1_{\{X>N\theta_U\}}\right)\right] - 4k_U^2 Np\left[P(X < N\theta_U) - P(X > N\theta_U)\right]\end{aligned}$$

The probabilities $P(X = N\theta_L)$, $P(X < N\theta_L)$, $P(X > N\theta_L)$, $P(X = N\theta_U)$, $P(X < N\theta_U)$, and $P(X > N\theta_U)$ and the truncated expectations $E\left(X1_{\{X<N\theta_L\}}\right)$, $E\left(X1_{\{X>N\theta_L\}}\right)$, $E\left(X1_{\{X<N\theta_L\}}\right)$, and $E\left(X1_{\{X>N\theta_L\}}\right)$ are approximated by assuming the normal-approximate distribution of X, $N(Np, Np(1-p))$. Letting $\phi(\cdot)$ and $\Phi(\cdot)$ denote the standard normal PDF and CDF, respectively, and defining d_L and d_U as

$$d_L = \frac{N\theta_L - Np}{[Np(1-p)]^{\frac{1}{2}}}$$
$$d_U = \frac{N\theta_U - Np}{[Np(1-p)]^{\frac{1}{2}}}$$

the terms are computed as follows:

$$\begin{aligned}
P(X = N\theta_L) &= 0 \\
P(X = N\theta_U) &= 0 \\
P(X < N\theta_L) &= \Phi(d_L) \\
P(X < N\theta_U) &= \Phi(d_U) \\
P(X > N\theta_L) &= 1 - \Phi(d_L) \\
P(X > N\theta_U) &= 1 - \Phi(d_U) \\
E\left(X1_{\{X<N\theta_L\}}\right) &= Np\Phi(d_L) - [Np(1-p)]^{\frac{1}{2}}\,\phi(d_L) \\
E\left(X1_{\{X<N\theta_U\}}\right) &= Np\Phi(d_U) - [Np(1-p)]^{\frac{1}{2}}\,\phi(d_U) \\
E\left(X1_{\{X>N\theta_L\}}\right) &= Np\left[1 - \Phi(d_L)\right] + [Np(1-p)]^{\frac{1}{2}}\,\phi(d_L) \\
E\left(X1_{\{X>N\theta_U\}}\right) &= Np\left[1 - \Phi(d_U)\right] + [Np(1-p)]^{\frac{1}{2}}\,\phi(d_U)
\end{aligned}$$

The mean and variance of $Z_{cL}(X)$ and $Z_{cU}(X)$ are thus approximated by

$$\mu_L = k_L\left[2Np - 2N\theta_L + 2\Phi(d_L) - 1\right]$$
$$\mu_U = k_U\left[2Np - 2N\theta_U + 2\Phi(d_U) - 1\right]$$

and

$$\sigma_L^2 = 4k_L^2\left[Np(1-p) + \Phi(d_L)\left(1 - \Phi(d_L)\right) - 2\left(Np(1-p)\right)^{\frac{1}{2}}\phi(d_L)\right]$$
$$\sigma_U^2 = 4k_U^2\left[Np(1-p) + \Phi(d_U)\left(1 - \Phi(d_U)\right) - 2\left(Np(1-p)\right)^{\frac{1}{2}}\phi(d_U)\right]$$

The approximate power is computed as

$$\text{power} = \Phi\left(\frac{z_\alpha - \mu_U}{\sigma_U}\right) + \Phi\left(\frac{z_\alpha + \mu_L}{\sigma_L}\right) - 1$$

The approximate sample size is computed by numerically inverting the power formula.

z Equivalence Test for Binomial Proportion with Continuity Adjustment Using Sample Variance (TEST=EQUIV_ADJZ VAREST=SAMPLE)

The hypotheses for the equivalence test are

$$H_0: p < \theta_L \quad \text{or} \quad p > \theta_U$$
$$H_1: \theta_L \leq p \leq \theta_U$$

where θ_L and θ_U are the lower and upper equivalence bounds, respectively.

The analysis is the two one-sided tests (TOST) procedure as described in Chow, Shao, and Wang (2003) on p. 84.

Two different hypothesis tests are carried out:

$$H_{a0}: p < \theta_L$$
$$H_{a1}: p \geq \theta_L$$

and

$$H_{b0}: p > \theta_U$$
$$H_{b1}: p \leq \theta_U$$

If H_{a0} is rejected in favor of H_{a1} *and* H_{b0} is rejected in favor of H_{b1}, then H_0 is rejected in favor of H_1.

The test statistic for the test of H_{a0} versus H_{a1} is

$$Z_{csL}(X) = \frac{X - N\theta_L + 0.5(1_{\{X<N\theta_L\}}) - 0.5(1_{\{X>N\theta_L\}})}{[N\hat{p}(1-\hat{p})]^{\frac{1}{2}}}$$

where $\hat{p} = X/N$.

The test statistic for the test of H_{b0} versus H_{b1} is

$$Z_{csU}(X) = \frac{X - N\theta_U + 0.5(1_{\{X<N\theta_U\}}) - 0.5(1_{\{X>N\theta_U\}})}{[N\hat{p}(1-\hat{p})]^{\frac{1}{2}}}$$

For the METHOD=EXACT option, let C_U denote the critical value of the exact upper one-sided test of H_{a0} versus H_{a1} using $Z_{csL}(X)$. This critical value is computed in the section "z Test for Binomial Proportion with Continuity Adjustment Using Sample Variance (TEST=ADJZ VAREST=SAMPLE)" on page 5854. Similarly, let C_L denote the critical value of the exact lower one-sided test of H_{b0} versus H_{b1} using $Z_{csU}(X)$. Both of these tests are rejected if and only if $C_U \leq X \leq C_L$. Thus, the exact power of the equivalence test is

$$\begin{aligned}\text{power} &= P\left(C_U \leq X \leq C_L\right) \\ &= P\left(X \geq C_U\right) - P\left(X \geq C_L + 1\right)\end{aligned}$$

The probabilities are computed using Johnson and Kotz (1970, equation 3.20).

For the METHOD=NORMAL option, the test statistic $Z_{csL}(X)$ is assumed to have the normal distribution $N(\mu_L, \sigma_L^2)$, and $Z_{csU}(X)$ is assumed to have the normal distribution $N(\mu_U, \sigma_U^2)$, where μ_L, μ_U, σ_L^2 and σ_U^2 are derived as follows.

For convenience of notation, define

$$k = \frac{1}{2\sqrt{Np(1-p)}}$$

Then

$$E\left[Z_{csL}(X)\right] \approx 2kNp - 2kN\theta_L + kP(X < N\theta_L) - kP(X > N\theta_L)$$
$$E\left[Z_{csU}(X)\right] \approx 2kNp - 2kN\theta_U + kP(X < N\theta_U) - kP(X > N\theta_U)$$

and

$$\begin{aligned}\mathrm{Var}\left[Z_{csL}(X)\right] \approx\ & 4k^2Np(1-p) + k^2\left[1 - P(X = N\theta_L)\right] - k^2\left[P(X < N\theta_L) - P(X > N\theta_L)\right]^2 \\ & + 4k^2\left[E\left(X1_{\{X<N\theta_L\}}\right) - E\left(X1_{\{X>N\theta_L\}}\right)\right] - 4k^2Np\left[P(X < N\theta_L) - P(X > N\theta_L)\right] \\ \mathrm{Var}\left[Z_{csU}(X)\right] \approx\ & 4k^2Np(1-p) + k^2\left[1 - P(X = N\theta_U)\right] - k^2\left[P(X < N\theta_U) - P(X > N\theta_U)\right]^2 \\ & + 4k^2\left[E\left(X1_{\{X<N\theta_U\}}\right) - E\left(X1_{\{X>N\theta_U\}}\right)\right] - 4k^2Np\left[P(X < N\theta_U) - P(X > N\theta_U)\right]\end{aligned}$$

The probabilities $P(X = N\theta_L)$, $P(X < N\theta_L)$, $P(X > N\theta_L)$, $P(X = N\theta_U)$, $P(X < N\theta_U)$, and $P(X > N\theta_U)$ and the truncated expectations $E\left(X1_{\{X<N\theta_L\}}\right)$, $E\left(X1_{\{X>N\theta_L\}}\right)$, $E\left(X1_{\{X<N\theta_L\}}\right)$, and $E\left(X1_{\{X>N\theta_L\}}\right)$ are approximated by assuming the normal-approximate distribution of X, $N(Np, Np(1-p))$. Letting $\phi(\cdot)$ and $\Phi(\cdot)$ denote the standard normal PDF and CDF, respectively, and defining d_L and d_U as

$$d_L = \frac{N\theta_L - Np}{[Np(1-p)]^{\frac{1}{2}}}$$
$$d_U = \frac{N\theta_U - Np}{[Np(1-p)]^{\frac{1}{2}}}$$

the terms are computed as follows:

$$\begin{aligned}P(X = N\theta_L) &= 0 \\ P(X = N\theta_U) &= 0 \\ P(X < N\theta_L) &= \Phi(d_L) \\ P(X < N\theta_U) &= \Phi(d_U) \\ P(X > N\theta_L) &= 1 - \Phi(d_L) \\ P(X > N\theta_U) &= 1 - \Phi(d_U) \\ E\left(X1_{\{X<N\theta_L\}}\right) &= Np\Phi(d_L) - [Np(1-p)]^{\frac{1}{2}}\phi(d_L) \\ E\left(X1_{\{X<N\theta_U\}}\right) &= Np\Phi(d_U) - [Np(1-p)]^{\frac{1}{2}}\phi(d_U) \\ E\left(X1_{\{X>N\theta_L\}}\right) &= Np\left[1 - \Phi(d_L)\right] + [Np(1-p)]^{\frac{1}{2}}\phi(d_L) \\ E\left(X1_{\{X>N\theta_U\}}\right) &= Np\left[1 - \Phi(d_U)\right] + [Np(1-p)]^{\frac{1}{2}}\phi(d_U)\end{aligned}$$

The mean and variance of $Z_{csL}(X)$ and $Z_{csU}(X)$ are thus approximated by

$$\mu_L = k\left[2Np - 2N\theta_L + 2\Phi(d_L) - 1\right]$$
$$\mu_U = k\left[2Np - 2N\theta_U + 2\Phi(d_U) - 1\right]$$

and

$$\sigma_L^2 = 4k^2\left[Np(1-p) + \Phi(d_L)\left(1-\Phi(d_L)\right) - 2\left(Np(1-p)\right)^{\frac{1}{2}}\phi(d_L)\right]$$
$$\sigma_U^2 = 4k^2\left[Np(1-p) + \Phi(d_U)\left(1-\Phi(d_U)\right) - 2\left(Np(1-p)\right)^{\frac{1}{2}}\phi(d_U)\right]$$

The approximate power is computed as

$$\text{power} = \Phi\left(\frac{z_\alpha - \mu_U}{\sigma_U}\right) + \Phi\left(\frac{z_\alpha + \mu_L}{\sigma_L}\right) - 1$$

The approximate sample size is computed by numerically inverting the power formula.

Wilson Score Confidence Interval for Binomial Proportion (CI=WILSON)

The two-sided $100(1-\alpha)\%$ confidence interval for p is

$$\frac{X + \frac{z_{1-\alpha/2}^2}{2}}{N + z_{1-\alpha/2}^2} \quad \pm \quad \frac{z_{1-\alpha/2}N^{\frac{1}{2}}}{N + z_{1-\alpha/2}^2}\left(\hat{p}(1-\hat{p}) + \frac{z_{1-\alpha/2}^2}{4N}\right)^{\frac{1}{2}}$$

So the half-width for the two-sided $100(1-\alpha)\%$ confidence interval is

$$\text{half-width} = \frac{z_{1-\alpha/2}N^{\frac{1}{2}}}{N + z_{1-\alpha/2}^2}\left(\hat{p}(1-\hat{p}) + \frac{z_{1-\alpha/2}^2}{4N}\right)^{\frac{1}{2}}$$

Prob(Width) is calculated exactly by adding up the probabilities of observing each $X \in \{1, \ldots, N\}$ that produces a confidence interval whose half-width is at most a target value h:

$$\text{Prob(Width)} = \sum_{i=0}^{N} P(X = i)1_{\text{half-width}<h}$$

For references and more details about this and all other confidence intervals associated with the CI= option, see "Binomial Proportion" on page 2345 of Chapter 36, "The FREQ Procedure."

Agresti-Coull "Add k Successes and Failures" Confidence Interval for Binomial Proportion (CI=AGRESTICOULL)

The two-sided $100(1-\alpha)\%$ confidence interval for p is

$$\frac{X+\frac{z_{1-\alpha/2}^2}{2}}{N+z_{1-\alpha/2}^2} \quad \pm \quad z_{1-\alpha/2}\left(\frac{\frac{X+\frac{z_{1-\alpha/2}^2}{2}}{N+z_{1-\alpha/2}^2}\left(1-\frac{X+\frac{z_{1-\alpha/2}^2}{2}}{N+z_{1-\alpha/2}^2}\right)}{N+z_{1-\alpha/2}^2}\right)^{\frac{1}{2}}$$

So the half-width for the two-sided $100(1-\alpha)\%$ confidence interval is

$$\text{half-width} = z_{1-\alpha/2}\left(\frac{\frac{X+\frac{z_{1-\alpha/2}^2}{2}}{N+z_{1-\alpha/2}^2}\left(1-\frac{X+\frac{z_{1-\alpha/2}^2}{2}}{N+z_{1-\alpha/2}^2}\right)}{N+z_{1-\alpha/2}^2}\right)^{\frac{1}{2}}$$

Prob(Width) is calculated exactly by adding up the probabilities of observing each $X \in \{1,\ldots,N\}$ that produces a confidence interval whose half-width is at most a target value h:

$$\text{Prob(Width)} = \sum_{i=0}^{N} P(X=i)1_{\text{half-width}<h}$$

Jeffreys Confidence Interval for Binomial Proportion (CI=JEFFREYS)

The two-sided $100(1-\alpha)\%$ confidence interval for p is

$$[L_J(X), U_J(X)]$$

where

$$L_J(X) = \begin{cases} 0, & X=0 \\ \text{Beta}_{\alpha/2;X+1/2,N-X+1/2}, & X>0 \end{cases}$$

and

$$U_J(X) = \begin{cases} \text{Beta}_{1-\alpha/2;X+1/2,N-X+1/2}, & X<N \\ 1, & X=N \end{cases}$$

The half-width of this two-sided $100(1-\alpha)\%$ confidence interval is defined as half the width of the full interval:

$$\text{half-width} = \frac{1}{2}\left(U_J(X) - L_J(X)\right)$$

Prob(Width) is calculated exactly by adding up the probabilities of observing each $X \in \{1, \ldots, N\}$ that produces a confidence interval whose half-width is at most a target value h:

$$\text{Prob(Width)} = \sum_{i=0}^{N} P(X = i) 1_{\text{half-width}<h}$$

Exact Clopper-Pearson Confidence Interval for Binomial Proportion (CI=EXACT)

The two-sided $100(1-\alpha)\%$ confidence interval for p is

$$[L_E(X), U_E(X)]$$

where

$$L_E(X) = \begin{cases} 0, & X = 0 \\ \text{Beta}_{\alpha/2;X,N-X+1}, & X > 0 \end{cases}$$

and

$$U_E(X) = \begin{cases} \text{Beta}_{1-\alpha/2;X+1,N-X}, & X < N \\ 1, & X = N \end{cases}$$

The half-width of this two-sided $100(1-\alpha)\%$ confidence interval is defined as half the width of the full interval:

$$\text{half-width} = \frac{1}{2}\left(U_E(X) - L_E(X)\right)$$

Prob(Width) is calculated exactly by adding up the probabilities of observing each $X \in \{1, \ldots, N\}$ that produces a confidence interval whose half-width is at most a target value h:

$$\text{Prob(Width)} = \sum_{i=0}^{N} P(X = i) 1_{\text{half-width}<h}$$

Wald Confidence Interval for Binomial Proportion (CI=WALD)

The two-sided $100(1-\alpha)\%$ confidence interval for p is

$$\hat{p} \quad \pm \quad z_{1-\alpha/2}\left(\frac{\hat{p}(1-\hat{p})}{N}\right)^{\frac{1}{2}}$$

So the half-width for the two-sided $100(1-\alpha)\%$ confidence interval is

$$\text{half-width} = z_{1-\alpha/2}\left(\frac{\hat{p}(1-\hat{p})}{N}\right)^{\frac{1}{2}}$$

Prob(Width) is calculated exactly by adding up the probabilities of observing each $X \in \{1,\ldots,N\}$ that produces a confidence interval whose half-width is at most a target value h:

$$\text{Prob(Width)} = \sum_{i=0}^{N} P(X=i)1_{\text{half-width}<h}$$

Continuity-Corrected Wald Confidence Interval for Binomial Proportion (CI=WALD_CORRECT)

The two-sided $100(1-\alpha)\%$ confidence interval for p is

$$\hat{p} \quad \pm \quad \left[z_{1-\alpha/2}\left(\frac{\hat{p}(1-\hat{p})}{N}\right)^{\frac{1}{2}} + \frac{1}{2N}\right]$$

So the half-width for the two-sided $100(1-\alpha)\%$ confidence interval is

$$\text{half-width} = z_{1-\alpha/2}\left(\frac{\hat{p}(1-\hat{p})}{N}\right)^{\frac{1}{2}} + \frac{1}{2N}$$

Prob(Width) is calculated exactly by adding up the probabilities of observing each $X \in \{1,\ldots,N\}$ that produces a confidence interval whose half-width is at most a target value h:

$$\text{Prob(Width)} = \sum_{i=0}^{N} P(X=i)1_{\text{half-width}<h}$$

Analyses in the ONESAMPLEMEANS Statement

One-Sample t Test (TEST=T)

The hypotheses for the one-sample t test are

$$H_0{:}\mu = \mu_0$$

$$H_1{:} \begin{cases} \mu \neq \mu_0, & \text{two-sided} \\ \mu > \mu_0, & \text{upper one-sided} \\ \mu < \mu_0, & \text{lower one-sided} \end{cases}$$

The test assumes normally distributed data and requires $N \geq 2$. The test statistics are

$$t = N^{\frac{1}{2}} \left(\frac{\bar{x} - \mu_0}{s} \right) \quad \sim \quad t(N-1, \delta)$$

$$t^2 \sim F(1, N-1, \delta^2)$$

where $\bar{x}$ is the sample mean, s is the sample standard deviation, and

$$\delta = N^{\frac{1}{2}} \left(\frac{\mu - \mu_0}{\sigma} \right)$$

The test is

$$\text{Reject} \quad H_0 \quad \text{if} \begin{cases} t^2 \geq F_{1-\alpha}(1, N-1), & \text{two-sided} \\ t \geq t_{1-\alpha}(N-1), & \text{upper one-sided} \\ t \leq t_{\alpha}(N-1), & \text{lower one-sided} \end{cases}$$

Exact power computations for t tests are discussed in O'Brien and Muller (1993, Section 8.2), although not specifically for the one-sample case. The power is based on the noncentral t and F distributions:

$$\text{power} = \begin{cases} P\left(F(1, N-1, \delta^2) \geq F_{1-\alpha}(1, N-1)\right), & \text{two-sided} \\ P\left(t(N-1, \delta) \geq t_{1-\alpha}(N-1)\right), & \text{upper one-sided} \\ P\left(t(N-1, \delta) \leq t_{\alpha}(N-1)\right), & \text{lower one-sided} \end{cases}$$

Solutions for N, α, and δ are obtained by numerically inverting the power equation. Closed-form solutions for other parameters, in terms of δ, are as follows:

$$\mu = \delta \sigma N^{-\frac{1}{2}} + \mu_0$$

$$\sigma = \begin{cases} \delta^{-1} N^{\frac{1}{2}} (\mu - \mu_0), & |\delta| > 0 \\ \text{undefined}, & \text{otherwise} \end{cases}$$

One-Sample t Test with Lognormal Data (TEST=T DIST=LOGNORMAL)

The lognormal case is handled by reexpressing the analysis equivalently as a normality-based test on the log-transformed data, by using properties of the lognormal distribution as discussed in Johnson, Kotz, and Balakrishnan (1994, Chapter 14). The approaches in the section "One-Sample t Test (TEST=T)" on page 5868 then apply.

In contrast to the usual t test on normal data, the hypotheses with lognormal data are defined in terms of geometric means rather than arithmetic means. This is because the transformation of a null arithmetic mean of lognormal data to the normal scale depends on the unknown coefficient of variation, resulting in an ill-defined hypothesis on the log-transformed data. Geometric means transform cleanly and are more natural for lognormal data.

The hypotheses for the one-sample t test with lognormal data are

$$H_0: \frac{\gamma}{\gamma_0} = 1$$
$$H_1: \begin{cases} \frac{\gamma}{\gamma_0} \neq 1, & \text{two-sided} \\ \frac{\gamma}{\gamma_0} > 1, & \text{upper one-sided} \\ \frac{\gamma}{\gamma_0} < 1, & \text{lower one-sided} \end{cases}$$

Let $\mu^\star$ and $\sigma^\star$ be the (arithmetic) mean and standard deviation of the normal distribution of the log-transformed data. The hypotheses can be rewritten as follows:

$$H_0: \mu^\star = \log(\gamma_0)$$
$$H_1: \begin{cases} \mu^\star \neq \log(\gamma_0), & \text{two-sided} \\ \mu^\star > \log(\gamma_0), & \text{upper one-sided} \\ \mu^\star < \log(\gamma_0), & \text{lower one-sided} \end{cases}$$

where $\mu^\star = \log(\gamma)$.

The test assumes lognormally distributed data and requires $N \geq 2$.

The power is

$$\text{power} = \begin{cases} P\left(F(1, N-1, \delta^2) \geq F_{1-\alpha}(1, N-1)\right), & \text{two-sided} \\ P\left(t(N-1, \delta) \geq t_{1-\alpha}(N-1)\right), & \text{upper one-sided} \\ P\left(t(N-1, \delta) \leq t_{\alpha}(N-1)\right), & \text{lower one-sided} \end{cases}$$

where

$$\delta = N^{\frac{1}{2}} \left(\frac{\mu^\star - \log(\gamma_0)}{\sigma^\star} \right)$$
$$\sigma^\star = \left[\log(\text{CV}^2 + 1)\right]^{\frac{1}{2}}$$

Equivalence Test for Mean of Normal Data (TEST=EQUIV DIST=NORMAL)

The hypotheses for the equivalence test are

$$H_0: \mu < \theta_L \quad \text{or} \quad \mu > \theta_U$$
$$H_1: \theta_L \leq \mu \leq \theta_U$$

The analysis is the two one-sided tests (TOST) procedure of Schuirmann (1987). The test assumes normally distributed data and requires $N \geq 2$. Phillips (1990) derives an expression for the exact power assuming a two-sample balanced design; the results are easily adapted to a one-sample design:

$$\text{power} = Q_{N-1}\left((-t_{1-\alpha}(N-1)), \frac{\mu-\theta_U}{\sigma N^{-\frac{1}{2}}}; 0, \frac{(N-1)^{\frac{1}{2}}(\theta_U-\theta_L)}{2\sigma N^{-\frac{1}{2}}(t_{1-\alpha}(N-1))}\right) - Q_{N-1}\left((t_{1-\alpha}(N-1)), \frac{\mu-\theta_L}{\sigma N^{-\frac{1}{2}}}; 0, \frac{(N-1)^{\frac{1}{2}}(\theta_U-\theta_L)}{2\sigma N^{-\frac{1}{2}}(t_{1-\alpha}(N-1))}\right)$$

where $Q.(\cdot,\cdot;\cdot,\cdot)$ is Owen's Q function, defined in the section "Common Notation" on page 5841.

Equivalence Test for Mean of Lognormal Data (TEST=EQUIV DIST=LOGNORMAL)

The lognormal case is handled by reexpressing the analysis equivalently as a normality-based test on the log-transformed data, by using properties of the lognormal distribution as discussed in Johnson, Kotz, and Balakrishnan (1994, Chapter 14). The approaches in the section "Equivalence Test for Mean of Normal Data (TEST=EQUIV DIST=NORMAL)" on page 5869 then apply.

In contrast to the additive equivalence test on normal data, the hypotheses with lognormal data are defined in terms of geometric means rather than arithmetic means. This is because the transformation of an arithmetic mean of lognormal data to the normal scale depends on the unknown coefficient of variation, resulting in an ill-defined hypothesis on the log-transformed data. Geometric means transform cleanly and are more natural for lognormal data.

The hypotheses for the equivalence test are

$$H_0{:}\gamma \leq \theta_L \quad \text{or} \quad \gamma \geq \theta_U$$
$$H_1{:}\theta_L < \gamma < \theta_U$$

$$\text{where} \quad 0 < \theta_L < \theta_U$$

The analysis is the two one-sided tests (TOST) procedure of Schuirmann (1987) on the log-transformed data. The test assumes lognormally distributed data and requires $N \geq 2$. Diletti, Hauschke, and Steinijans (1991) derive an expression for the exact power assuming a crossover design; the results are easily adapted to a one-sample design:

$$\text{power} = Q_{N-1}\left((-t_{1-\alpha}(N-1)), \frac{\log(\gamma)-\log(\theta_U)}{\sigma^\star N^{-\frac{1}{2}}}; 0, \frac{(N-1)^{\frac{1}{2}}(\log(\theta_U)-\log(\theta_L))}{2\sigma^\star N^{-\frac{1}{2}}(t_{1-\alpha}(N-1))}\right) - Q_{N-1}\left((t_{1-\alpha}(N-1)), \frac{\log(\gamma)-\log(\theta_L)}{\sigma^\star N^{-\frac{1}{2}}}; 0, \frac{(N-1)^{\frac{1}{2}}(\log(\theta_U)-\log(\theta_L))}{2\sigma^\star N^{-\frac{1}{2}}(t_{1-\alpha}(N-1))}\right)$$

where

$$\sigma^\star = \left[\log(\text{CV}^2+1)\right]^{\frac{1}{2}}$$

is the standard deviation of the log-transformed data, and $Q.(\cdot,\cdot;\cdot,\cdot)$ is Owen's Q function, defined in the section "Common Notation" on page 5841.

Confidence Interval for Mean (CI=T)

This analysis of precision applies to the standard t-based confidence interval:

$$\begin{cases} \left[\bar{x} - t_{1-\frac{\alpha}{2}}(N-1)\frac{s}{\sqrt{N}}, \quad \bar{x} + t_{1-\frac{\alpha}{2}}(N-1)\frac{s}{\sqrt{N}}\right], & \text{two-sided} \\ \left[\bar{x} - t_{1-\alpha}(N-1)\frac{s}{\sqrt{N}}, \quad \infty\right), & \text{upper one-sided} \\ \left(-\infty, \quad \bar{x} + t_{1-\alpha}(N-1)\frac{s}{\sqrt{N}}\right], & \text{lower one-sided} \end{cases}$$

where $\bar{x}$ is the sample mean and s is the sample standard deviation. The "half-width" is defined as the distance from the point estimate $\bar{x}$ to a finite endpoint,

$$\text{half-width} = \begin{cases} t_{1-\frac{\alpha}{2}}(N-1)\frac{s}{\sqrt{N}}, & \text{two-sided} \\ t_{1-\alpha}(N-1)\frac{s}{\sqrt{N}}, & \text{one-sided} \end{cases}$$

A "valid" conference interval captures the true mean. The exact probability of obtaining at most the target confidence interval half-width h, unconditional or conditional on validity, is given by Beal (1989):

$$\Pr(\text{half-width} \le h) = \begin{cases} P\left(\chi^2(N-1) \le \frac{h^2 N(N-1)}{\sigma^2(t^2_{1-\frac{\alpha}{2}}(N-1))}\right), & \text{two-sided} \\ P\left(\chi^2(N-1) \le \frac{h^2 N(N-1)}{\sigma^2(t^2_{1-\alpha}(N-1))}\right), & \text{one-sided} \end{cases}$$

$$\Pr(\text{half-width} \le h \mid \text{validity}) = \begin{cases} \left(\frac{1}{1-\alpha}\right) 2\left[Q_{N-1}\left((t_{1-\frac{\alpha}{2}}(N-1)), 0; \right.\right. \\ \quad \left.\left. 0, b_1\right) - Q_{N-1}(0,0;0,b_1)\right], & \text{two-sided} \\ \left(\frac{1}{1-\alpha}\right) Q_{N-1}\left((t_{1-\alpha}(N-1)), 0; 0, b_1\right), & \text{one-sided} \end{cases}$$

where

$$b_1 = \frac{h(N-1)^{\frac{1}{2}}}{\sigma(t_{1-\frac{\alpha}{c}}(N-1))N^{-\frac{1}{2}}}$$

$$c = \text{number of sides}$$

and $Q_{\cdot}(\cdot,\cdot;\cdot,\cdot)$ is Owen's Q function, defined in the section "Common Notation" on page 5841.

A "quality" confidence interval is both sufficiently narrow (half-width $\le h$) and valid:

$$\begin{aligned} \Pr(\text{quality}) &= \Pr(\text{half-width} \le h \text{ and validity}) \\ &= \Pr(\text{half-width} \le h \mid \text{validity})(1-\alpha) \end{aligned}$$

Analyses in the ONEWAYANOVA Statement

One-Degree-of-Freedom Contrast (TEST=CONTRAST)

The hypotheses are

$$H_0: c_1\mu_1 + \cdots + c_G\mu_G = c_0$$

$$H_1: \begin{cases} c_1\mu_1 + \cdots + c_G\mu_G \ne c_0, & \text{two-sided} \\ c_1\mu_1 + \cdots + c_G\mu_G > c_0, & \text{upper one-sided} \\ c_1\mu_1 + \cdots + c_G\mu_G < c_0, & \text{lower one-sided} \end{cases}$$

where G is the number of groups, $\{c_1, \ldots, c_G\}$ are the contrast coefficients, and c_0 is the null contrast value.

The test is the usual F test for a contrast in one-way ANOVA. It assumes normal data with common group variances and requires $N \geq G + 1$ and $n_i \geq 1$.

O'Brien and Muller (1993, Section 8.2.3.2) give the exact power as

$$\text{power} = \begin{cases} P\left(F(1, N-G, \delta^2) \geq F_{1-\alpha}(1, N-G)\right), & \text{two-sided} \\ P\left(t(N-G, \delta) \geq t_{1-\alpha}(N-G)\right), & \text{upper one-sided} \\ P\left(t(N-G, \delta) \leq t_{\alpha}(N-G)\right), & \text{lower one-sided} \end{cases}$$

where

$$\delta = N^{\frac{1}{2}} \left(\frac{\sum_{i=1}^{G} c_i \mu_i - c_0}{\sigma \left(\sum_{i=1}^{G} \frac{c_i^2}{w_i} \right)^{\frac{1}{2}}} \right)$$

Overall F Test (TEST=OVERALL)

The hypotheses are

$$H_0: \mu_1 = \mu_2 = \cdots = \mu_G$$
$$H_1: \mu_i \neq \mu_j \text{ for some } i, j$$

where G is the number of groups.

The test is the usual overall F test for equality of means in one-way ANOVA. It assumes normal data with common group variances and requires $N \geq G + 1$ and $n_i \geq 1$.

O'Brien and Muller (1993, Section 8.2.3.1) give the exact power as

$$\text{power} = P\left(F(G-1, N-G, \lambda) \geq F_{1-\alpha}(G-1, N-G)\right)$$

where the noncentrality is

$$\lambda = N \left(\frac{\sum_{i=1}^{G} w_i (\mu_i - \bar{\mu})^2}{\sigma^2} \right)$$

and

$$\bar{\mu} = \sum_{i=1}^{G} w_i \mu_i$$

Analyses in the PAIREDFREQ Statement

Overview of Conditional McNemar tests

Notation:

		Case		
		Failure	Success	
Control	Failure	n_{00}	n_{01}	$n_{0\cdot}$
	Success	n_{10}	n_{11}	$n_{1\cdot}$
		$n_{\cdot 0}$	$n_{\cdot 1}$	N

$$
\begin{aligned}
n_{00} &= \#\{\text{control=failure, case=failure }\} \\
n_{01} &= \#\{\text{control=failure, case=success }\} \\
n_{10} &= \#\{\text{control=success, case=failure }\} \\
n_{11} &= \#\{\text{control=success, case=success }\} \\
N &= n_{00} + n_{01} + n_{10} + n_{11} \\
n_D &= n_{01} + n_{10} \equiv \ \#\text{ discordant pairs} \\
\hat{\pi}_{ij} &= \frac{n_{ij}}{N} \\
\pi_{ij} &= \text{theoretical population value of } \hat{\pi}_{ij} \\
\pi_{1\cdot} &= \pi_{10} + \pi_{11} \\
\pi_{\cdot 1} &= \pi_{01} + \pi_{11} \\
\phi &= \text{Corr(control observation, case observation)} \quad \text{(within a pair)} \\
\text{DPR} &= \text{“discordant proportion ratio”} = \frac{\pi_{01}}{\pi_{10}} \\
\text{DPR}_0 &= \text{null DPR}
\end{aligned}
$$

Power formulas are given here in terms of the discordant proportions π_{10} and π_{01}. If the input is specified in terms of $\{\pi_{1\cdot}, \pi_{\cdot 1}, \phi\}$, then it can be converted into values for $\{\pi_{10}, \pi_{01}\}$ as follows:

$$
\begin{aligned}
\pi_{01} &= \pi_{\cdot 1}(1 - \pi_{1\cdot}) - \phi((1 - \pi_{1\cdot})\pi_{1\cdot}(1 - \pi_{\cdot 1})\pi_{\cdot 1})^{\frac{1}{2}} \\
\pi_{10} &= \pi_{01} + \pi_{1\cdot} - \pi_{\cdot 1}
\end{aligned}
$$

All McNemar tests covered in PROC POWER are *conditional*, meaning that n_D is assumed fixed at its observed value.

For the usual $\text{DPR}_0 = 1$, the hypotheses are

$$
\begin{aligned}
&H_0{:}\pi_{\cdot 1} = \pi_{1\cdot} \\
&H_1{:} \begin{cases} \pi_{\cdot 1} \neq \pi_{1\cdot}, & \text{two-sided} \\ \pi_{\cdot 1} > \pi_{1\cdot}, & \text{upper one-sided} \\ \pi_{\cdot 1} < \pi_{1\cdot}, & \text{lower one-sided} \end{cases}
\end{aligned}
$$

The test statistic for both tests covered in PROC POWER (DIST=EXACT_COND and DIST=NORMAL) is the McNemar statistic Q_M, which has the following form when $\text{DPR}_0 = 1$:

$$Q_{M_0} = \frac{(n_{01} - n_{10})^2}{n_{01} + n_{10}}$$

For the conditional McNemar tests, this is equivalent to the square of the $Z(X)$ statistic for the test of a single proportion (normal approximation to binomial), where the proportion is $\frac{\pi_{01}}{\pi_{01}+\pi_{10}}$, the null is 0.5, and "$N$" is n_D (see, for example, Schork and Williams 1980):

$$\begin{aligned} Z(X) &= \frac{n_{01} - n_D(0.5)}{[n_D 0.5(1-0.5)]^{\frac{1}{2}}} \quad \dot{\sim} \text{N}\left(\frac{n_D^{\frac{1}{2}}(\frac{\pi_{01}}{\pi_{01}+\pi_{10}} - 0.5)}{[0.5(1-0.5)]^{\frac{1}{2}}}, \frac{\frac{\pi_{01}}{\pi_{01}+\pi_{10}}\left(1 - \frac{\pi_{01}}{\pi_{01}+\pi_{10}}\right)}{0.5(1-0.5)} \right) \\ &= \frac{n_{01} - (n_{01} + n_{10})(0.5)}{[(n_{01} + n_{10})0.5(1-0.5)]^{\frac{1}{2}}} \\ &= \frac{n_{01} - n_{10}}{[n_{01} + n_{10}]^{\frac{1}{2}}} \\ &= \sqrt{Q_{M_0}} \end{aligned}$$

This can be generalized to a custom null for $\frac{\pi_{01}}{\pi_{01}+\pi_{10}}$, which is equivalent to specifying a custom null DPR:

$$\left[\frac{\pi_{01}}{\pi_{01} + \pi_{10}}\right]_0 \equiv \left[\frac{1}{1 + \frac{1}{\frac{\pi_{01}}{\pi_{10}}}}\right]_0 \equiv \frac{1}{1 + \frac{1}{\text{DPR}_0}}$$

So, a conditional McNemar test (asymptotic or exact) with a custom null is equivalent to the test of a single proportion $p_1 \equiv \frac{\pi_{01}}{\pi_{01}+\pi_{10}}$ with a null value $p_0 \equiv \frac{1}{1+\frac{1}{\text{DPR}_0}}$, with a sample size of n_D:

$$H_0: p_1 = p_0$$

$$H_1: \begin{cases} p_1 \neq p_0, & \text{two-sided} \\ p_1 > p_0, & \text{one-sided U} \\ p_1 < p_0, & \text{one-sided L} \end{cases}$$

which is equivalent to

$$H_0: \text{DPR} = \text{DPR}_0$$

$$H_1: \begin{cases} \text{DPR} \neq \text{DPR}_0, & \text{two-sided} \\ \text{DPR} > \text{DPR}_0, & \text{one-sided U} \\ \text{DPR} < \text{DPR}_0, & \text{one-sided L} \end{cases}$$

The general form of the test statistic is thus

$$Q_M = \frac{(n_{01} - n_D p_0)^2}{n_D p_0 (1 - p_0)}$$

The two most common conditional McNemar tests assume either the exact conditional distribution of Q_M (covered by the DIST=EXACT_COND analysis) or a standard normal distribution for Q_M (covered by the DIST=NORMAL analysis).

McNemar Exact Conditional Test (TEST=MCNEMAR DIST=EXACT_COND)

For DIST=EXACT_COND, the power is calculated assuming that the test is conducted by using the exact conditional distribution of Q_M (conditional on n_D). The power is calculated by first computing the conditional power for each possible n_D. The unconditional power is computed as a weighted average over all possible outcomes of n_D:

$$\text{power} = \sum_{n_D=0}^{N} P(n_D)\,P(\text{Reject } p_1 = p_0 | n_D)$$

where $n_D \sim \text{Bin}(\pi_{01} + \pi_{10}, N)$, and $P(\text{Reject } p_1 = p_0 | n_D)$ is calculated by using the exact method in the section "Exact Test of a Binomial Proportion (TEST=EXACT)" on page 5849.

The achieved significance level, reported as "Actual Alpha" in the analysis, is computed in the same way except by using the actual alpha of the one-sample test in place of its power:

$$\text{actual alpha} = \sum_{n_D=0}^{N} P(n_D)\alpha^{\star}(p_1, p_0 | n_D)$$

where $\alpha^{\star}(p_1, p_0 | n_D)$ is the actual alpha calculated by using the exact method in the section "Exact Test of a Binomial Proportion (TEST=EXACT)" on page 5849 with proportion p_1, null p_0, and sample size n_D.

McNemar Normal Approximation Test (TEST=MCNEMAR DIST=NORMAL)

For DIST=NORMAL, power is calculated assuming the test is conducted by using the normal-approximate distribution of Q_M (conditional on n_D).

For the METHOD=EXACT option, the power is calculated in the same way as described in the section "McNemar Exact Conditional Test (TEST=MCNEMAR DIST=EXACT_COND)" on page 5875, except that $P(\text{Reject } p_1 = p_0 | n_D)$ is calculated by using the exact method in the section "z Test for Binomial Proportion Using Null Variance (TEST=Z VAREST=NULL)" on page 5850. The achieved significance level is calculated in the same way as described at the end of the section "McNemar Exact Conditional Test (TEST=MCNEMAR DIST=EXACT_COND)" on page 5875.

For the METHOD=MIETTINEN option, approximate sample size for the one-sided cases is computed according to equation (5.6) in Miettinen (1968):

$$N = \frac{\left\{ z_{1-\alpha}(p_{10} + p_{01}) + z_{power}\left[(p_{10} + p_{01})^2 - \frac{1}{4}(p_{01} - p_{10})^2(3 + p_{10} + p_{01})\right]^{\frac{1}{2}} \right\}^2}{(p_{10} + p_{01})(p_{01} - p_{10})^2}$$

Approximate power for the one-sided cases is computed by solving the sample size equation for power, and approximate power for the two-sided case follows easily by summing the one-sided powers each at $\alpha/2$:

$$\text{power} = \begin{cases} \Phi\left(\dfrac{(p_{01}-p_{10})[N(p_{10}+p_{01})]^{\frac{1}{2}} - z_{1-\alpha}(p_{10}+p_{01})}{\left[(p_{10}+p_{01})^2 - \frac{1}{4}(p_{01}-p_{10})^2(3+p_{10}+p_{01})\right]^{\frac{1}{2}}}\right), & \text{upper one-sided} \\ \Phi\left(\dfrac{-(p_{01}-p_{10})[N(p_{10}+p_{01})]^{\frac{1}{2}} - z_{1-\alpha}(p_{10}+p_{01})}{\left[(p_{10}+p_{01})^2 - \frac{1}{4}(p_{01}-p_{10})^2(3+p_{10}+p_{01})\right]^{\frac{1}{2}}}\right), & \text{lower one-sided} \\ \Phi\left(\dfrac{(p_{01}-p_{10})[N(p_{10}+p_{01})]^{\frac{1}{2}} - z_{1-\frac{\alpha}{2}}(p_{10}+p_{01})}{\left[(p_{10}+p_{01})^2 - \frac{1}{4}(p_{01}-p_{10})^2(3+p_{10}+p_{01})\right]^{\frac{1}{2}}}\right) + & \\ \quad \Phi\left(\dfrac{-(p_{01}-p_{10})[N(p_{10}+p_{01})]^{\frac{1}{2}} - z_{1-\frac{\alpha}{2}}(p_{10}+p_{01})}{\left[(p_{10}+p_{01})^2 - \frac{1}{4}(p_{01}-p_{10})^2(3+p_{10}+p_{01})\right]^{\frac{1}{2}}}\right), & \text{two-sided} \end{cases}$$

The two-sided solution for N is obtained by numerically inverting the power equation.

In general, compared to METHOD=CONNOR, the METHOD=MIETTINEN approximation tends to be slightly more accurate but can be slightly anticonservative in the sense of underestimating sample size and overestimating power (Lachin 1992, p. 1250).

For the METHOD=CONNOR option, approximate sample size for the one-sided cases is computed according to equation (3) in Connor (1987):

$$N = \frac{\left\{z_{1-\alpha}(p_{10}+p_{01})^{\frac{1}{2}} + z_{power}\left[p_{10}+p_{01}-(p_{01}-p_{10})^2\right]^{\frac{1}{2}}\right\}^2}{(p_{01}-p_{10})^2}$$

Approximate power for the one-sided cases is computed by solving the sample size equation for power, and approximate power for the two-sided case follows easily by summing the one-sided powers each at $\alpha/2$:

$$\text{power} = \begin{cases} \Phi\left(\dfrac{(p_{01}-p_{10})N^{\frac{1}{2}} - z_{1-\alpha}(p_{10}+p_{01})^{\frac{1}{2}}}{\left[p_{10}+p_{01}-(p_{01}-p_{10})^2\right]^{\frac{1}{2}}}\right), & \text{upper one-sided} \\ \Phi\left(\dfrac{-(p_{01}-p_{10})N^{\frac{1}{2}} - z_{1-\alpha}(p_{10}+p_{01})^{\frac{1}{2}}}{\left[p_{10}+p_{01}-(p_{01}-p_{10})^2\right]^{\frac{1}{2}}}\right), & \text{lower one-sided} \\ \Phi\left(\dfrac{(p_{01}-p_{10})N^{\frac{1}{2}} - z_{1-\frac{\alpha}{2}}(p_{10}+p_{01})^{\frac{1}{2}}}{\left[p_{10}+p_{01}-(p_{01}-p_{10})^2\right]^{\frac{1}{2}}}\right) + & \\ \quad \Phi\left(\dfrac{-(p_{01}-p_{10})N^{\frac{1}{2}} - z_{1-\frac{\alpha}{2}}(p_{10}+p_{01})^{\frac{1}{2}}}{\left[p_{10}+p_{01}-(p_{01}-p_{10})^2\right]^{\frac{1}{2}}}\right), & \text{two-sided} \end{cases}$$

The two-sided solution for N is obtained by numerically inverting the power equation.

In general, compared to METHOD=MIETTINEN, the METHOD=CONNOR approximation tends to be slightly less accurate but slightly conservative in the sense of overestimating sample size and underestimating power (Lachin 1992, p. 1250).

Analyses in the PAIREDMEANS Statement

Paired t Test (TEST=DIFF)

The hypotheses for the paired t test are

$$H_0: \mu_{\text{diff}} = \mu_0$$

$$H_1: \begin{cases} \mu_{\text{diff}} \neq \mu_0, & \text{two-sided} \\ \mu_{\text{diff}} > \mu_0, & \text{upper one-sided} \\ \mu_{\text{diff}} < \mu_0, & \text{lower one-sided} \end{cases}$$

The test assumes normally distributed data and requires $N \geq 2$. The test statistics are

$$t = N^{\frac{1}{2}} \left(\frac{\bar{d} - \mu_0}{s_d} \right) \quad \sim t(N-1, \delta)$$

$$t^2 \sim F(1, N-1, \delta^2)$$

where $\bar{d}$ and s_d are the sample mean and standard deviation of the differences and

$$\delta = N^{\frac{1}{2}} \left(\frac{\mu_{\text{diff}} - \mu_0}{\sigma_{\text{diff}}} \right)$$

and

$$\sigma_{\text{diff}} = \left(\sigma_1^2 + \sigma_2^2 - 2\rho\sigma_1\sigma_2 \right)^{\frac{1}{2}}$$

The test is

$$\text{Reject} \quad H_0 \quad \text{if} \begin{cases} t^2 \geq F_{1-\alpha}(1, N-1), & \text{two-sided} \\ t \geq t_{1-\alpha}(N-1), & \text{upper one-sided} \\ t \leq t_{\alpha}(N-1), & \text{lower one-sided} \end{cases}$$

Exact power computations for t tests are given in O'Brien and Muller (1993, Section 8.2.2):

$$\text{power} = \begin{cases} P\left(F(1, N-1, \delta^2) \geq F_{1-\alpha}(1, N-1) \right), & \text{two-sided} \\ P\left(t(N-1, \delta) \geq t_{1-\alpha}(N-1) \right), & \text{upper one-sided} \\ P\left(t(N-1, \delta) \leq t_{\alpha}(N-1) \right), & \text{lower one-sided} \end{cases}$$

Paired t Test for Mean Ratio with Lognormal Data (TEST=RATIO)

The lognormal case is handled by reexpressing the analysis equivalently as a normality-based test on the log-transformed data, by using properties of the lognormal distribution as discussed in Johnson, Kotz, and Balakrishnan (1994, Chapter 14). The approaches in the section "Paired t Test (TEST=DIFF)" on page 5877 then apply.

In contrast to the usual t test on normal data, the hypotheses with lognormal data are defined in terms of geometric means rather than arithmetic means.

The hypotheses for the paired t test with lognormal pairs $\{Y_1, Y_2\}$ are

$$H_0: \frac{\gamma_2}{\gamma_1} = \gamma_0$$

$$H_1: \begin{cases} \frac{\gamma_2}{\gamma_1} \neq \gamma_0, & \text{two-sided} \\ \frac{\gamma_2}{\gamma_1} > \gamma_0, & \text{upper one-sided} \\ \frac{\gamma_2}{\gamma_1} < \gamma_0, & \text{lower one-sided} \end{cases}$$

Let $\mu_1^\star$, $\mu_2^\star$, $\sigma_1^\star$, $\sigma_2^\star$, and $\rho^\star$ be the (arithmetic) means, standard deviations, and correlation of the bivariate normal distribution of the log-transformed data $\{\log Y_1, \log Y_2\}$. The hypotheses can be rewritten as follows:

$$H_0: \mu_2^\star - \mu_1^\star = \log(\gamma_0)$$

$$H_1: \begin{cases} \mu_2^\star - \mu_1^\star \neq \log(\gamma_0), & \text{two-sided} \\ \mu_2^\star - \mu_1^\star > \log(\gamma_0), & \text{upper one-sided} \\ \mu_2^\star - \mu_1^\star < \log(\gamma_0), & \text{lower one-sided} \end{cases}$$

where

$$\mu_1^\star = \log \gamma_1$$
$$\mu_2^\star = \log \gamma_2$$
$$\sigma_1^\star = \left[\log(\mathrm{CV}_1^2 + 1)\right]^{\frac{1}{2}}$$
$$\sigma_2^\star = \left[\log(\mathrm{CV}_2^2 + 1)\right]^{\frac{1}{2}}$$
$$\rho^\star = \frac{\log\{\rho \mathrm{CV}_1 \mathrm{CV}_2 + 1\}}{\sigma_1^\star \sigma_2^\star}$$

and CV_1, CV_2, and ρ are the coefficients of variation and the correlation of the original untransformed pairs $\{Y_1, Y_2\}$. The conversion from ρ to $\rho^\star$ is shown in Jones and Miller (1966).

The test assumes lognormally distributed data and requires $N \geq 2$. The power is

$$\text{power} = \begin{cases} P\left(F(1, N-1, \delta^2) \geq F_{1-\alpha}(1, N-1)\right), & \text{two-sided} \\ P\left(t(N-1, \delta) \geq t_{1-\alpha}(N-1)\right), & \text{upper one-sided} \\ P\left(t(N-1, \delta) \leq t_{\alpha}(N-1)\right), & \text{lower one-sided} \end{cases}$$

where

$$\delta = N^{\frac{1}{2}} \left(\frac{\mu_1^\star - \mu_2^\star - \log(\gamma_0)}{\sigma^\star} \right)$$

and

$$\sigma^\star = \left(\sigma_1^{\star 2} + \sigma_2^{\star 2} - 2\rho^\star \sigma_1^\star \sigma_2^\star\right)^{\frac{1}{2}}$$

Additive Equivalence Test for Mean Difference with Normal Data (TEST=EQUIV_DIFF)

The hypotheses for the equivalence test are

$$H_0{:}\mu_{\text{diff}} < \theta_L \quad \text{or} \quad \mu_{\text{diff}} > \theta_U$$
$$H_1{:}\theta_L \leq \mu_{\text{diff}} \leq \theta_U$$

The analysis is the two one-sided tests (TOST) procedure of Schuirmann (1987). The test assumes normally distributed data and requires $N \geq 2$. Phillips (1990) derives an expression for the exact power assuming a two-sample balanced design; the results are easily adapted to a paired design:

$$\text{power} = Q_{N-1}\left((-t_{1-\alpha}(N-1)), \frac{\mu_{\text{diff}} - \theta_U}{\sigma_{\text{diff}} N^{-\frac{1}{2}}}; 0, \frac{(N-1)^{\frac{1}{2}}(\theta_U - \theta_L)}{2\sigma_{\text{diff}} N^{-\frac{1}{2}}(t_{1-\alpha}(N-1))}\right) -$$
$$Q_{N-1}\left((t_{1-\alpha}(N-1)), \frac{\mu_{\text{diff}} - \theta_L}{\sigma_{\text{diff}} N^{-\frac{1}{2}}}; 0, \frac{(N-1)^{\frac{1}{2}}(\theta_U - \theta_L)}{2\sigma_{\text{diff}} N^{-\frac{1}{2}}(t_{1-\alpha}(N-1))}\right)$$

where

$$\sigma_{\text{diff}} = \left(\sigma_1^2 + \sigma_2^2 - 2\rho\sigma_1\sigma_2\right)^{\frac{1}{2}}$$

and $Q_{\cdot}(\cdot, \cdot; \cdot, \cdot)$ is Owen's Q function, defined in the section "Common Notation" on page 5841.

Multiplicative Equivalence Test for Mean Ratio with Lognormal Data (TEST=EQUIV_RATIO)

The lognormal case is handled by reexpressing the analysis equivalently as a normality-based test on the log-transformed data, by using properties of the lognormal distribution as discussed in Johnson, Kotz, and Balakrishnan (1994, Chapter 14). The approaches in the section "Additive Equivalence Test for Mean Difference with Normal Data (TEST=EQUIV_DIFF)" on page 5879 then apply.

In contrast to the additive equivalence test on normal data, the hypotheses with lognormal data are defined in terms of geometric means rather than arithmetic means.

The hypotheses for the equivalence test are

$$H_0{:}\frac{\gamma_T}{\gamma_R} \leq \theta_L \quad \text{or} \quad \frac{\gamma_T}{\gamma_R} \geq \theta_U$$
$$H_1{:}\theta_L < \frac{\gamma_T}{\gamma_R} < \theta_U$$
$$\text{where} \quad 0 < \theta_L < \theta_U$$

The analysis is the two one-sided tests (TOST) procedure of Schuirmann (1987) on the log-transformed data. The test assumes lognormally distributed data and requires $N \geq 2$. Diletti, Hauschke, and Steinijans (1991) derive an expression for the exact power assuming a crossover design; the results are easily adapted to a paired design:

$$\text{power} = Q_{N-1}\left((-t_{1-\alpha}(N-1)), \frac{\log\left(\frac{\gamma_T}{\gamma_R}\right) - \log(\theta_U)}{\sigma^\star N^{-\frac{1}{2}}}; 0, \frac{(N-1)^{\frac{1}{2}}(\log(\theta_U) - \log(\theta_L))}{2\sigma^\star N^{-\frac{1}{2}}(t_{1-\alpha}(N-1))}\right) -$$
$$Q_{N-1}\left((t_{1-\alpha}(N-1)), \frac{\log\left(\frac{\gamma_T}{\gamma_R}\right) - \log(\theta_L)}{\sigma^\star N^{-\frac{1}{2}}}; 0, \frac{(N-1)^{\frac{1}{2}}(\log(\theta_U) - \log(\theta_L))}{2\sigma^\star N^{-\frac{1}{2}}(t_{1-\alpha}(N-1))}\right)$$

where $\sigma^\star$ is the standard deviation of the differences between the log-transformed pairs (in other words, the standard deviation of $\log(Y_T) - \log(Y_R)$, where Y_T and Y_R are observations from the treatment and reference, respectively), computed as

$$\begin{aligned}
\sigma^\star &= \left(\sigma_R^{\star 2} + \sigma_T^{\star 2} - 2\rho^\star \sigma_R^\star \sigma_T^\star\right)^{\frac{1}{2}} \\
\sigma_R^\star &= \left[\log(\mathrm{CV}_R^2 + 1)\right]^{\frac{1}{2}} \\
\sigma_T^\star &= \left[\log(\mathrm{CV}_T^2 + 1)\right]^{\frac{1}{2}} \\
\rho^\star &= \frac{\log\{\rho \mathrm{CV}_R \mathrm{CV}_T + 1\}}{\sigma_R^\star \sigma_T^\star}
\end{aligned}$$

where CV_R, CV_T, and ρ are the coefficients of variation and the correlation of the original untransformed pairs $\{Y_T, Y_R\}$, and $Q_\cdot(\cdot,\cdot;\cdot,\cdot)$ is Owen's Q function. The conversion from ρ to $\rho^\star$ is shown in Jones and Miller (1966), and Owen's Q function is defined in the section "Common Notation" on page 5841.

Confidence Interval for Mean Difference (CI=DIFF)

This analysis of precision applies to the standard t-based confidence interval:

$$\begin{cases}
\left[\bar{d} - t_{1-\frac{\alpha}{2}}(N-1)\frac{s_d}{\sqrt{N}}, \quad \bar{d} + t_{1-\frac{\alpha}{2}}(N-1)\frac{s_d}{\sqrt{N}}\right], & \text{two-sided} \\
\left[\bar{d} - t_{1-\alpha}(N-1)\frac{s_d}{\sqrt{N}}, \quad \infty\right), & \text{upper one-sided} \\
\left(-\infty, \quad \bar{d} + t_{1-\alpha}(N-1)\frac{s_d}{\sqrt{N}}\right], & \text{lower one-sided}
\end{cases}$$

where $\bar{d}$ and s_d are the sample mean and standard deviation of the differences. The "half-width" is defined as the distance from the point estimate $\bar{d}$ to a finite endpoint,

$$\text{half-width} = \begin{cases}
t_{1-\frac{\alpha}{2}}(N-1)\frac{s_d}{\sqrt{N}}, & \text{two-sided} \\
t_{1-\alpha}(N-1)\frac{s_d}{\sqrt{N}}, & \text{one-sided}
\end{cases}$$

A "valid" conference interval captures the true mean difference. The exact probability of obtaining at most the target confidence interval half-width h, unconditional or conditional on validity, is given by Beal (1989):

$$\Pr(\text{half-width} \le h) = \begin{cases}
P\left(\chi^2(N-1) \le \frac{h^2 N(N-1)}{\sigma_{\text{diff}}^2 (t_{1-\frac{\alpha}{2}}^2 (N-1))}\right), & \text{two-sided} \\
P\left(\chi^2(N-1) \le \frac{h^2 N(N-1)}{\sigma_{\text{diff}}^2 (t_{1-\alpha}^2 (N-1))}\right), & \text{one-sided}
\end{cases}$$

$$\Pr(\text{half-width} \le h \mid \text{validity}) = \begin{cases}
\left(\frac{1}{1-\alpha}\right) 2\left[Q_{N-1}\left((t_{1-\frac{\alpha}{2}}(N-1)), 0; \right.\right. \\
\quad \left.\left. 0, b_1\right) - Q_{N-1}(0,0;0,b_1)\right], & \text{two-sided} \\
\left(\frac{1}{1-\alpha}\right) Q_{N-1}\left((t_{1-\alpha}(N-1)), 0; 0, b_1\right), & \text{one-sided}
\end{cases}$$

where

$$\sigma_{\text{diff}} = \left(\sigma_1^2 + \sigma_2^2 - 2\rho\sigma_1\sigma_2\right)^{\frac{1}{2}}$$
$$b_1 = \frac{h(N-1)^{\frac{1}{2}}}{\sigma_{\text{diff}}(t_{1-\frac{\alpha}{c}}(N-1))N^{-\frac{1}{2}}}$$
$$c = \text{number of sides}$$

and $Q.(\cdot,\cdot;\cdot,\cdot)$ is Owen's Q function, defined in the section "Common Notation" on page 5841.

A "quality" confidence interval is both sufficiently narrow (half-width $\leq h$) and valid:

$$\begin{aligned}\Pr(\text{quality}) &= \Pr(\text{half-width} \leq h \text{ and validity}) \\ &= \Pr(\text{half-width} \leq h \mid \text{validity})(1-\alpha)\end{aligned}$$

Analyses in the TWOSAMPLEFREQ Statement

Overview of the 2×2 Table

Notation:

		Outcome		
		Failure	Success	
Group	1	$n_1 - x_1$	x_1	n_1
	2	$n_2 - x_2$	x_2	n_2
		$N - m$	m	N

$$x_1 = \#\text{ successes in group 1}$$
$$x_2 = \#\text{ successes in group 2}$$
$$m = x_1 + x_2 = \text{ total \# successes}$$
$$\hat{p}_1 = \frac{x_1}{n_1}$$
$$\hat{p}_2 = \frac{x_2}{n_2}$$
$$\hat{p} = \frac{m}{N} = w_1\hat{p}_1 + w_2\hat{p}_2$$

The hypotheses are

$$H_0: p_2 - p_1 = p_0$$
$$H_1: \begin{cases} p_2 - p_1 \neq p_0, & \text{two-sided} \\ p_2 - p_1 > p_0, & \text{upper one-sided} \\ p_2 - p_1 < p_0, & \text{lower one-sided} \end{cases}$$

where p_0 is constrained to be 0 for all but the unconditional Pearson chi-square test.

Internal calculations are performed in terms of p_1, p_2, and p_0. An input set consisting of OR, p_1, and OR_0 is transformed as follows:

$$
\begin{aligned}
p_2 &= \frac{(OR)p_1}{1-p_1+(OR)p_1} \\
p_{10} &= p_1 \\
p_{20} &= \frac{OR_0 p_{10}}{1-p_{10}+(OR_0)p_{10}} \\
p_0 &= p_{20}-p_{10}
\end{aligned}
$$

An input set consisting of RR, p_1, and RR_0 is transformed as follows:

$$
\begin{aligned}
p_2 &= (RR)p_1 \\
p_{10} &= p_1 \\
p_{20} &= (RR_0)p_{10} \\
p_0 &= p_{20}-p_{10}
\end{aligned}
$$

Note that the transformation of either OR_0 or RR_0 to p_0 is not unique. The chosen parameterization fixes the null value p_{10} at the input value of p_1.

Pearson Chi-Square Test for Two Proportions (TEST=PCHI)

The usual Pearson chi-square test is unconditional. The test statistic

$$
z_P = \frac{\hat{p}_2-\hat{p}_1-p_0}{\left[\hat{p}(1-\hat{p})\left(\frac{1}{n_1}+\frac{1}{n_2}\right)\right]^{\frac{1}{2}}} = [Nw_1w_2]^{\frac{1}{2}}\,\frac{\hat{p}_2-\hat{p}_1-p_0}{\hat{p}(1-\hat{p})}
$$

is assumed to have a null distribution of $N(0,1)$.

Sample size for the one-sided cases is given by equation (4) in Fleiss, Tytun, and Ury (1980). One-sided power is computed as suggested by Diegert and Diegert (1981) by inverting the sample size formula. Power for the two-sided case is computed by adding the lower-sided and upper-sided powers each with $\alpha/2$, and sample size for the two-sided case is obtained by numerically inverting the power formula. A custom null value p_0 for the proportion difference p_2-p_1 is also supported.

$$
\text{power} = \begin{cases}
\Phi\left(\dfrac{(p_2-p_1-p_0)(Nw_1w_2)^{\frac{1}{2}}-z_{1-\alpha}[(w_1p_1+w_2p_2)(1-w_1p_1-w_2p_2)]^{\frac{1}{2}}}{[w_2p_1(1-p_1)+w_1p_2(1-p_2)]^{\frac{1}{2}}}\right), & \text{upper one-sided} \\
\Phi\left(\dfrac{-(p_2-p_1-p_0)(Nw_1w_2)^{\frac{1}{2}}-z_{1-\alpha}[(w_1p_1+w_2p_2)(1-w_1p_1-w_2p_2)]^{\frac{1}{2}}}{[w_2p_1(1-p_1)+w_1p_2(1-p_2)]^{\frac{1}{2}}}\right), & \text{lower one-sided} \\
\Phi\left(\dfrac{(p_2-p_1-p_0)(Nw_1w_2)^{\frac{1}{2}}-z_{1-\frac{\alpha}{2}}[(w_1p_1+w_2p_2)(1-w_1p_1-w_2p_2)]^{\frac{1}{2}}}{[w_2p_1(1-p_1)+w_1p_2(1-p_2)]^{\frac{1}{2}}}\right)+ & \\
\quad\Phi\left(\dfrac{-(p_2-p_1-p_0)(Nw_1w_2)^{\frac{1}{2}}-z_{1-\frac{\alpha}{2}}[(w_1p_1+w_2p_2)(1-w_1p_1-w_2p_2)]^{\frac{1}{2}}}{[w_2p_1(1-p_1)+w_1p_2(1-p_2)]^{\frac{1}{2}}}\right), & \text{two-sided}
\end{cases}
$$

For the one-sided cases, a closed-form inversion of the power equation yield an approximate total sample size

$$
N = \frac{\left[z_{1-\alpha}\{(w_1p_1+w_2p_2)(1-w_1p_1-w_2p_2)\}^{\frac{1}{2}}+z_{\text{power}}\{w_2p_1(1-p_1)+w_1p_2(1-p_2)\}^{\frac{1}{2}}\right]^2}{w_1w_2(p_2-p_1-p_0)^2}
$$

For the two-sided case, the solution for N is obtained by numerically inverting the power equation.

Likelihood Ratio Chi-Square Test for Two Proportions (TEST=LRCHI)

The usual likelihood ratio chi-square test is unconditional. The test statistic

$$z_{LR} = (-1_{\{p_2<p_1\}})\sqrt{2N\sum_{i=1}^{2}\left[w_i\,\hat{p}_i\log\left(\frac{\hat{p}_i}{\hat{p}}\right)+w_i(1-\hat{p}_i)\log\left(\frac{1-\hat{p}_i}{1-\hat{p}}\right)\right]}$$

is assumed to have a null distribution of $N(0,1)$ and an alternative distribution of $N(\delta,1)$, where

$$\delta = N^{\frac{1}{2}}(-1_{\{p_2<p_1\}})\sqrt{2\sum_{i=1}^{2}\left[w_i\,p_i\log\left(\frac{p_i}{w_1p_1+w_2p_2}\right)+w_i(1-p_i)\log\left(\frac{1-p_i}{1-(w_1p_1+w_2p_2)}\right)\right]}$$

The approximate power is

$$\text{power} = \begin{cases} \Phi\left(\delta - z_{1-\alpha}\right), & \text{upper one-sided} \\ \Phi\left(-\delta - z_{1-\alpha}\right), & \text{lower one-sided} \\ \Phi\left(\delta - z_{1-\frac{\alpha}{2}}\right) + \Phi\left(-\delta - z_{1-\frac{\alpha}{2}}\right), & \text{two-sided} \end{cases}$$

For the one-sided cases, a closed-form inversion of the power equation yield an approximate total sample size

$$N = \left(\frac{z_{\text{power}} + z_{1-\alpha}}{\delta}\right)^2$$

For the two-sided case, the solution for N is obtained by numerically inverting the power equation.

Fisher's Exact Conditional Test for Two Proportions (Test=FISHER)

Fisher's exact test is conditional on the observed total number of successes m. Power and sample size computations are based on a test with similar power properties, the continuity-adjusted arcsine test. The test statistic

$$z_A = (4Nw_1w_2)^{\frac{1}{2}}\left[\arcsin\left(\left[\hat{p}_2+\frac{1}{2Nw_2}(1_{\{\hat{p}_2<\hat{p}_1\}}-1_{\{\hat{p}_2>\hat{p}_1\}})\right]^{\frac{1}{2}}\right)\right.$$
$$\left.-\arcsin\left(\left[\hat{p}_1+\frac{1}{2Nw_1}(1_{\{\hat{p}_1<\hat{p}_2\}}-1_{\{\hat{p}_1>\hat{p}_2\}})\right]^{\frac{1}{2}}\right)\right]$$

is assumed to have a null distribution of $N(0,1)$ and an alternative distribution of $N(\delta,1)$, where

$$\delta = (4Nw_1w_2)^{\frac{1}{2}}\left[\arcsin\left(\left[p_2+\frac{1}{2Nw_2}(1_{\{p_2<p_1\}}-1_{\{p_2>p_1\}})\right]^{\frac{1}{2}}\right)\right.$$
$$\left.-\arcsin\left(\left[p_1+\frac{1}{2Nw_1}(1_{\{p_1<p_2\}}-1_{\{p_1>p_2\}})\right]^{\frac{1}{2}}\right)\right]$$

The approximate power for the one-sided balanced case is given by Walters (1979) and is easily extended to the unbalanced and two-sided cases:

$$\text{power} = \begin{cases} \Phi\left(\delta - z_{1-\alpha}\right), & \text{upper one-sided} \\ \Phi\left(-\delta - z_{1-\alpha}\right), & \text{lower one-sided} \\ \Phi\left(\delta - z_{1-\frac{\alpha}{2}}\right) + \Phi\left(-\delta - z_{1-\frac{\alpha}{2}}\right), & \text{two-sided} \end{cases}$$

Analyses in the TWOSAMPLEMEANS Statement

Two-Sample t *Test Assuming Equal Variances (TEST=DIFF)*

The hypotheses for the two-sample t test are

$$H_0: \mu_{\text{diff}} = \mu_0$$

$$H_1: \begin{cases} \mu_{\text{diff}} \neq \mu_0, & \text{two-sided} \\ \mu_{\text{diff}} > \mu_0, & \text{upper one-sided} \\ \mu_{\text{diff}} < \mu_0, & \text{lower one-sided} \end{cases}$$

The test assumes normally distributed data and common standard deviation per group, and it requires $N \geq 3$, $n_1 \geq 1$, and $n_2 \geq 1$. The test statistics are

$$t = N^{\frac{1}{2}}(w_1 w_2)^{\frac{1}{2}}\left(\frac{\bar{x}_2 - \bar{x}_1 - \mu_0}{s_p}\right) \quad \sim \quad t(N-2, \delta)$$

$$t^2 \sim F(1, N-2, \delta^2)$$

where $\bar{x}_1$ and $\bar{x}_2$ are the sample means and s_p is the pooled standard deviation, and

$$\delta = N^{\frac{1}{2}}(w_1 w_2)^{\frac{1}{2}}\left(\frac{\mu_{\text{diff}} - \mu_0}{\sigma}\right)$$

The test is

$$\text{Reject} \quad H_0 \quad \text{if} \begin{cases} t^2 \geq F_{1-\alpha}(1, N-2), & \text{two-sided} \\ t \geq t_{1-\alpha}(N-2), & \text{upper one-sided} \\ t \leq t_{\alpha}(N-2), & \text{lower one-sided} \end{cases}$$

Exact power computations for t tests are given in O'Brien and Muller (1993, Section 8.2.1):

$$\text{power} = \begin{cases} P\left(F(1, N-2, \delta^2) \geq F_{1-\alpha}(1, N-2)\right), & \text{two-sided} \\ P\left(t(N-2, \delta) \geq t_{1-\alpha}(N-2)\right), & \text{upper one-sided} \\ P\left(t(N-2, \delta) \leq t_{\alpha}(N-2)\right), & \text{lower one-sided} \end{cases}$$

Solutions for N, n_1, n_2, α, and δ are obtained by numerically inverting the power equation. Closed-form solutions for other parameters, in terms of δ, are as follows:

$$\mu_{\text{diff}} = \delta\sigma(Nw_1w_2)^{-\frac{1}{2}} + \mu_0$$

$$\mu_1 = \delta\sigma(Nw_1w_2)^{-\frac{1}{2}} + \mu_0 - \mu_2$$

$$\mu_2 = \delta\sigma(Nw_1w_2)^{-\frac{1}{2}} + \mu_0 - \mu_1$$

$$\sigma = \begin{cases} \delta^{-1}(Nw_1w_2)^{\frac{1}{2}}(\mu_{\text{diff}} - \mu_0), & |\delta| > 0 \\ \text{undefined}, & \text{otherwise} \end{cases}$$

$$w_1 = \begin{cases} \frac{1}{2} \pm \frac{1}{2}\left[1 - \frac{4\delta^2\sigma^2}{N(\mu_{\text{diff}}-\mu_0)^2}\right]^{\frac{1}{2}}, & 0 < |\delta| \le \frac{1}{2}N^{\frac{1}{2}}\frac{|\mu_{\text{diff}}-\mu_0|}{\sigma} \\ \text{undefined}, & \text{otherwise} \end{cases}$$

$$w_2 = \begin{cases} \frac{1}{2} \pm \frac{1}{2}\left[1 - \frac{4\delta^2\sigma^2}{N(\mu_{\text{diff}}-\mu_0)^2}\right]^{\frac{1}{2}}, & 0 < |\delta| \le \frac{1}{2}N^{\frac{1}{2}}\frac{|\mu_{\text{diff}}-\mu_0|}{\sigma} \\ \text{undefined}, & \text{otherwise} \end{cases}$$

Finally, here is a derivation of the solution for w_1:

Solve the δ equation for w_1 (which requires the quadratic formula). Then determine the range of δ given w_1:

$$\min_{w_1}(\delta) = \begin{cases} 0, & \text{when} \quad w_1 = 0 \quad \text{or} \quad 1, \quad \text{if} \quad (\mu_{\text{diff}} - \mu_0) \ge 0 \\ \frac{1}{2}N^{\frac{1}{2}}\frac{(\mu_{\text{diff}}-\mu_0)}{\sigma}, & \text{when} \quad w_1 = \frac{1}{2}, \quad \text{if} \quad (\mu_{\text{diff}} - \mu_0) < 0 \end{cases}$$

$$\max_{w_1}(\delta) = \begin{cases} 0, & \text{when} \quad w_1 = 0 \quad \text{or} \quad 1, \quad \text{if} \quad (\mu_{\text{diff}} - \mu_0) < 0 \\ \frac{1}{2}N^{\frac{1}{2}}\frac{(\mu_{\text{diff}}-\mu_0)}{\sigma}, & \text{when} \quad w_1 = \frac{1}{2}, \quad \text{if} \quad (\mu_{\text{diff}} - \mu_0) \ge 0 \end{cases}$$

This implies

$$|\delta| \le \frac{1}{2}N^{\frac{1}{2}}\frac{|\mu_{\text{diff}} - \mu_0|}{\sigma}$$

Two-Sample Satterthwaite t *Test Assuming Unequal Variances (TEST=DIFF_SATT)*

The hypotheses for the two-sample Satterthwaite t test are

$$H_0{:}\mu_{\text{diff}} = \mu_0$$

$$H_1{:}\begin{cases} \mu_{\text{diff}} \ne \mu_0, & \text{two-sided} \\ \mu_{\text{diff}} > \mu_0, & \text{upper one-sided} \\ \mu_{\text{diff}} < \mu_0, & \text{lower one-sided} \end{cases}$$

The test assumes normally distributed data and requires $N \geq 3$, $n_1 \geq 1$, and $n_2 \geq 1$. The test statistics are

$$t = \frac{\bar{x}_2 - \bar{x}_1 - \mu_0}{\left[\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}\right]^{\frac{1}{2}}} = N^{\frac{1}{2}} \frac{\bar{x}_2 - \bar{x}_1 - \mu_0}{\left[\frac{s_1^2}{w_1} + \frac{s_2^2}{w_2}\right]^{\frac{1}{2}}}$$

$$F = t^2$$

where $\bar{x}_1$ and $\bar{x}_2$ are the sample means and s_1 and s_2 are the sample standard deviations.

As DiSantostefano and Muller (1995, p. 585) state, the test is based on assuming that under H_0, F is distributed as $F(1, \nu)$, where ν is given by Satterthwaite's approximation (Satterthwaite 1946),

$$\nu = \frac{\left[\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}\right]^2}{\frac{\left[\frac{\sigma_1^2}{n_1}\right]^2}{n_1 - 1} + \frac{\left[\frac{\sigma_2^2}{n_2}\right]^2}{n_2 - 1}} = \frac{\left[\frac{\sigma_1^2}{w_1} + \frac{\sigma_2^2}{w_2}\right]^2}{\frac{\left[\frac{\sigma_1^2}{w_1}\right]^2}{Nw_1 - 1} + \frac{\left[\frac{\sigma_2^2}{w_2}\right]^2}{Nw_2 - 1}}$$

Since ν is unknown, in practice it must be replaced by an estimate

$$\hat{\nu} = \frac{\left[\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}\right]^2}{\frac{\left[\frac{s_1^2}{n_1}\right]^2}{n_1 - 1} + \frac{\left[\frac{s_2^2}{n_2}\right]^2}{n_2 - 1}} = \frac{\left[\frac{s_1^2}{w_1} + \frac{s_2^2}{w_2}\right]^2}{\frac{\left[\frac{s_1^2}{w_1}\right]^2}{Nw_1 - 1} + \frac{\left[\frac{s_2^2}{w_2}\right]^2}{Nw_2 - 1}}$$

So the test is

$$\text{Reject} \quad H_0 \quad \text{if} \begin{cases} F \geq F_{1-\alpha}(1, \hat{\nu}), & \text{two-sided} \\ t \geq t_{1-\alpha}(\hat{\nu}), & \text{upper one-sided} \\ t \leq t_{\alpha}(\hat{\nu}), & \text{lower one-sided} \end{cases}$$

Exact solutions for power for the two-sided and upper one-sided cases are given in Moser, Stevens, and Watts (1989). The lower one-sided case follows easily by using symmetry. The equations are as follows:

$$\text{power} = \begin{cases} \int_0^\infty P\left(F(1, N-2, \lambda) > \right. \\ \quad \left. h(u) F_{1-\alpha}(1, v(u)) | u\right) f(u) \mathrm{d}u, & \text{two-sided} \\ \int_0^\infty P\left(t(N-2, \lambda^{\frac{1}{2}}) > \right. \\ \quad \left. [h(u)]^{\frac{1}{2}} t_{1-\alpha}(v(u)) | u\right) f(u) \mathrm{d}u, & \text{upper one-sided} \\ \int_0^\infty P\left(t(N-2, \lambda^{\frac{1}{2}}) < \right. \\ \quad \left. [h(u)]^{\frac{1}{2}} t_{\alpha}(v(u)) | u\right) f(u) \mathrm{d}u, & \text{lower one-sided} \end{cases}$$

where

$$h(u) = \frac{\left(\frac{1}{n_1} + \frac{u}{n_2}\right)(n_1 + n_2 - 2)}{\left[(n_1 - 1) + (n_2 - 1)\frac{u\sigma_1^2}{\sigma_2^2}\right]\left(\frac{1}{n_1} + \frac{\sigma_2^2}{\sigma_1^2 n_2}\right)}$$

$$v(u) = \frac{\left(\frac{1}{n_1} + \frac{u}{n_2}\right)^2}{\frac{1}{n_1^2(n_1-1)} + \frac{u^2}{n_2^2(n_2-1)}}$$

$$\lambda = \frac{(\mu_{\text{diff}} - \mu_0)^2}{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}}$$

$$f(u) = \frac{\Gamma\left(\frac{n_1+n_2-2}{2}\right)}{\Gamma\left(\frac{n_1-1}{2}\right)\Gamma\left(\frac{n_2-1}{2}\right)} \left[\frac{\sigma_1^2(n_2-1)}{\sigma_2^2(n_1-1)}\right]^{\frac{n_2-1}{2}} u^{\frac{n_2-3}{2}} \left[1 + \left(\frac{n_2-1}{n_1-1}\right)\frac{u\sigma_1^2}{\sigma_2^2}\right]^{-\left(\frac{n_1+n_2-2}{2}\right)}$$

The density $f(u)$ is obtained from the fact that

$$\frac{u\sigma_1^2}{\sigma_2^2} \sim F(n_2 - 1, n_1 - 1)$$

Two-Sample Pooled t *Test of Mean Ratio with Lognormal Data (TEST=RATIO)*

The lognormal case is handled by reexpressing the analysis equivalently as a normality-based test on the log-transformed data, by using properties of the lognormal distribution as discussed in Johnson, Kotz, and Balakrishnan (1994, Chapter 14). The approaches in the section "Two-Sample *t* Test Assuming Equal Variances (TEST=DIFF)" on page 5884 then apply.

In contrast to the usual t test on normal data, the hypotheses with lognormal data are defined in terms of geometric means rather than arithmetic means. The test assumes equal coefficients of variation in the two groups.

The hypotheses for the two-sample t test with lognormal data are

$$H_0: \frac{\gamma_2}{\gamma_1} = \gamma_0$$

$$H_1: \begin{cases} \frac{\gamma_2}{\gamma_1} \neq \gamma_0, & \text{two-sided} \\ \frac{\gamma_2}{\gamma_1} > \gamma_0, & \text{upper one-sided} \\ \frac{\gamma_2}{\gamma_1} < \gamma_0, & \text{lower one-sided} \end{cases}$$

Let $\mu_1^\star$, $\mu_2^\star$, and $\sigma^\star$ be the (arithmetic) means and common standard deviation of the corresponding normal distributions of the log-transformed data. The hypotheses can be rewritten as follows:

$$H_0{:}\mu_2^\star - \mu_1^\star = \log(\gamma_0)$$
$$H_1{:}\begin{cases} \mu_2^\star - \mu_1^\star \neq \log(\gamma_0), & \text{two-sided} \\ \mu_2^\star - \mu_1^\star > \log(\gamma_0), & \text{upper one-sided} \\ \mu_2^\star - \mu_1^\star < \log(\gamma_0), & \text{lower one-sided} \end{cases}$$

where

$$\mu_1^\star = \log \gamma_1$$
$$\mu_2^\star = \log \gamma_2$$

The test assumes lognormally distributed data and requires $N \geq 3$, $n_1 \geq 1$, and $n_2 \geq 1$.

The power is

$$\text{power} = \begin{cases} P\left(F(1, N-2, \delta^2) \geq F_{1-\alpha}(1, N-2)\right), & \text{two-sided} \\ P\left(t(N-2, \delta) \geq t_{1-\alpha}(N-2)\right), & \text{upper one-sided} \\ P\left(t(N-2, \delta) \leq t_{\alpha}(N-2)\right), & \text{lower one-sided} \end{cases}$$

where

$$\delta = N^{\frac{1}{2}}(w_1 w_2)^{\frac{1}{2}}\left(\frac{\mu_2^\star - \mu_1^\star - \log(\gamma_0)}{\sigma^\star}\right)$$
$$\sigma^\star = \left[\log(\text{CV}^2 + 1)\right]^{\frac{1}{2}}$$

Additive Equivalence Test for Mean Difference with Normal Data (TEST=EQUIV_DIFF)

The hypotheses for the equivalence test are

$$H_0{:}\mu_{\text{diff}} < \theta_L \quad \text{or} \quad \mu_{\text{diff}} > \theta_U$$
$$H_1{:}\theta_L \leq \mu_{\text{diff}} \leq \theta_U$$

The analysis is the two one-sided tests (TOST) procedure of Schuirmann (1987). The test assumes normally distributed data and requires $N \geq 3$, $n_1 \geq 1$, and $n_2 \geq 1$. Phillips (1990) derives an expression for the exact power assuming a balanced design; the results are easily adapted to an unbalanced design:

$$\text{power} = Q_{N-2}\left((-t_{1-\alpha}(N-2)), \frac{\mu_{\text{diff}} - \theta_U}{\sigma N^{-\frac{1}{2}}(w_1 w_2)^{-\frac{1}{2}}}; 0, \frac{(N-2)^{\frac{1}{2}}(\theta_U - \theta_L)}{2\sigma N^{-\frac{1}{2}}(w_1 w_2)^{-\frac{1}{2}}(t_{1-\alpha}(N-2))}\right) -$$
$$Q_{N-2}\left((t_{1-\alpha}(N-2)), \frac{\mu_{\text{diff}} - \theta_L}{\sigma N^{-\frac{1}{2}}(w_1 w_2)^{-\frac{1}{2}}}; 0, \frac{(N-2)^{\frac{1}{2}}(\theta_U - \theta_L)}{2\sigma N^{-\frac{1}{2}}(w_1 w_2)^{-\frac{1}{2}}(t_{1-\alpha}(N-2))}\right)$$

where $Q_\cdot(\cdot, \cdot; \cdot, \cdot)$ is Owen's Q function, defined in the section "Common Notation" on page 5841.

Multiplicative Equivalence Test for Mean Ratio with Lognormal Data (TEST=EQUIV_RATIO)

The lognormal case is handled by reexpressing the analysis equivalently as a normality-based test on the log-transformed data, by using properties of the lognormal distribution as discussed in Johnson, Kotz, and Balakrishnan (1994, Chapter 14). The approaches in the section "Additive Equivalence Test for Mean Difference with Normal Data (TEST=EQUIV_DIFF)" on page 5888 then apply.

In contrast to the additive equivalence test on normal data, the hypotheses with lognormal data are defined in terms of geometric means rather than arithmetic means.

The hypotheses for the equivalence test are

$$H_0: \frac{\gamma_T}{\gamma_R} \leq \theta_L \quad \text{or} \quad \frac{\gamma_T}{\gamma_R} \geq \theta_U$$
$$H_1: \theta_L < \frac{\gamma_T}{\gamma_R} < \theta_U$$
$$\text{where} \quad 0 < \theta_L < \theta_U$$

The analysis is the two one-sided tests (TOST) procedure of Schuirmann (1987) on the log-transformed data. The test assumes lognormally distributed data and requires $N \geq 3$, $n_1 \geq 1$, and $n_2 \geq 1$. Diletti, Hauschke, and Steinijans (1991) derive an expression for the exact power assuming a crossover design; the results are easily adapted to an unbalanced two-sample design:

$$\text{power} = Q_{N-2}\left((-t_{1-\alpha}(N-2)), \frac{\log\left(\frac{\gamma_T}{\gamma_R}\right) - \log(\theta_U)}{\sigma^\star N^{-\frac{1}{2}}(w_1 w_2)^{-\frac{1}{2}}}; 0, \frac{(N-2)^{\frac{1}{2}}(\log(\theta_U) - \log(\theta_L))}{2\sigma^\star N^{-\frac{1}{2}}(w_1 w_2)^{-\frac{1}{2}}(t_{1-\alpha}(N-2))}\right) -$$
$$Q_{N-2}\left((t_{1-\alpha}(N-2)), \frac{\log\left(\frac{\gamma_T}{\gamma_R}\right) - \log(\theta_L)}{\sigma^\star N^{-\frac{1}{2}}(w_1 w_2)^{-\frac{1}{2}}}; 0, \frac{(N-2)^{\frac{1}{2}}(\log(\theta_U) - \log(\theta_L))}{2\sigma^\star N^{-\frac{1}{2}}(w_1 w_2)^{-\frac{1}{2}}(t_{1-\alpha}(N-2))}\right)$$

where

$$\sigma^\star = \left[\log(\text{CV}^2 + 1)\right]^{\frac{1}{2}}$$

is the (assumed common) standard deviation of the normal distribution of the log-transformed data, and $Q_\cdot(\cdot,\cdot;\cdot,\cdot)$ is Owen's Q function, defined in the section "Common Notation" on page 5841.

Confidence Interval for Mean Difference (CI=DIFF)

This analysis of precision applies to the standard t-based confidence interval:

$$\begin{array}{ll}
\left[(\bar{x}_2 - \bar{x}_1) - t_{1-\frac{\alpha}{2}}(N-2)\frac{s_p}{\sqrt{N w_1 w_2}},\right. & \\
\quad \left.(\bar{x}_2 - \bar{x}_1) + t_{1-\frac{\alpha}{2}}(N-2)\frac{s_p}{\sqrt{N w_1 w_2}}\right], & \text{two-sided} \\
\left[(\bar{x}_2 - \bar{x}_1) - t_{1-\alpha}(N-2)\frac{s_p}{\sqrt{N w_1 w_2}}, \quad \infty\right), & \text{upper one-sided} \\
\left(-\infty, \quad (\bar{x}_2 - \bar{x}_1) + t_{1-\alpha}(N-2)\frac{s_p}{\sqrt{N w_1 w_2}}\right], & \text{lower one-sided}
\end{array}$$

where $\bar{x}_1$ and $\bar{x}_2$ are the sample means and s_p is the pooled standard deviation. The "half-width" is defined as the distance from the point estimate $\bar{x}_2 - \bar{x}_1$ to a finite endpoint,

$$\text{half-width} = \begin{cases} t_{1-\frac{\alpha}{2}}(N-2)\frac{s_p}{\sqrt{N w_1 w_2}}, & \text{two-sided} \\ t_{1-\alpha}(N-2)\frac{s_p}{\sqrt{N w_1 w_2}}, & \text{one-sided} \end{cases}$$

A "valid" confidence interval captures the true mean. The exact probability of obtaining at most the target confidence interval half-width h, unconditional or conditional on validity, is given by Beal (1989):

$$\Pr(\text{half-width} \le h) = \begin{cases} P\left(\chi^2(N-2) \le \frac{h^2 N(N-2)(w_1 w_2)}{\sigma^2 (t^2_{1-\frac{\alpha}{2}}(N-2))}\right), & \text{two-sided} \\ P\left(\chi^2(N-2) \le \frac{h^2 N(N-2)(w_1 w_2)}{\sigma^2 (t^2_{1-\alpha}(N-2))}\right), & \text{one-sided} \end{cases}$$

$$\Pr(\text{half-width} \le h \mid \text{validity}) = \begin{cases} \left(\frac{1}{1-\alpha}\right) 2\left[Q_{N-2}\left((t_{1-\frac{\alpha}{2}}(N-2)), 0; \right.\right. \\ \quad \left.\left. 0, b_2\right) - Q_{N-2}(0,0;0,b_2)\right], & \text{two-sided} \\ \left(\frac{1}{1-\alpha}\right) Q_{N-2}\left((t_{1-\alpha}(N-2)), 0; 0, b_2\right), & \text{one-sided} \end{cases}$$

where

$$b_2 = \frac{h(N-2)^{\frac{1}{2}}}{\sigma(t_{1-\frac{\alpha}{c}}(N-2)) N^{-\frac{1}{2}} (w_1 w_2)^{-\frac{1}{2}}}$$

$$c = \text{number of sides}$$

and $Q.(\cdot,\cdot;\cdot,\cdot)$ is Owen's Q function, defined in the section "Common Notation" on page 5841.

A "quality" confidence interval is both sufficiently narrow (half-width $\le h$) and valid:

$$\begin{aligned} \Pr(\text{quality}) &= \Pr(\text{half-width} \le h \text{ and validity}) \\ &= \Pr(\text{half-width} \le h \mid \text{validity})(1-\alpha) \end{aligned}$$

Analyses in the TWOSAMPLESURVIVAL Statement

Rank Tests for Two Survival Curves (TEST=LOGRANK, TEST=GEHAN, TEST=TARONEWARE)

The method is from Lakatos (1988) and Cantor (1997, pp. 83–92).

Define the following notation:

$X_j(i) =$ ith input time point on survival curve for group j
$S_j(i) =$ input survivor function value corresponding to $X_j(i)$
$h_j(t) =$ hazard rate for group j at time t
$\Psi_j(t) =$ loss hazard rate for group j at time t
$\lambda_j =$ exponential hazard rate for group j
$R =$ hazard ratio of group 2 to group 1 $\equiv$ (assumed constant) value of $\frac{h_2(t)}{h_1(t)}$
$m_j =$ median survival time for group j
$b =$ number of subintervals per time unit
$T =$ accrual time
$\tau =$ postaccrual follow-up time
$L_j =$ exponential loss rate for group j
$XL_j =$ input time point on loss curve for group j
$SL_j =$ input survivor function value corresponding to XL_j
$mL_j =$ median survival time for group j
$r_i =$ rank for ith time point

Each survival curve can be specified in one of several ways.

- For exponential curves:
  - a single point $(X_j(1), S_j(1))$ on the curve
  - median survival time
  - hazard rate
  - hazard ratio (for curve 2, with respect to curve 1)
- For piecewise linear curves with proportional hazards:
  - a set of points $\{(X_1(1), S_1(1)), (X_1(2), S_1(2)), \ldots\}$ (for curve 1)
  - hazard ratio (for curve 2, with respect to curve 1)
- For arbitrary piecewise linear curves:
  - a set of points $\{(X_j(1), S_j(1)), (X_j(2), S_j(2)), \ldots\}$

A total of $M+1$ evenly spaced time points $\{t_0 = 0, t_1, t_2, \ldots, t_M = T + \tau\}$ are used in calculations, where

$$M = \text{floor}\,((T + \tau)b)$$

The hazard function is calculated for each survival curve at each time point. For an exponential curve, the (constant) hazard is given by one of the following, depending on the input parameterization:

$$h_j(t) = \begin{cases} \lambda_j \\ \lambda_1 R \\ \frac{-\log(\frac{1}{2})}{m_j} \\ \frac{-\log(S_j(1))}{X_j(1)} \\ \frac{-\log(S_1(1))}{X_1(1)} R \end{cases}$$

For a piecewise linear curve, define the following additional notation:

$$t_i^- = \text{largest input time } X \text{ such that } X \le t_i$$
$$t_i^+ = \text{smallest input time } X \text{ such that } X > t_i$$

The hazard is computed by using linear interpolation as follows:

$$h_j(t_i) = \frac{S_j(t_i^-) - S_j(t_i^+)}{\left[S_j(t_i^+) - S_j(t_i^-)\right]\left[t_i - t_i^-\right] + S_j(t_i^-)\left[t_i^+ - t_i^-\right]}$$

With proportional hazards, the hazard rate of group 2's curve in terms of the hazard rate of group 1's curve is

$$h_2(t) = h_1(t)R$$

Hazard function values $\{\Psi_j(t_i)\}$ for the loss curves are computed in an analogous way from $\{L_j, XL_j, SL_j, mL_j\}$.

The expected number at risk $N_j(i)$ at time i in group j is calculated for each group and time points 0 through $M-1$, as follows:

$$N_j(0) = Nw_j$$
$$N_j(i+1) = N_j(i)\left[1 - h_j(t_i)\left(\frac{1}{b}\right) - \Psi_j(t_i)\left(\frac{1}{b}\right) - \left(\frac{1}{b(T+\tau-t_i)}\right)1_{\{t_i>\tau\}}\right]$$

Define θ_i as the ratio of hazards and ϕ_i as the ratio of expected numbers at risk for time t_i:

$$\theta_i = \frac{h_2(t_i)}{h_1(t_i)}$$
$$\phi_i = \frac{N_2(i)}{N_1(i)}$$

The expected number of deaths in each subinterval is calculated as follows:

$$D_i = \left[h_1(t_i)N_1(i) + h_2(t_i)N_2(i)\right]\left(\frac{1}{b}\right)$$

The rank values are calculated as follows according to which test statistic is used:

$$r_i = \begin{cases} 1, & \text{log-rank} \\ N_1(i) + N_2(i), & \text{Gehan} \\ \sqrt{N_1(i) + N_2(i)}, & \text{Tarone-Ware} \end{cases}$$

The distribution of the test statistic is approximated by $N(E, 1)$ where

$$E = \frac{\sum_{i=0}^{M-1} D_i r_i \left[\frac{\phi_i \theta_i}{1+\phi_i \theta_i} - \frac{\phi_i}{1+\phi_i} \right]}{\sqrt{\sum_{i=0}^{M-1} D_i r_i^2 \frac{\phi_i}{(1+\phi_i)^2}}}$$

Note that $N^{\frac{1}{2}}$ can be factored out of the mean E, and so it can be expressed equivalently as

$$E = N^{\frac{1}{2}} E^\star = N^{\frac{1}{2}} \left[\frac{\sum_{i=0}^{M-1} D_i^\star r_i^\star \left[\frac{\phi_i \theta_i}{1+\phi_i \theta_i} - \frac{\phi_i}{1+\phi_i} \right]}{\sqrt{\sum_{i=0}^{M-1} D_i^\star r_i^{\star 2} \frac{\phi_i}{(1+\phi_i)^2}}} \right]$$

where $E^\star$ is free of N and

$$D_i^\star = \left[h_1(t_i) N_1^\star(i) + h_2(t_i) N_2^\star(i) \right] \left(\frac{1}{b} \right)$$

$$r_i^\star = \begin{cases} 1, & \text{log-rank} \\ N_1^\star(i) + N_2^\star(i), & \text{Gehan} \\ \sqrt{N_1^\star(i) + N_2^\star(i)}, & \text{Tarone-Ware} \end{cases}$$

$$N_j^\star(0) = w_j$$

$$N_j^\star(i+1) = N_j^\star(i) \left[1 - h_j(t_i) \left(\frac{1}{b} \right) - \Psi_j(t_i) \left(\frac{1}{b} \right) - \left(\frac{1}{b(T + \tau - t_i)} \right) 1_{\{t_i > \tau\}} \right]$$

The approximate power is

$$\text{power} = \begin{cases} \Phi\left(-N^{\frac{1}{2}} E^\star - z_{1-\alpha} \right), & \text{upper one-sided} \\ \Phi\left(N^{\frac{1}{2}} E^\star - z_{1-\alpha} \right), & \text{lower one-sided} \\ \Phi\left(-N^{\frac{1}{2}} E^\star - z_{1-\frac{\alpha}{2}} \right) + \Phi\left(N^{\frac{1}{2}} E^\star - z_{1-\frac{\alpha}{2}} \right), & \text{two-sided} \end{cases}$$

Note that the upper and lower one-sided cases are expressed differently than in other analyses. This is because $E^\star > 0$ corresponds to a higher survival curve in group 1 and thus, by the convention used in PROC power for two-group analyses, the lower side.

For the one-sided cases, a closed-form inversion of the power equation yield an approximate total sample size

$$N = \left(\frac{z_{\text{power}} + z_{1-\alpha}}{E^\star} \right)^2$$

For the two-sided case, the solution for N is obtained by numerically inverting the power equation.

Accrual rates are converted to and from sample sizes according to the equation $a_j = n_j / T$, where a_j is the accrual rate for group j.

Expected numbers of events—that is, deaths, whether observed or censored—are converted to and from sample sizes according to the equation

$$e_j = \begin{cases} n_j \left[1 - S_j(\tau)\right], & T = 0 \\ n_j \left[1 - \frac{1}{T}\int_0^T S_j(T+\tau-t)dt\right], & T > 0 \end{cases}$$

where e_j is the expected number of events in group j. For an exponential curve, the equation simplifies to

$$e_j = \begin{cases} n_j \left[1 - \exp(-\lambda_j \tau)\right], & T = 0 \\ n_j \left[1 - \frac{1}{\lambda_j T}\left(\exp(-\lambda_j \tau) - \exp(-\lambda_j (T+\tau))\right)\right], & T > 0 \end{cases}$$

For a piecewise linear curve, first define K_j as the number of time points in the following collection: τ, $T+\tau$, and input time points for group j strictly between τ and $T+\tau$. Denote the ordered set of these points as $\{u_{j1}, \ldots, u_{jK_j}\}$. The survival function values $S_j(\tau)$ and $S_j(T+\tau)$ are calculated by linear interpolation between adjacent input time points if they do not coincide with any input time points. Then the equation for a piecewise linear curve simplifies to

$$e_j = \begin{cases} n_j \left[1 - S_j(\tau)\right], & T = 0 \\ n_j \left[1 - \frac{1}{2T}\sum_{i=1}^{K_j-1}\left(u_{j,i+1} - u_{ji}\right)\left(S_j(u_{ji}) + S_j(u_{j,i+1})\right)\right], & T > 0 \end{cases}$$

Analyses in the TWOSAMPLEWILCOXON Statement

Wilcoxon-Mann-Whitney Test for Comparing Two Distributions (TEST=WMW)

The power approximation in this section is applicable to the Wilcoxon-Mann-Whitney (WMW) test as invoked with the WILCOXON option in the PROC NPAR1WAY statement of the NPAR1WAY procedure. The approximation is based on O'Brien and Castelloe (2006) and an estimator called $\widehat{WMW}_{\text{odds}}$. See O'Brien and Castelloe (2006) for a definition of $\widehat{WMW}_{\text{odds}}$, which need not be derived in detail here for purposes of explaining the power formula.

Let Y_1 and Y_2 be independent observations from any two distributions that you want to compare using the WMW test. For purposes of deriving the asymptotic distribution of $\widehat{WMW}_{\text{odds}}$ (and consequently the power computation as well), these distributions must be formulated as ordered categorical ("ordinal") distributions.

If a distribution is continuous, it can be discretized using a large number of categories with negligible loss of accuracy. Each nonordinal distribution is divided into b categories, where b is the value of the NBINS parameter, with breakpoints evenly spaced on the probability scale. That is, each bin contains an equal probability $1/b$ for that distribution. Then the breakpoints across both distributions are pooled to form a collection of C bins (heretofore called "categories"), and the probabilities of bin membership for each distribution are recalculated. The motivation for this method of binning is to avoid degenerate representations of the distributions—that is, small handfuls of large probabilities among mostly empty bins—as can be caused by something like an evenly spaced grid across raw values rather than probabilities.

After the discretization process just mentioned, there are now two ordinal distributions, each with a set of probabilities across a common set of C ordered categories. For simplicity of notation, assume (without loss of generality) the response values to be $1, \ldots, C$. Represent the conditional probabilities as

$$\tilde{p}_{ij} = \text{Prob}\left(Y_i = j \mid \text{group} = i\right), i \in \{1,2\} \quad \text{and} \quad j \in \{1, \ldots, C\}$$

and the group allocation weights as

$$w_i = \frac{n_i}{N} = \text{Prob}\,(\text{group} = i)\,, \quad i \in \{1, 2\}$$

The joint probabilities can then be calculated simply as

$$p_{ij} = \text{Prob}\,(\text{group} = i, Y_i = j) = w_i\,\tilde{p}_{ij}, i \in \{1, 2\} \quad \text{and} \quad j \in \{1, \ldots, C\}$$

The next step in the power computation is to compute the probabilities that a randomly chosen pair of observations from the two groups is concordant, discordant, or tied. It is useful to define these probabilities as functions of the terms Rs_{ij} and Rd_{ij}, defined as follows, where Y is a random observation drawn from the joint distribution across groups and categories:

$$\begin{aligned} Rs_{ij} &= \text{Prob}\,(Y \text{ is concordant with cell}(i, j)) + \frac{1}{2}\text{Prob}\,(Y \text{ is tied with cell}(i, j)) \\ &= \text{Prob}\,((\text{group} < i \text{ and } Y < j) \text{ or } (\text{group} > i \text{ and } Y > j)) + \\ &\quad \frac{1}{2}\text{Prob}\,(\text{group} \neq i \text{ and } Y = j) \\ &= \sum_{g=1}^{2}\sum_{c=1}^{C} w_g\,\tilde{p}_{gc}\left[\text{I}_{(g-i)(c-j)>0} + \frac{1}{2}\text{I}_{g\neq i, c=j}\right] \end{aligned}$$

and

$$\begin{aligned} Rd_{ij} &= \text{Prob}\,(Y \text{ is discordant with cell}(i, j)) + \frac{1}{2}\text{Prob}\,(Y \text{ is tied with cell}(i, j)) \\ &= \text{Prob}\,((\text{group} < i \text{ and } Y > j) \text{ or } (\text{group} > i \text{ and } Y < j)) + \\ &\quad \frac{1}{2}\text{Prob}\,(\text{group} \neq i \text{ and } Y = j) \\ &= \sum_{g=1}^{2}\sum_{c=1}^{C} w_g\,\tilde{p}_{gc}\left[\text{I}_{(g-i)(c-j)<0} + \frac{1}{2}\text{I}_{g\neq i, c=j}\right] \end{aligned}$$

For an independent random draw Y_1, Y_2 from the two distributions,

$$\begin{aligned} P_c &= \text{Prob}\,(Y_1, Y_2 \text{ concordant}) + \frac{1}{2}\text{Prob}\,(Y_1, Y_2 \text{ tied}) \\ &= \sum_{i=1}^{2}\sum_{j=1}^{C} w_i\,\tilde{p}_{ij}\,Rs_{ij} \end{aligned}$$

and

$$\begin{aligned} P_d &= \text{Prob}\,(Y_1, Y_2 \text{ discordant}) + \frac{1}{2}\text{Prob}\,(Y_1, Y_2 \text{ tied}) \\ &= \sum_{i=1}^{2}\sum_{j=1}^{C} w_i\,\tilde{p}_{ij}\,Rd_{ij} \end{aligned}$$

Then

$$WMW_{\text{odds}} = \frac{P_c}{P_d}$$

Proceeding to compute the theoretical standard error associated with WMW_{odds} (that is, the population analogue to the sample standard error),

$$\text{SE}(WMW_{\text{odds}}) = \frac{2}{P_d}\left[\sum_{i=1}^{2}\sum_{j=1}^{C} w_i\,\tilde{p}_{ij}\left(WMW_{\text{odds}}\,Rd_{ij} - Rs_{ij}\right)^2/N\right]^{\frac{1}{2}}$$

Converting to the natural log scale and using the delta method,

$$\text{SE}(\log(WMW_{\text{odds}})) = \frac{\text{SE}(WMW_{\text{odds}})}{WMW_{\text{odds}}}$$

The next step is to produce a "smoothed" version of the $2 \times C$ cell probabilities that conforms to the null hypothesis of the Wilcoxon-Mann-Whitney test (in other words, independence in the $2 \times C$ contingency table of probabilities). Let $\text{SE}_{H_0}(\log(WMW_{\text{odds}}))$ denote the theoretical standard error of $\log(WMW_{\text{odds}})$ assuming H_0.

Finally we have all of the terms needed to compute the power, using the noncentral chi-square and normal distributions:

$$\text{power} = \begin{cases} P\left(Z \geq \frac{\text{SE}_{H_0}(\log(WMW_{\text{odds}}))}{\text{SE}(\log(WMW_{\text{odds}}))} z_{1-\alpha} - \delta^{\star} N^{\frac{1}{2}}\right), & \text{upper one-sided} \\ P\left(Z \leq \frac{\text{SE}_{H_0}(\log(WMW_{\text{odds}}))}{\text{SE}(\log(WMW_{\text{odds}}))} z_{\alpha} - \delta^{\star} N^{\frac{1}{2}}\right), & \text{lower one-sided} \\ P\left(\chi^2(1, (\delta^{\star})^2 N) \geq \left[\frac{\text{SE}_{H_0}(\log(WMW_{\text{odds}}))}{\text{SE}(\log(WMW_{\text{odds}}))}\right]^2 \chi^2_{1-\alpha}(1)\right), & \text{two-sided} \end{cases}$$

where

$$\delta^{\star} = \frac{\log(WMW_{\text{odds}})}{N^{\frac{1}{2}}\text{SE}(\log(WMW_{\text{odds}}))}$$

is the primary noncentrality—that is, the "effect size" that quantifies how much the two conjectured distributions differ. Z is a standard normal random variable, $\chi^2(df, nc)$ is a noncentral χ^2 random variable with degrees of freedom df and noncentrality nc, and N is the total sample size.

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, "Statistical Graphics Using ODS."

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section "Enabling and Disabling ODS Graphics" on page 612 in Chapter 21, "Statistical Graphics Using ODS."

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section "A Primer on ODS Statistical Graphics" on page 611 in Chapter 21, "Statistical Graphics Using ODS."

If ODS Graphics is not enabled, then PROC POWER creates traditional graphics.

You can reference every graph produced through ODS Graphics with a name. The names of the graphs that PROC POWER generates are listed in Table 70.31, along with the required statements and options.

Table 70.31 Graphs Produced by PROC POWER

ODS Graph Name	Plot Description	Option
PowerPlot	Plot with two of the following three parameters on the X and Y axes: power, sample size, and effect size	PLOT
PowerAbort	Empty plot that shows an error message when a plot could not be produced	PLOT

ODS Styles Suitable for Use with PROC POWER

ODS styles control the appearance of graphs produced by PROC POWER. ODS provides over 50 styles, but most are not suitable for use in PROC POWER. PROC POWER requires a style that distinguishes curves based on a combination of color, line style, and symbol marker. Styles that are well-suited for use in PROC POWER include: STATISTICAL, ANALYSIS, DEFAULT, LISTING, and HTMLBLUECML. The HTMLBLUE and PLATEAU styles are commonly used, but they are not well-suited for use with PROC POWER because they rely primarily on color to distinguish curves rather than a combination of color, line style, and symbol marker.

In this chapter, a style is explicitly specified at the start of each example that uses ODS Graphics to remind you to use one of the suitable styles. Styles are specified in an ODS destination statement. Destinations include LISTING, HTML, RTF, PDF, and many others. You can set the style and the destination as follows:

```
ods html style=htmlbluecml;
ods graphics on;

proc power;
   onesamplemeans
      mean   = 5 10
      ntotal = 150
      stddev =  30 50
      power  = .;
   plot x=n min=100 max=200;
run;

ods graphics off;
ods html close;
```

For more information about ODS and ODS destinations, see Chapter 20, "Using the Output Delivery System." For more information ODS styles, see Chapter 21, "Statistical Graphics Using ODS."

Examples: POWER Procedure

Example 70.1: One-Way ANOVA

This example deals with the same situation as in Example 43.1 of Chapter 43, "The GLMPOWER Procedure."

Hocking (1985, p. 109) describes a study of the effectiveness of electrolytes in reducing lactic acid buildup for long-distance runners. You are planning a similar study in which you will allocate five different fluids to runners on a 10-mile course and measure lactic acid buildup immediately after the run. The fluids consist of water and two commercial electrolyte drinks, EZDure and LactoZap, each prepared at two concentrations, low (EZD1 and LZ1) and high (EZD2 and LZ2).

You conjecture that the standard deviation of lactic acid measurements given any particular fluid is about 3.75, and that the expected lactic acid values will correspond roughly to those in Table 70.32. You are least familiar with the LZ1 drink and hence decide to consider a range of reasonable values for that mean.

Table 70.32 Mean Lactic Acid Buildup by Fluid

Water	EZD1	EZD2	LZ1	LZ2
35.6	33.7	30.2	29 or 28	25.9

You are interested in four different comparisons, shown in Table 70.33 with appropriate contrast coefficients.

Table 70.33 Planned Comparisons

	Contrast Coefficients				
Comparison	Water	EZD1	EZD2	LZ1	LZ2
Water versus electrolytes	4	–1	–1	–1	–1
EZD versus LZ	0	1	1	–1	–1
EZD1 versus EZD2	0	1	–1	0	0
LZ1 versus LZ2	0	0	0	1	–1

For each of these contrasts you want to determine the sample size required to achieve a power of 0.9 for detecting an effect with magnitude in accord with Table 70.32. You are not yet attempting to choose a single sample size for the study, but rather checking the range of sample sizes needed for individual contrasts. You plan to test each contrast at $\alpha = 0.025$. In the interests of reducing costs, you will provide twice as many runners with water as with any of the electrolytes; in other words, you will use a sample size weighting scheme of 2:1:1:1:1. Use the ONEWAYANOVA statement in the POWER procedure to compute the sample sizes.

The statements required to perform this analysis are as follows:

```
proc power;
   onewayanova
      groupmeans = 35.6 | 33.7 | 30.2 | 29 28 | 25.9
      stddev = 3.75
      groupweights = (2 1 1 1 1)
      alpha = 0.025
      ntotal = .
      power = 0.9
      contrast = (4 -1 -1 -1 -1) (0  1  1 -1 -1)
                 (0  1 -1  0  0) (0  0  0  1 -1);
run;
```

The NTOTAL= option with a missing value (.) indicates total sample size as the result parameter. The GROUPMEANS= option with values from Table 70.32 specifies your conjectures for the means. With only one mean varying (the LZ1 mean), the "crossed" notation is simpler, showing scenarios for each group mean, separated by vertical bars (|). See the section "Specifying Value Lists in Analysis Statements" on page 5834 for more details on crossed and matched notations for grouped values. The contrasts in Table 70.33 are specified with the CONTRAST= option, by using the "matched" notation with each contrast enclosed in parentheses. The STDDEV=, ALPHA=, and POWER= options specify the error standard deviation, significance level, and power. The GROUPWEIGHTS= option specifies the weighting schemes. Default values for the NULLCONTRAST= and SIDES= options specify a two-sided t test of the contrast equal to 0. See Output 70.1.1 for the results.

Output 70.1.1 Sample Sizes for One-Way ANOVA Contrasts

The POWER Procedure
Single DF Contrast in One-Way ANOVA

Fixed Scenario Elements

Method	Exact
Alpha	0.025
Standard Deviation	3.75
Group Weights	2 1 1 1 1
Nominal Power	0.9
Number of Sides	2
Null Contrast Value	0

Computed N Total

Index	Contrast					Means					Actual Power	N Total
1	4	-1	-1	-1	-1	35.6	33.7	30.2	29	25.9	0.947	30
2	4	-1	-1	-1	-1	35.6	33.7	30.2	28	25.9	0.901	24
3	0	1	1	-1	-1	35.6	33.7	30.2	29	25.9	0.929	60
4	0	1	1	-1	-1	35.6	33.7	30.2	28	25.9	0.922	48
5	0	1	-1	0	0	35.6	33.7	30.2	29	25.9	0.901	174
6	0	1	-1	0	0	35.6	33.7	30.2	28	25.9	0.901	174
7	0	0	0	1	-1	35.6	33.7	30.2	29	25.9	0.902	222
8	0	0	0	1	-1	35.6	33.7	30.2	28	25.9	0.902	480

The sample sizes in Output 70.1.1 range from 24 for the comparison of water versus electrolytes to 480 for the comparison of LZ1 versus LZ2, both assuming the smaller LZ1 mean. The sample size for the latter comparison is relatively large because the small mean difference of $28 - 25.9 = 2.1$ is hard to detect.

The Nominal Power of 0.9 in the "Fixed Scenario Elements" table in Output 70.1.1 represents the input target power, and the Actual Power column in the "Computed N Total" table is the power at the sample size (N Total) adjusted to achieve the specified sample weighting. Note that all of the sample sizes are rounded up to multiples of 6 to preserve integer group sizes (since the group weights add up to 6). You can use the NFRACTIONAL option in the ONEWAYANOVA statement to compute raw fractional sample sizes.

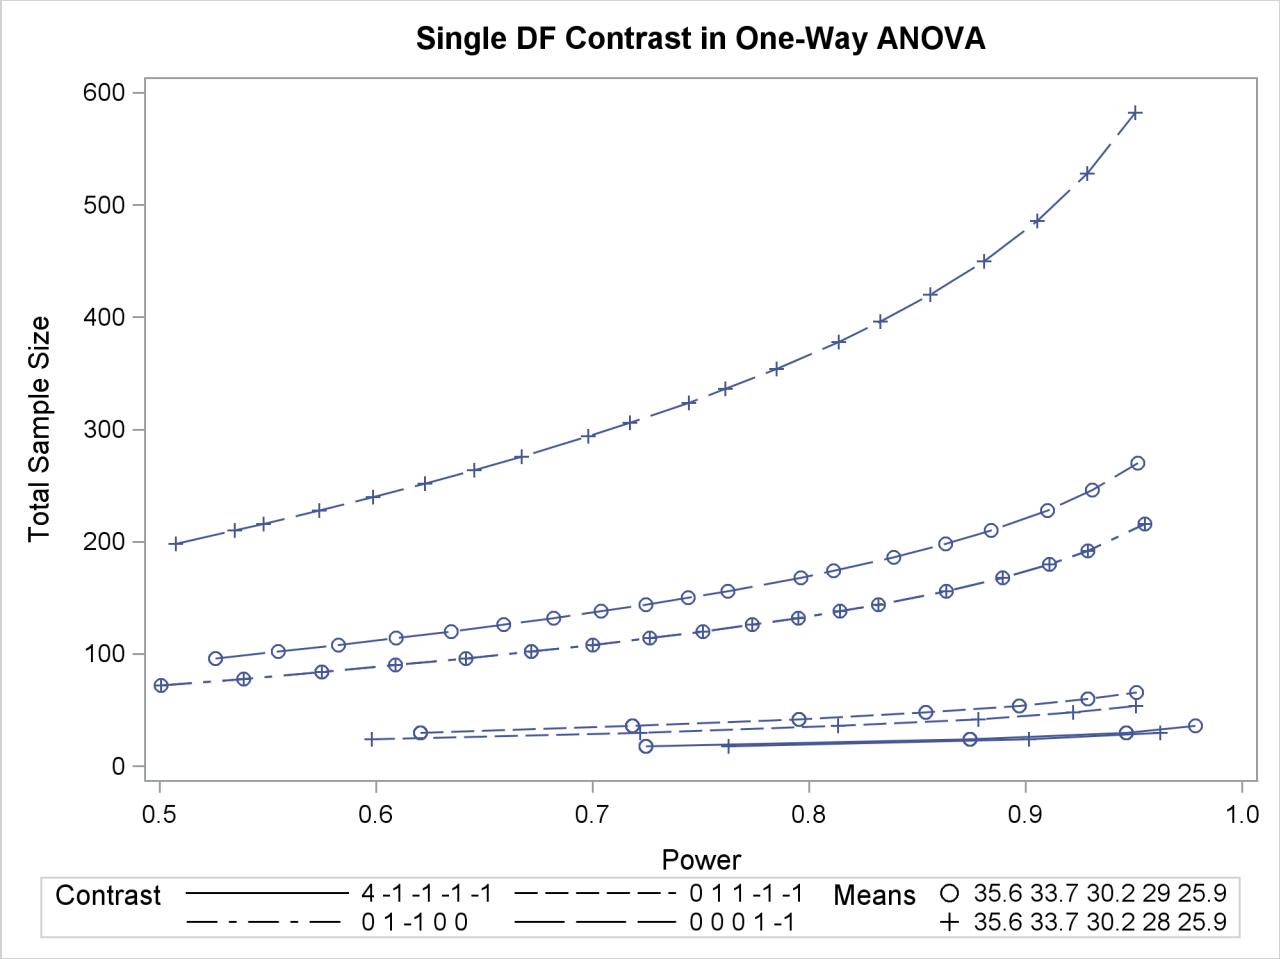
Suppose you want to plot the required sample size for the range of power values from 0.5 to 0.95. First, define the analysis by specifying the same statements as before, but add the PLOTONLY option to the PROC POWER statement to disable the nongraphical results. Next, specify the PLOT statement with X=POWER to request a plot with power on the X axis. (The result parameter, here sample size, is always plotted on the other axis.) Use the MIN= and MAX= options in the PLOT statement to specify the power range. The following statements produce the plot shown in Output 70.1.2.

```
ods listing style=htmlbluecml;
ods graphics on;

proc power plotonly;
   onewayanova
      groupmeans = 35.6 | 33.7 | 30.2 | 29 28 | 25.9
      stddev = 3.75
      groupweights = (2 1 1 1 1)
      alpha = 0.025
      ntotal = .
      power = 0.9
      contrast = (4 -1 -1 -1 -1) (0  1  1 -1 -1)
                 (0  1 -1  0  0) (0  0  0  1 -1);
   plot x=power min=.5 max=.95;
run;
```

The ODS LISTING STYLE=HTMLBLUECML statement specifies the HTMLBLUECML style, which is suitable for use with PROC POWER because it allows both marker symbols and line styles to vary. See the section "ODS Styles Suitable for Use with PROC POWER" on page 5897 for more information.

Output 70.1.2 Plot of Sample Size versus Power for One-Way ANOVA Contrasts



In Output 70.1.2, the line style identifies the contrast, and the plotting symbol identifies the group means scenario. The plot shows that the required sample size is highest for the (0 0 0 1 –1) contrast, corresponding to the test of LZ1 versus LZ2 that was previously found to require the most resources, in either cell means scenario.

Note that some of the plotted points in Output 70.1.2 are unevenly spaced. This is because the plotted points are the *rounded* sample size results at their corresponding *actual* power levels. The range specified with the MIN= and MAX= values in the PLOT statement corresponds to *nominal* power levels. In some cases, actual power is substantially higher than nominal power. To obtain plots with evenly spaced points (but with *fractional* sample sizes at the computed points), you can use the NFRACTIONAL option in the analysis statement preceding the PLOT statement.

Finally, suppose you want to plot the power for the range of sample sizes you will likely consider for the study (the range of 24 to 480 that achieves 0.9 power for different comparisons). In the ONEWAYANOVA statement, identify power as the result (POWER=.), and specify NTOTAL=24. The following statements produce the plot:

```
proc power plotonly;
   onewayanova
      groupmeans = 35.6 | 33.7 | 30.2 | 29 28 | 25.9
      stddev = 3.75
      groupweights = (2 1 1 1 1)
      alpha = 0.025
      ntotal = 24
      power = .
      contrast = (4 -1 -1 -1 -1) (0  1  1 -1 -1)
                 (0  1 -1  0  0) (0  0  0  1 -1);
   plot x=n min=24 max=480;
run;

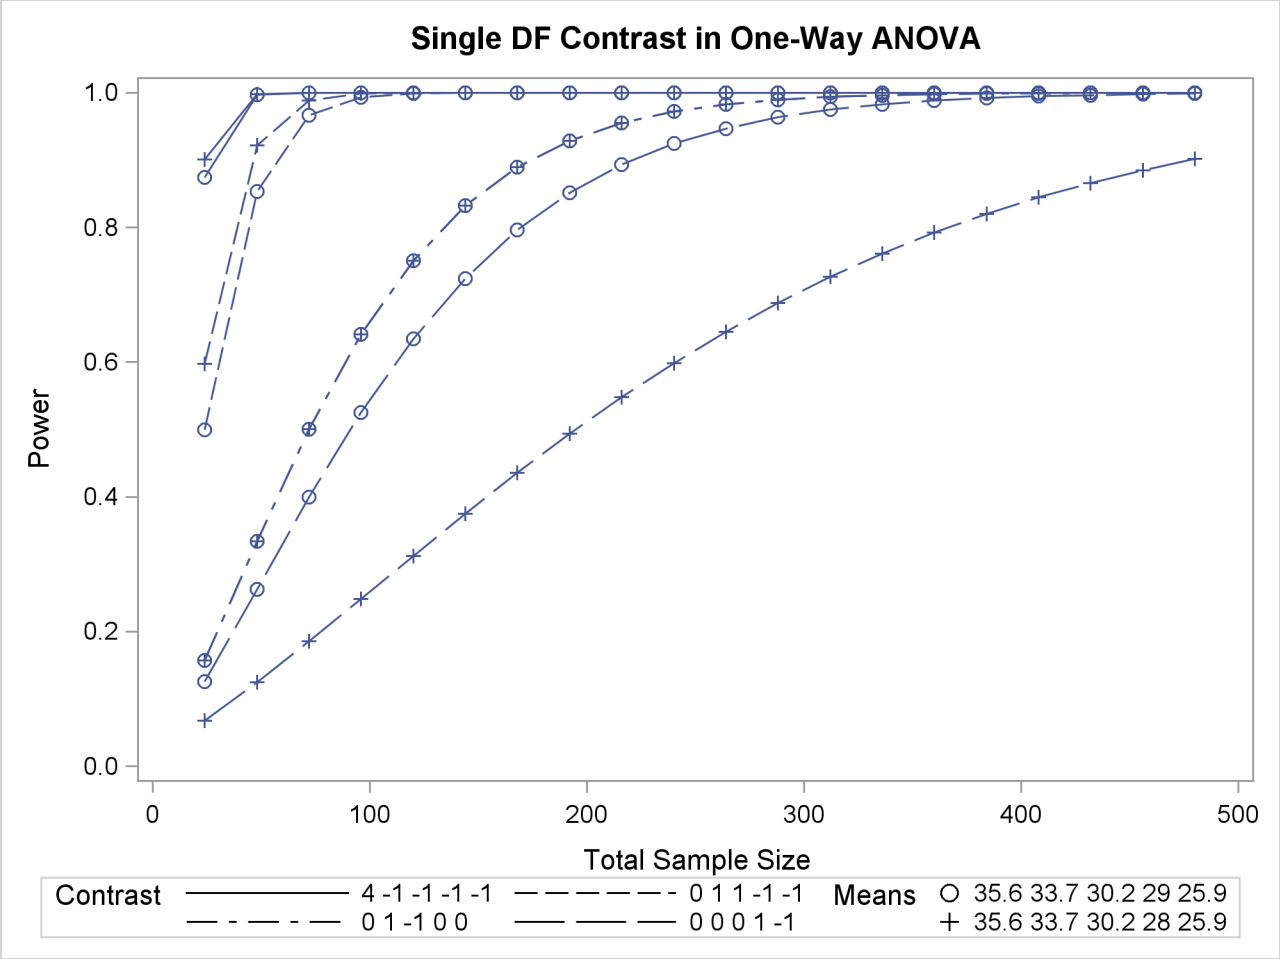
ods graphics off;
```

The X=N option in the PLOT statement requests a plot with sample size on the X axis.

Note that the value specified with the NTOTAL=24 option is not used. It is overridden in the plot by the MIN= and MAX= options in the PLOT statement, and the PLOTONLY option in the PROC POWER statement disables nongraphical results. But the NTOTAL= option (along with a value) is still needed in the ONEWAYANOVA statement as a placeholder, to identify the desired parameterization for sample size.

Output 70.1.3 shows the resulting plot.

Output 70.1.3 Plot of Power versus Sample Size for One-Way ANOVA Contrasts



Although Output 70.1.2 and Output 70.1.3 surface essentially the same computations for practical power ranges, they each provide a different quick visual assessment. Output 70.1.2 reveals the range of required sample sizes for powers of interest, and Output 70.1.3 reveals the range of achieved powers for sample sizes of interest.

Example 70.2: The Sawtooth Power Function in Proportion Analyses

For many common statistical analyses, the power curve is monotonically increasing: the more samples you take, the more power you achieve. However, in statistical analyses of discrete data, such as tests of proportions, the power curve is often nonmonotonic. A small increase in sample size can result in a *decrease* in power, a decrease that is sometimes substantial. The explanation is that the actual significance level (in other words, the achieved Type I error rate) for discrete tests strays below the target level and varies with sample size. The power loss from a decrease in the Type I error rate can outweigh the power gain from an increase in sample size. The example discussed here demonstrates this "sawtooth" phenomenon. For additional discussion on the topic, see Chernick and Liu (2002).

Suppose you have a new scheduling system for an airline, and you want to determine how many flights you must observe to have at least an 80% chance of establishing an improvement in the proportion of late arrivals on a specific travel route. You will use a one-sided exact binomial proportion test with a null proportion of 30%, the frequency of late arrivals under the previous scheduling system, and a nominal significance level of $\alpha = 0.05$. Well-supported predictions estimate the new late arrival rate to be about 20%, and you will base your sample size determination on this assumption.

The POWER procedure does not currently compute exact sample size directly for the exact binomial test. But you can get an initial estimate by computing the approximate sample size required for a z test. Use the ONESAMPLEFREQ statement in the POWER procedure with TEST=Z and METHOD=NORMAL to compute the approximate sample size to achieve a power of 0.8 by using the z test. The following statements perform the analysis:

```
proc power;
   onesamplefreq test=z method=normal
      sides           = 1
      alpha           = 0.05
      nullproportion  = 0.3
      proportion      = 0.2
      ntotal          = .
      power           = 0.8;
run;
```

The NTOTAL= option with a missing value (.) indicates sample size as the result parameter. The SIDES=1 option specifies a one-sided test. The ALPHA=, NULLPROPORTION=, and POWER= options specify the significance level of 0.05, null value of 0.3, and target power of 0.8, respectively. The PROPORTION= option specifies your conjecture of 0.3 for the true proportion.

Output 70.2.1 Approximate Sample Size for z Test of a Proportion

The POWER Procedure
Z Test for Binomial Proportion

Fixed Scenario Elements

Method	Normal approximation
Number of Sides	1
Null Proportion	0.3
Alpha	0.05
Binomial Proportion	0.2
Nominal Power	0.8
Variance Estimate	Null Variance

Computed N Total

Actual Power	N Total
0.800	119

The results, shown in Output 70.2.1, indicate that you need to observe about N=119 flights to have an 80% chance of rejecting the hypothesis of a late arrival proportion of 30% or higher, if the true proportion is 20%, by using the z test. A similar analysis (Output 70.2.2) reveals an approximate sample size of N=129 for the

z test with continuity correction, which is performed by using TEST=ADJZ:

```
proc power;
   onesamplefreq test=adjz method=normal
      sides          = 1
      alpha          = 0.05
      nullproportion = 0.3
      proportion     = 0.2
      ntotal         = .
      power          = 0.8;
run;
```

Output 70.2.2 Approximate Sample Size for z Test with Continuity Correction

The POWER Procedure
Z Test for Binomial Proportion with Continuity Adjustment

Fixed Scenario Elements

Method	Normal approximation
Number of Sides	1
Null Proportion	0.3
Alpha	0.05
Binomial Proportion	0.2
Nominal Power	0.8
Variance Estimate	Null Variance

Computed N Total

Actual Power	N Total
0.801	129

Based on the approximate sample size results, you decide to explore the power of the exact binomial test for sample sizes between 110 and 140. The following statements produce the plot:

```
ods listing style=htmlbluecml;
ods graphics on;

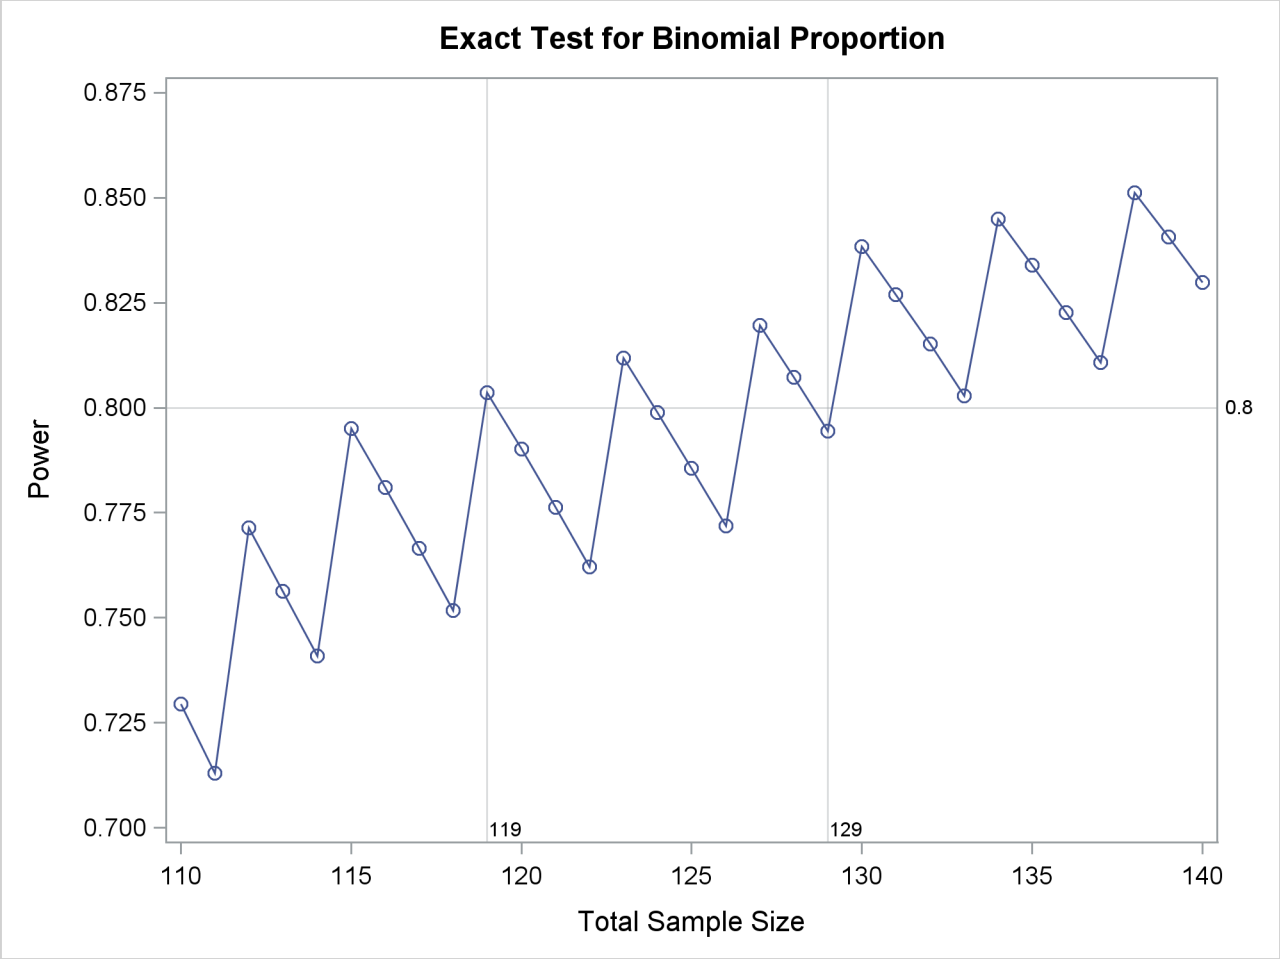
proc power plotonly;
   onesamplefreq test=exact
      sides          = 1
      alpha          = 0.05
      nullproportion = 0.3
      proportion     = 0.2
      ntotal         = 119
      power          = .;
   plot x=n min=110 max=140 step=1
      yopts=(ref=.8) xopts=(ref=119 129);
run;
```

The ODS LISTING STYLE=HTMLBLUECML statement specifies the HTMLBLUECML style, which is suitable for use with PROC POWER because it allows both marker symbols and line styles to vary. See the

section "ODS Styles Suitable for Use with PROC POWER" on page 5897 for more information.

The TEST=EXACT option in the ONESAMPLEFREQ statement specifies the exact binomial test, and the missing value (.) for the POWER= option indicates power as the result parameter. The PLOTONLY option in the PROC POWER statement disables nongraphical output. The PLOT statement with X=N requests a plot with sample size on the X axis. The MIN= and MAX= options in the PLOT statement specify the sample size range. The YOPTS=(REF=) and XOPTS=(REF=) options add reference lines to highlight the approximate sample size results. The STEP=1 option produces a point at each integer sample size. The sample size value specified with the NTOTAL= option in the ONESAMPLEFREQ statement is overridden by the MIN= and MAX= options in the PLOT statement. Output 70.2.3 shows the resulting plot.

Output 70.2.3 Plot of Power versus Sample Size for Exact Binomial Test



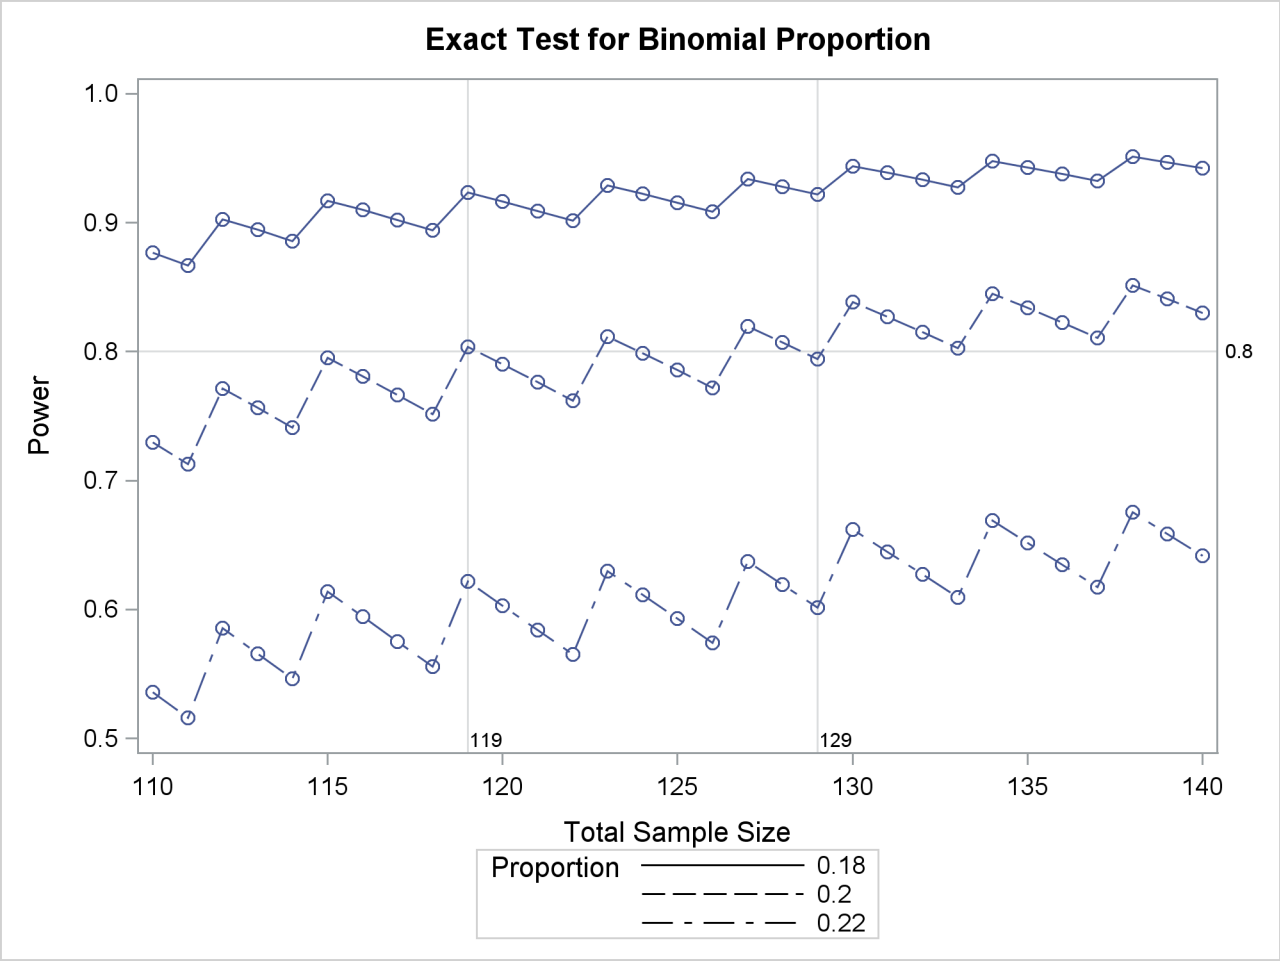
Note the sawtooth pattern in Output 70.2.3. Although the power surpasses the target level of 0.8 at N=119, it decreases to 0.79 with N=120 and further to 0.76 with N=122 before rising again to 0.81 with N=123. Not until N=130 does the power stay above the 0.8 target. Thus, a more conservative sample size recommendation of 130 might be appropriate, depending on the precise goals of the sample size determination.

In addition to considering alternative sample sizes, you might also want to assess the sensitivity of the power to inaccuracies in assumptions about the true proportion. The following statements produce a plot including true proportion values of 0.18 and 0.22. They are identical to the previous statements except for the additional true proportion values specified with the PROPORTION= option in the ONESAMPLEFREQ statement.

```
proc power plotonly;
   onesamplefreq test=exact
      sides           = 1
      alpha           = 0.05
      nullproportion = 0.3
      proportion      = 0.18 0.2 0.22
      ntotal          = 119
      power           = .;
   plot x=n min=110 max=140 step=1
      yopts=(ref=.8) xopts=(ref=119 129);
run;
```

Output 70.2.4 shows the resulting plot.

Output 70.2.4 Plot for Assessing Sensitivity to True Proportion Value



The plot reveals a dramatic sensitivity to the true proportion value. For N=119, the power is about 0.92 if the true proportion is 0.18, and as low as 0.62 if the proportion is 0.22. Note also that the power jumps occur at the same sample sizes in all three curves; the curves are only shifted and stretched vertically. This is because spikes and valleys in power curves are invariant to the true proportion value; they are due to changes in the critical value of the test.

A closer look at some ancillary output from the analysis sheds light on this property of the sawtooth pattern. You can add an ODS OUTPUT statement to save the plot content corresponding to Output 70.2.3 to a data set:

```
proc power plotonly;
   ods output plotcontent=PlotData;
   onesamplefreq test=exact
      sides          = 1
      alpha          = 0.05
      nullproportion = 0.3
      proportion     = 0.2
      ntotal         = 119
      power          = .;
   plot x=n min=110 max=140 step=1
      yopts=(ref=.8) xopts=(ref=119 129);
run;
```

The PlotData data set contains parameter values for each point in the plot. The parameters include underlying characteristics of the putative test. The following statements print the critical value and actual significance level along with sample size and power:

```
proc print data=PlotData;
   var NTotal LowerCritVal Alpha Power;
run;
```

Output 70.2.5 shows the plot data.

Output 70.2.5 Numerical Content of Plot

Obs	NTotal	Lower CritVal	Alpha	Power
1	110	24	0.0356	0.729
2	111	24	0.0313	0.713
3	112	25	0.0446	0.771
4	113	25	0.0395	0.756
5	114	25	0.0349	0.741
6	115	26	0.0490	0.795
7	116	26	0.0435	0.781
8	117	26	0.0386	0.767
9	118	26	0.0341	0.752
10	119	27	0.0478	0.804
11	120	27	0.0425	0.790
12	121	27	0.0377	0.776
13	122	27	0.0334	0.762
14	123	28	0.0465	0.812
15	124	28	0.0414	0.799
16	125	28	0.0368	0.786
17	126	28	0.0327	0.772
18	127	29	0.0453	0.820
19	128	29	0.0404	0.807
20	129	29	0.0359	0.794
21	130	30	0.0493	0.838
22	131	30	0.0441	0.827
23	132	30	0.0394	0.815
24	133	30	0.0351	0.803
25	134	31	0.0480	0.845
26	135	31	0.0429	0.834
27	136	31	0.0384	0.823
28	137	31	0.0342	0.811
29	138	32	0.0466	0.851
30	139	32	0.0418	0.841
31	140	32	0.0374	0.830

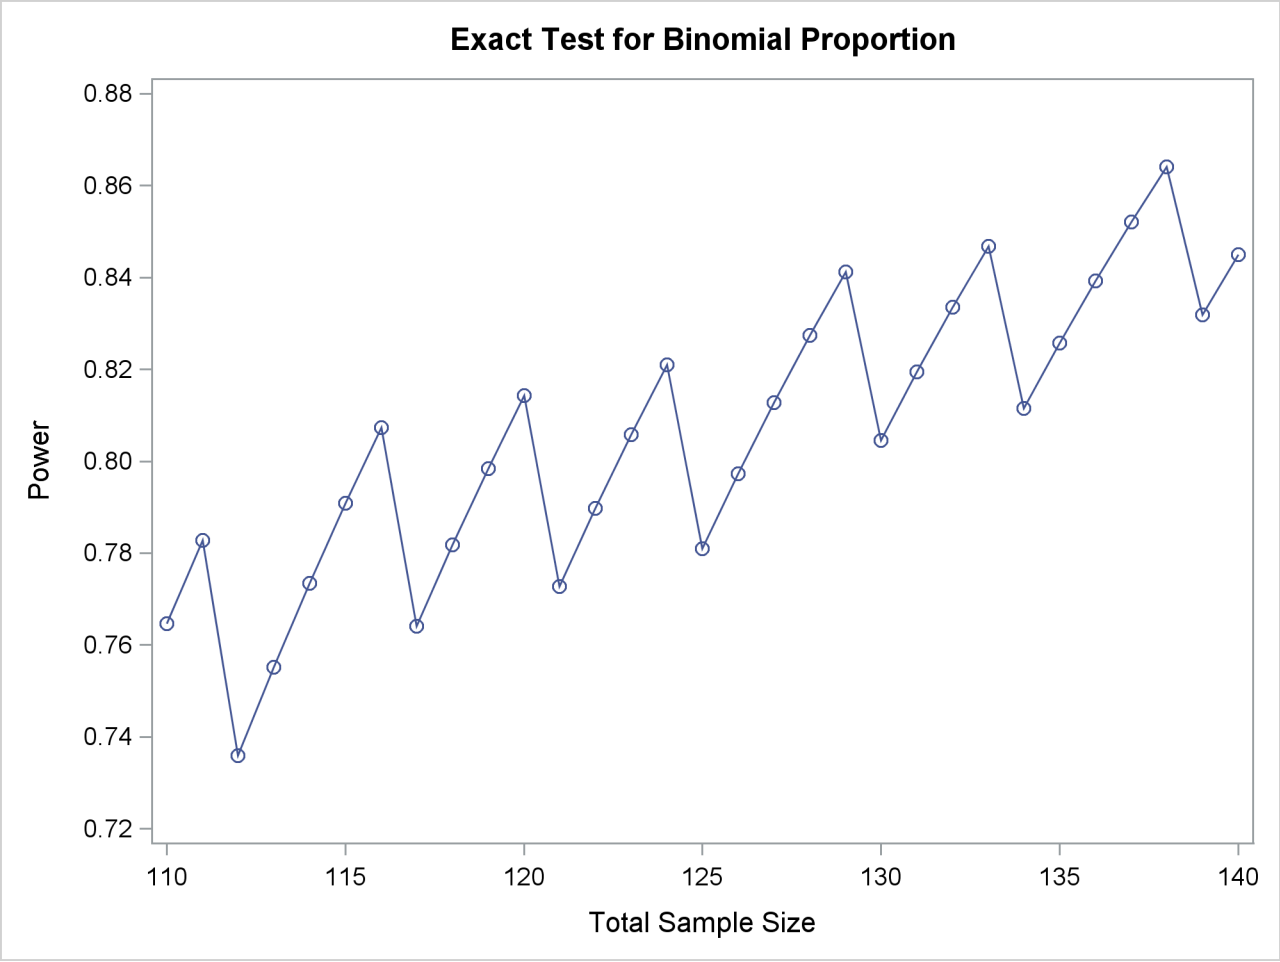
Note that whenever the critical value changes, the actual α jumps up to a value close to the nominal α=0.05, and the power also jumps up. Then while the critical value stays constant, the actual α and power slowly decrease. The critical value is independent of the true proportion value. So you can achieve a locally maximal power by choosing a sample size corresponding to a spike on the sawtooth curve, and this choice is locally optimal *regardless* of the unknown value of the true proportion. Locally optimal sample sizes in this case include 115, 119, 123, 127, 130, and 134.

As a point of interest, the power does not always jump sharply and decrease gradually. The shape of the sawtooth depends on the direction of the test and the location of the null proportion relative to 0.5. For example, if the direction of the hypothesis in this example is reversed (by switching true and null proportion values) so that the rejection region is in the upper tail, then the power curve exhibits sharp decreases and gradual increases. The following statements are similar to those producing the plot in Output 70.2.3 but with values of the PROPORTION= and NULLPROPORTION= options switched:

```
proc power plotonly;
   onesamplefreq test=exact
      sides           = 1
      alpha           = 0.05
      nullproportion = 0.2
      proportion      = 0.3
      ntotal          = 119
      power           = .;
   plot x=n min=110 max=140 step=1;
run;
```

The resulting plot is shown in Output 70.2.6.

Output 70.2.6 Plot of Power versus Sample Size for Another One-sided Test



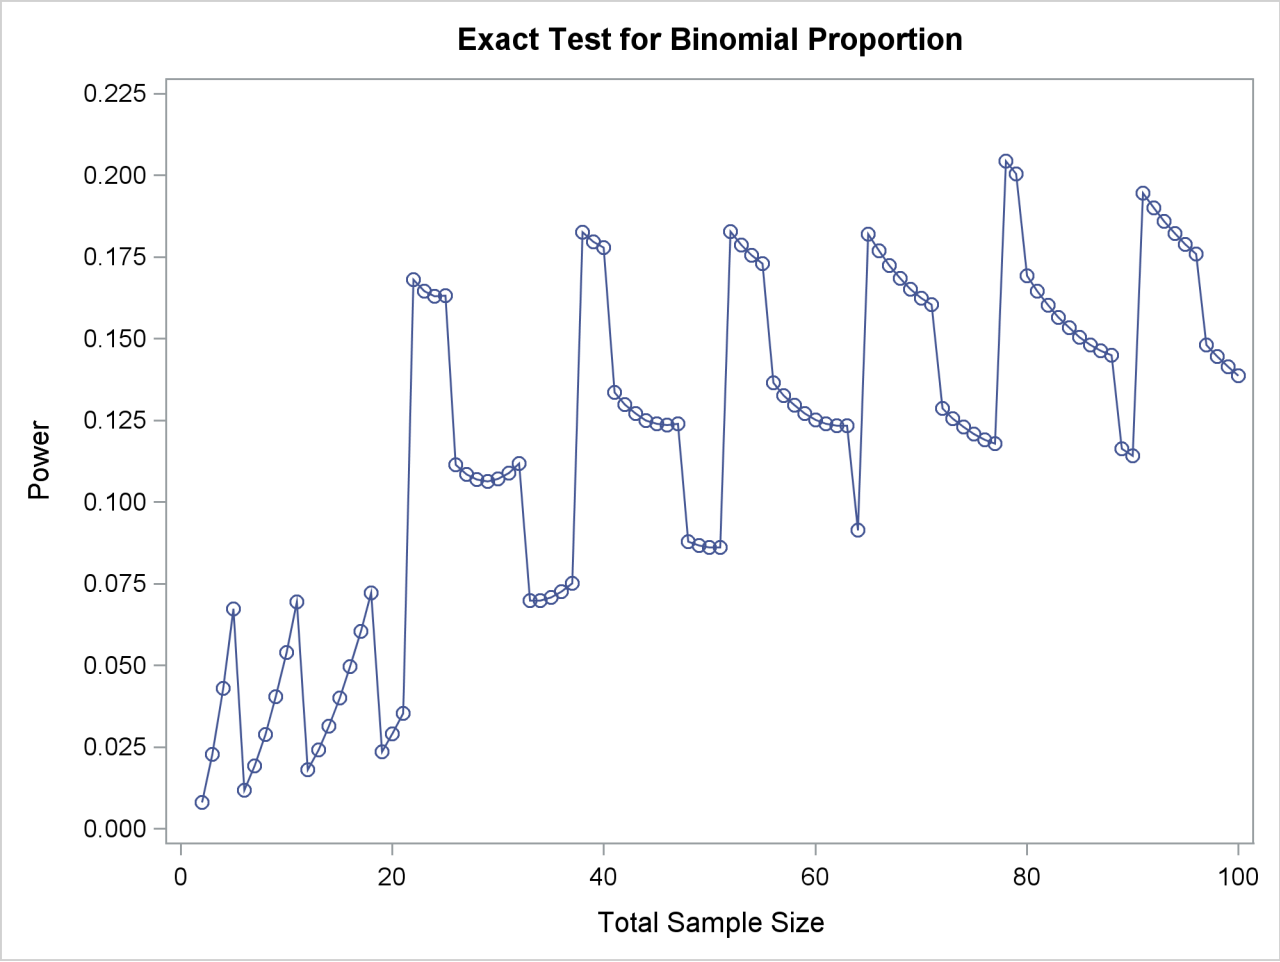
Finally, two-sided tests can lead to even more irregular power curve shapes, since changes in lower and upper critical values affect the power in different ways. The following statements produce a plot of power versus sample size for the scenario of a two-sided test with high alpha and a true proportion close to the null value:

```
proc power plotonly;
   onesamplefreq test=exact
      sides           = 2
      alpha           = 0.2
      nullproportion = 0.1
      proportion      = 0.09
      ntotal          = 10
      power           = .;
   plot x=n min=2 max=100 step=1;
run;

ods graphics off;
```

Output 70.2.7 shows the resulting plot.

Output 70.2.7 Plot of Power versus Sample Size for a Two-Sided Test



Due to the irregular shapes of power curves for proportion tests, the question "Which sample size should I use?" is often insufficient. A sample size solution produced directly in PROC POWER reveals the smallest possible sample size to achieve your target power. But as the examples in this section demonstrate, it is helpful to consult graphs for answers to questions such as the following:

- Which sample size will guarantee that all higher sample sizes also achieve my target power?
- Given a candidate sample size, can I increase it slightly to achieve locally maximal power, or perhaps even decrease it and get higher power?

Example 70.3: Simple AB/BA Crossover Designs

Crossover trials are experiments in which each subject is given a sequence of different treatments. They are especially common in clinical trials for medical studies. The reduction in variability from taking multiple measurements on a subject allows for more precise treatment comparisons. The simplest such design is the AB/BA crossover, in which each subject receives each of two treatments in a randomized order.

Under certain simplifying assumptions, you can test the treatment difference in an AB/BA crossover trial by using either a paired or two-sample t test (or equivalence test, depending on the hypothesis). This example will demonstrate when and how you can use the PAIREDMEANS statement in PROC POWER to perform power analyses for AB/BA crossover designs.

Senn (1993, Chapter 3) discusses a study comparing the effects of two bronchodilator medications in treatment of asthma, by using an AB/BA crossover design. Suppose you want to plan a similar study comparing two new medications, "Xilodol" and "Brantium." Half of the patients would be assigned to sequence AB, getting a dose of Xilodol in the first treatment period, a wash-out period of one week, and then a dose of Brantium in the second treatment period. The other half would be assigned to sequence BA, following the same schedule but with the drugs reversed. In each treatment period you would administer the drugs in the morning and then measure peak expiratory flow (PEF) at the end of the day, with higher PEF representing better lung function.

You conjecture that the mean and standard deviation of PEF are about $\mu_A = 330$ and $\sigma_A = 40$ for Xilodol and $\mu_B = 310$ and $\sigma_B = 55$ for Brantium, and that each pair of measurements on the same subject will have a correlation of about 0.3. You want to compute the power of both one-sided and two-sided tests of mean difference, with a significance level of $\alpha = 0.01$, for a sample size of 100 patients and also plot the power for a range of 50 to 200 patients. Note that the allocation ratio of patients to the two sequences is irrelevant in this analysis.

The choice of statistical test depends on which assumptions are reasonable. One possibility is a t test. A paired or two-sample t test is valid when there is no carryover effect and no interactions between patients, treatments, and periods. See Senn (1993, Chapter 3) for more details. The choice between a paired or a two-sample test depends on what you assume about the period effect. If you assume no period effect, then a paired t test is the appropriate analysis for the design, with the first member of each pair being the Xilodol measurement (regardless of which sequence the patient belongs to). Otherwise, the two-sample t test approach is called for, since this analysis adjusts for the period effect by using an extra degree of freedom.

Suppose you assume no period effect. Then you can use the PAIREDMEANS statement in PROC POWER with the TEST=DIFF option to perform a sample size analysis for the paired t test. Indicate power as the result parameter by specifying the POWER= option with a missing value (.). Specify the conjectured means and standard deviations for each drug by using the PAIREDMEANS= and PAIREDSTDDEVS= options and the correlation by using the CORR= option. Specify both one- and two-sided tests by using the SIDES= option, the significance level by using the ALPHA= option, and the sample size (in terms of number of

pairs) by using the NPAIRS= option. Generate a plot of power versus sample size by specifying the PLOT statement with X=N to request a plot with sample size on the X axis. (The result parameter, here power, is always plotted on the other axis.) Use the MIN= and MAX= options in the PLOT statement to specify the sample size range (as numbers of pairs).

The following statements perform the sample size analysis:

```
ods listing style=htmlbluecml;
ods graphics on;

proc power;
   pairedmeans test=diff
      pairedmeans   = (330 310)
      pairedstddevs = (40 55)
      corr          = 0.3
      sides         = 1 2
      alpha         = 0.01
      npairs        = 100
      power         = .;
   plot x=n min=50 max=200;
run;

ods graphics off;
```

The ODS LISTING STYLE=HTMLBLUECML statement specifies the HTMLBLUECML style, which is suitable for use with PROC POWER because it allows both marker symbols and line styles to vary. See the section "ODS Styles Suitable for Use with PROC POWER" on page 5897 for more information.

Default values for the NULLDIFF= and DIST= options specify a null mean difference of 0 and the assumption of normally distributed data. The output is shown in Output 70.3.1 and Output 70.3.2.

Output 70.3.1 Power for Paired *t* Analysis of Crossover Design

The POWER Procedure
Paired t Test for Mean Difference

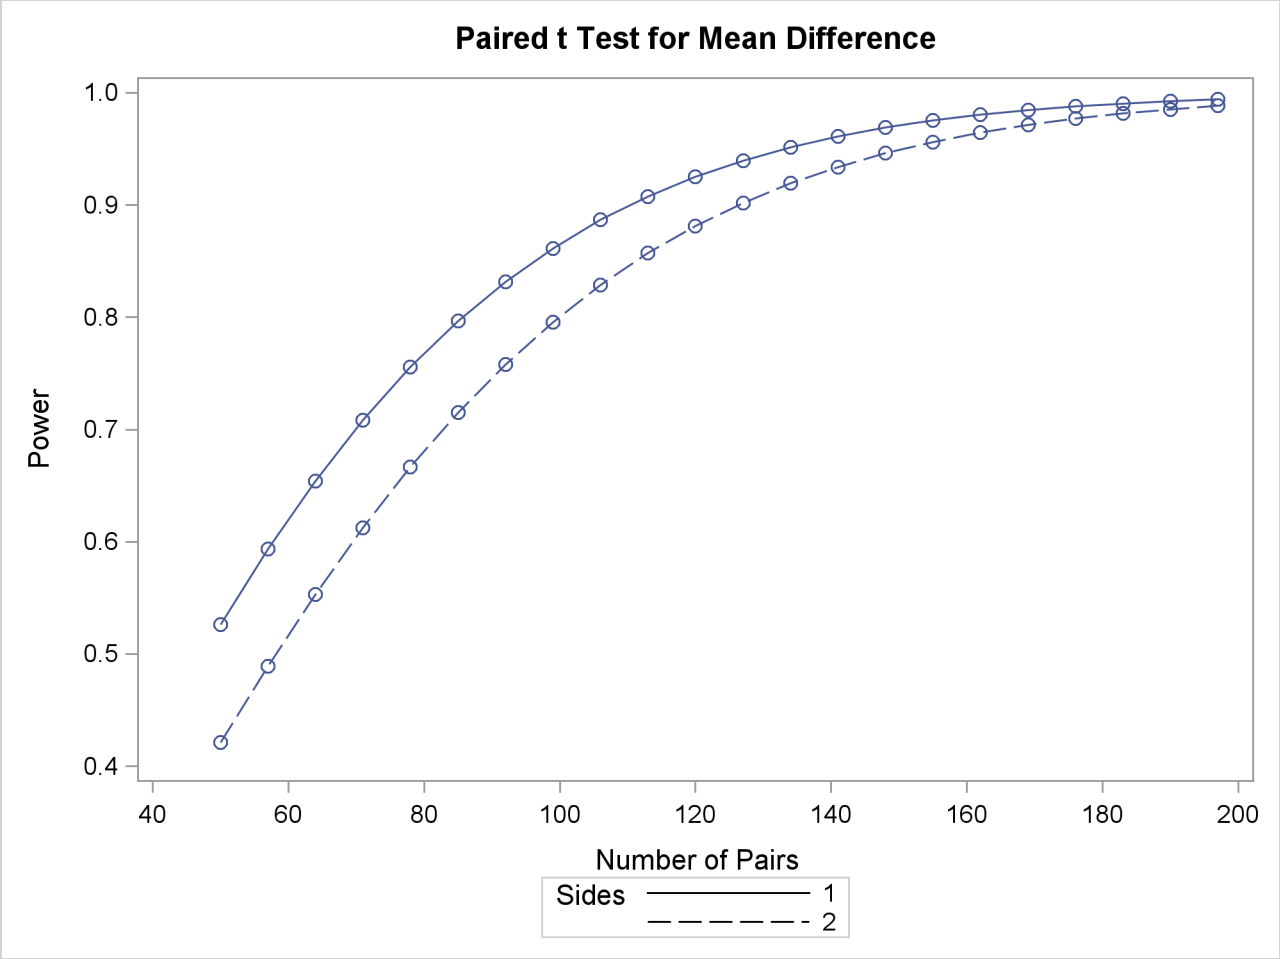
Fixed Scenario Elements

Distribution	Normal
Method	Exact
Alpha	0.01
Mean 1	330
Mean 2	310
Standard Deviation 1	40
Standard Deviation 2	55
Correlation	0.3
Number of Pairs	100
Null Difference	0

Computed Power

Index	Sides	Power
1	1	0.865
2	2	0.801

Output 70.3.2 Plot of Power versus Sample Size for Paired *t* Analysis of Crossover Design



The "Computed Power" table in Output 70.3.1 shows that the power with 100 patients is about 0.8 for the two-sided test and 0.87 for the one-sided test with the alternative of larger Brantium mean. In Output 70.3.2, the line style identifies the number of sides of the test. The plotting symbols identify locations of actual computed powers; the curves are linear interpolations of these points. The plot demonstrates how much higher the power is in the one-sided test than in the two-sided test for the range of sample sizes.

Suppose now that instead of detecting a difference between Xilodol and Brantium, you want to establish that they are similar—in particular, that the absolute mean PEF difference is at most 35. You might consider this goal if, for example, one of the drugs has fewer side effects and if a difference of no more than 35 is considered clinically small. Instead of a standard *t* test, you would conduct an *equivalence test* of the treatment mean difference for the two drugs. You would test the hypothesis that the true difference is less than –35 or more than 35 against the alternative that the mean difference is between –35 and 35, by using an additive model and a two one-sided tests ("TOST") analysis.

Assuming no period effect, you can use the PAIREDMEANS statement with the TEST=EQUIV_DIFF option to perform a sample size analysis for the paired equivalence test. Indicate power as the result parameter by specifying the POWER= option with a missing value (.). Use the LOWER= and UPPER= options to specify the equivalence bounds of –35 and 35. Use the PAIREDMEANS=, PAIREDSTDDEVS=, CORR=, and ALPHA= options in the same way as in the *t* test at the beginning of this example to specify the

remaining parameters.

The following statements perform the sample size analysis:

```
proc power;
   pairedmeans test=equiv_add
      lower         = -35
      upper         = 35
      pairedmeans   = (330 310)
      pairedstddevs = (40 55)
      corr          = 0.3
      alpha         = 0.01
      npairs        = 100
      power         = .;
run;
```

The default option DIST=NORMAL specifies an assumption of normally distributed data. The output is shown in Output 70.3.3.

Output 70.3.3 Power for Paired Equivalence Test for Crossover Design

The POWER Procedure
Equivalence Test for Paired Mean Difference

Fixed Scenario Elements

Distribution	Normal
Method	Exact
Lower Equivalence Bound	-35
Upper Equivalence Bound	35
Alpha	0.01
Reference Mean	330
Treatment Mean	310
Standard Deviation 1	40
Standard Deviation 2	55
Correlation	0.3
Number of Pairs	100

Computed Power

Power
0.598

The power for the paired equivalence test with 100 patients is about 0.6.

Example 70.4: Noninferiority Test with Lognormal Data

The typical goal in noninferiority testing is to conclude that a new treatment or process or product is not appreciably worse than some standard. This is accomplished by convincingly rejecting a one-sided null

hypothesis that the new treatment is appreciably worse than the standard. When designing such studies, investigators must define precisely what constitutes "appreciably worse."

You can use the POWER procedure for sample size analyses for a variety of noninferiority tests, by specifying custom, one-sided null hypotheses for common tests. This example illustrates the strategy (often called Blackwelder's scheme; Blackwelder 1982) by comparing the means of two independent lognormal samples. The logic applies to one-sample, two-sample, and paired-sample problems involving normally distributed measures and proportions.

Suppose you are designing a study hoping to show that a new (less expensive) manufacturing process does not produce appreciably more pollution than the current process. Quantifying "appreciably worse" as 10%, you seek to show that the mean pollutant level from the new process is less than 110% of that from the current process. In standard hypothesis testing notation, you seek to reject

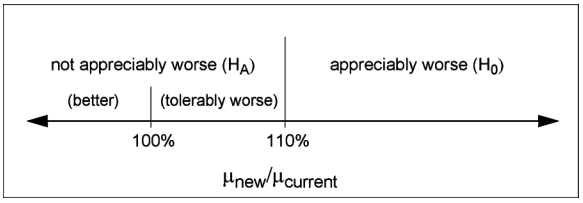
$$H_0: \frac{\mu_{\text{new}}}{\mu_{\text{current}}} \geq 1.10$$

in favor of

$$H_A: \frac{\mu_{\text{new}}}{\mu_{\text{current}}} < 1.10$$

This is described graphically in Figure 70.8. Mean ratios below 100% are better levels for the new process; a ratio of 100% indicates absolute equivalence; ratios of 100–110% are "tolerably" worse; and ratios exceeding 110% are appreciably worse.

Figure 70.8 Hypotheses for the Pollutant Study



An appropriate test for this situation is the common two-group t test on log-transformed data. The hypotheses become

$$H_0: \log(\mu_{\text{new}}) - \log(\mu_{\text{current}}) \geq \log(1.10)$$
$$H_A: \log(\mu_{\text{new}}) - \log(\mu_{\text{current}}) < \log(1.10)$$

Measurements of the pollutant level will be taken by using laboratory models of the two processes and will be treated as independent lognormal observations with a coefficient of variation (σ/μ) between 0.5 and 0.6 for both processes. You will end up with 300 measurements for the current process and 180 for the new one. It is important to avoid a Type I error here, so you set the Type I error rate to 0.01. Your theoretical work suggests that the new process will actually reduce the pollutant by about 10% (to 90% of current), but you need to compute and graph the power of the study if the new levels are actually between 70% and 120% of current levels.

Implement the sample size analysis by using the TWOSAMPLEMEANS statement in PROC POWER with the TEST=RATIO option. Indicate power as the result parameter by specifying the POWER= option with a missing value (.). Specify a series of scenarios for the mean ratio between 0.7 and 1.2 by using the

MEANRATIO= option. Use the NULLRATIO= option to specify the null mean ratio of 1.10. Specify SIDES=L to indicate a one-sided test with the alternative hypothesis stating that the mean ratio is *lower* than the null value. Specify the significance level, scenarios for the coefficient of variation, and the group sample sizes by using the ALPHA=, CV=, and GROUPNS= options. Generate a plot of power versus mean ratio by specifying the PLOT statement with the X=EFFECT option to request a plot with mean ratio on the X axis. (The result parameter, here power, is always plotted on the other axis.) Use the STEP= option in the PLOT statement to specify an interval of 0.05 between computed points in the plot.

The following statements perform the desired analysis:

```
ods listing style=htmlbluecml;
ods graphics on;

proc power;
   twosamplemeans test=ratio
      meanratio = 0.7 to 1.2 by 0.1
      nullratio = 1.10
      sides     = L
      alpha     = 0.01
      cv        = 0.5 0.6
      groupns   = (300 180)
      power     = .;
   plot x=effect step=0.05;
run;

ods graphics off;
```

The ODS LISTING STYLE=HTMLBLUECML statement specifies the HTMLBLUECML style, which is suitable for use with PROC POWER because it allows both marker symbols and line styles to vary. See the section "ODS Styles Suitable for Use with PROC POWER" on page 5897 for more information.

Note the use of SIDES=L, which forces computations for cases that need a rejection region that is opposite to the one providing the most one-tailed power; in this case, it is the lower tail. Such cases will show power that is less than the prescribed Type I error rate. The default option DIST=LOGNORMAL specifies the assumption of lognormally distributed data. The default MIN= and MAX= options in the plot statement specify an X axis range identical to the effect size range in the TWOSAMPLEMEANS statement (mean ratios between 0.7 and 1.2).

Output 70.4.1 and Output 70.4.2 show the results.

Output 70.4.1 Power for Noninferiority Test of Ratio

The POWER Procedure
Two-Sample t Test for Mean Ratio

Fixed Scenario Elements

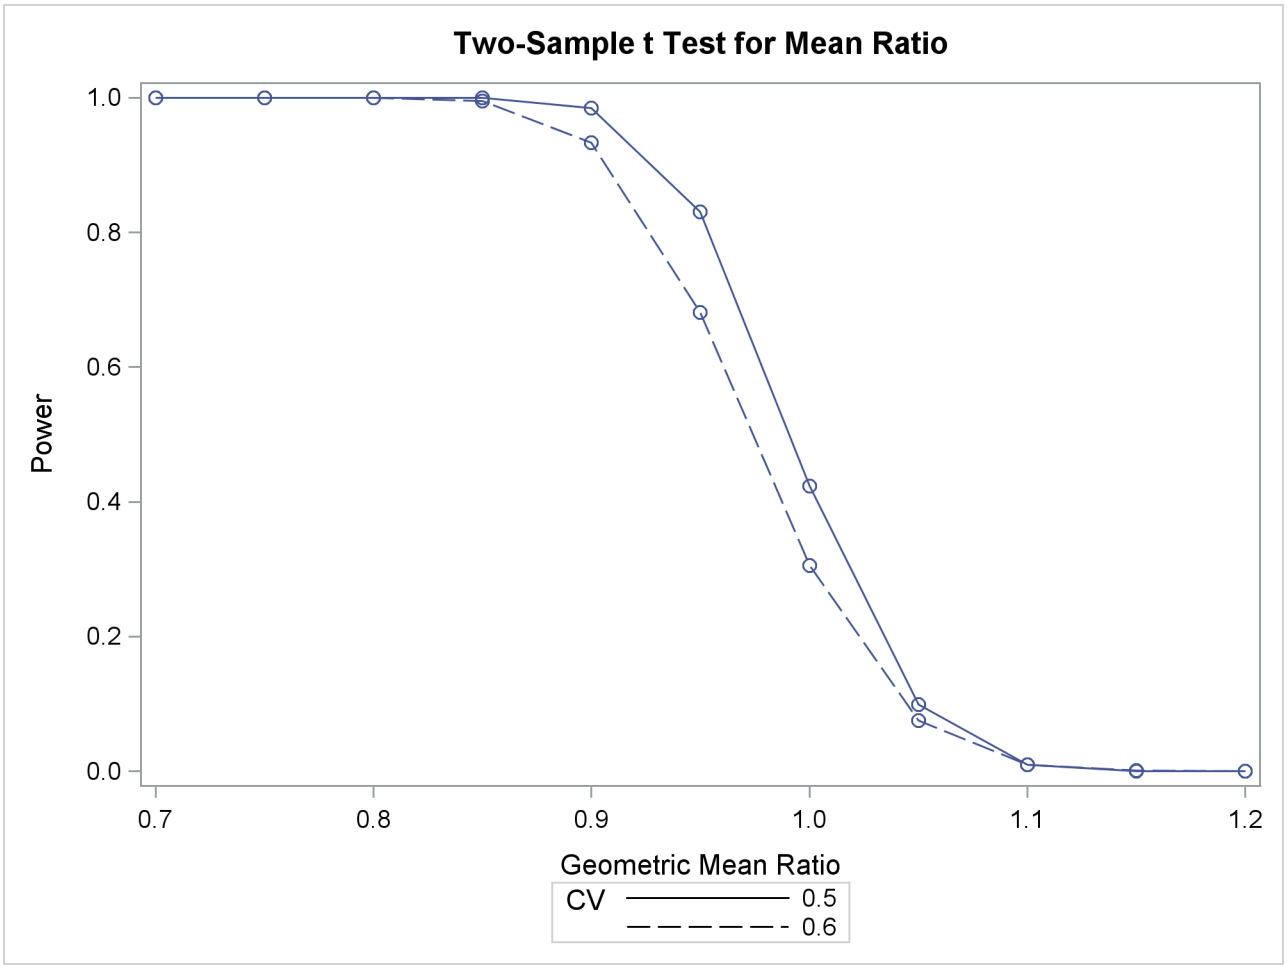
Distribution	Lognormal
Method	Exact
Number of Sides	L
Null Geometric Mean Ratio	1.1
Alpha	0.01
Group 1 Sample Size	300
Group 2 Sample Size	180

Output 70.4.1 *continued*

Computed Power

Index	Geo Mean Ratio	CV	Power
1	0.7	0.5	>.999
2	0.7	0.6	>.999
3	0.8	0.5	>.999
4	0.8	0.6	>.999
5	0.9	0.5	0.985
6	0.9	0.6	0.933
7	1.0	0.5	0.424
8	1.0	0.6	0.306
9	1.1	0.5	0.010
10	1.1	0.6	0.010
11	1.2	0.5	<.001
12	1.2	0.6	<.001

Output 70.4.2 Plot of Power versus Mean Ratio for Noninferiority Test



The "Computed Power" table in Output 70.4.1 shows that power exceeds 0.90 if the true mean ratio is 90% or less, as surmised. But power is unacceptably low (0.31–0.42) if the processes happen to be truly equivalent. Note that the power is identical to the alpha level (0.01) if the true mean ratio is 1.10 and below 0.01 if the true mean ratio is appreciably worse (>110%). In Output 70.4.2, the line style identifies the coefficient of variation. The plotting symbols identify locations of actual computed powers; the curves are linear interpolations of these points.

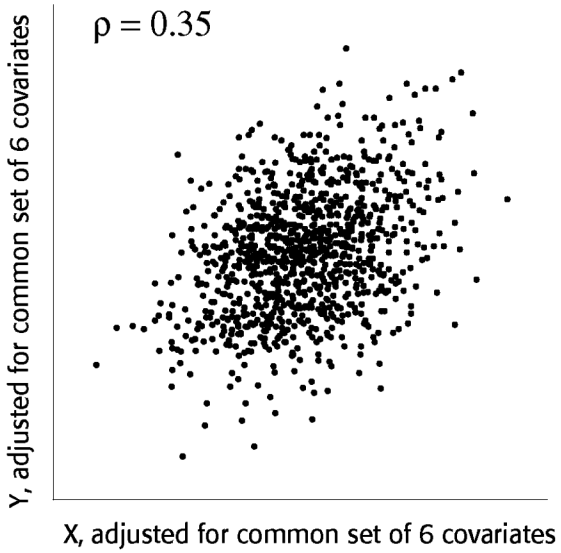
Example 70.5: Multiple Regression and Correlation

You are working with a team of preventive cardiologists investigating whether elevated serum homocysteine levels are linked to atherosclerosis (plaque buildup) in coronary arteries. The planned analysis is an ordinary least squares regression to assess the relationship between total homocysteine level (tHcy) and a plaque burden index (PBI), adjusting for six other variables: age, gender, plasma levels of folate, vitamin B_6, vitamin B_{12}, and a serum cholesterol index. You will regress PBI on tHcy and the six other predictors (plus the intercept) and use a Type III F test to assess whether tHcy is a significant predictor after adjusting for the others. You wonder whether 100 subjects will provide adequate statistical power.

This is a correlational study at a single time. Subjects will be screened so that about half will have had a heart problem. All eight variables will be measured during one visit. Most clinicians are familiar with simple correlations between two variables, so you decide to pose the statistical problem in terms of estimating and testing the partial correlation between X_1 = tHcy and Y = PBI, controlling for the six other predictor variables ($R_{YX_1|X_{-1}}$). This greatly simplifies matters, especially the elicitation of the conjectured effect.

You use partial regression plots like that shown in Figure 70.9 to teach the team that the partial correlation between PBI and tHcy is the correlation of two sets of residuals obtained from ordinary regression models, one from regressing PBI on the six covariates and the other from regressing tHcy on the same covariates. Thus each subject has "expected" tHcy and PBI values based on the six covariates. The cardiologists believe that subjects whose tHcy is relatively higher than expected will also have a PBI that is relatively higher than expected. The partial correlation quantifies that adjusted association just as a standard simple correlation does with the unadjusted linear association between two variables.

Figure 70.9 Partial Regression Plot



Based on previously published studies of various coronary risk factors and after viewing a set of scatterplots showing various correlations, the team surmises that the true partial correlation is likely to be at least 0.35.

You want to compute the statistical power for a sample size of $N = 100$ by using $\alpha = 0.05$. You also want to plot power for sample sizes between 50 and 150. Use the MULTREG statement to compute the power and the PLOT statement to produce the graph. Since the predictors are observed rather than fixed in advanced, and a joint multivariate normal assumption seems tenable, use MODEL=RANDOM. The following statements perform the power analysis:

```
ods listing style=htmlbluecml;
ods graphics on;

proc power;
   multreg
      model = random
      nfullpredictors = 7
      ntestpredictors = 1
      partialcorr = 0.35
      ntotal = 100
      power = .;
   plot x=n min=50 max=150;
run;

ods graphics off;
```

The ODS LISTING STYLE=HTMLBLUECML statement specifies the HTMLBLUECML style, which is suitable for use with PROC POWER because it allows both marker symbols and line styles to vary. See the section "ODS Styles Suitable for Use with PROC POWER" on page 5897 for more information.

The POWER=. option identifies power as the parameter to compute. The NFULLPREDICTORS= option specifies seven total predictors (not including the intercept), and the NTESTPREDICTORS= option indicates that one of those predictors is being tested. The PARTIALCORR= and NTOTAL= options specify the

partial correlation and sample size, respectively. The default value for the ALPHA= option sets the significance level to 0.05. The X=N option in the plot statement requests a plot of sample size on the X axis, and the MIN= and MAX= options specify the sample size range.

Output 70.5.1 shows the output, and Output 70.5.2 shows the plot.

Output 70.5.1 Power Analysis for Multiple Regression

The POWER Procedure
Type III F Test in Multiple Regression

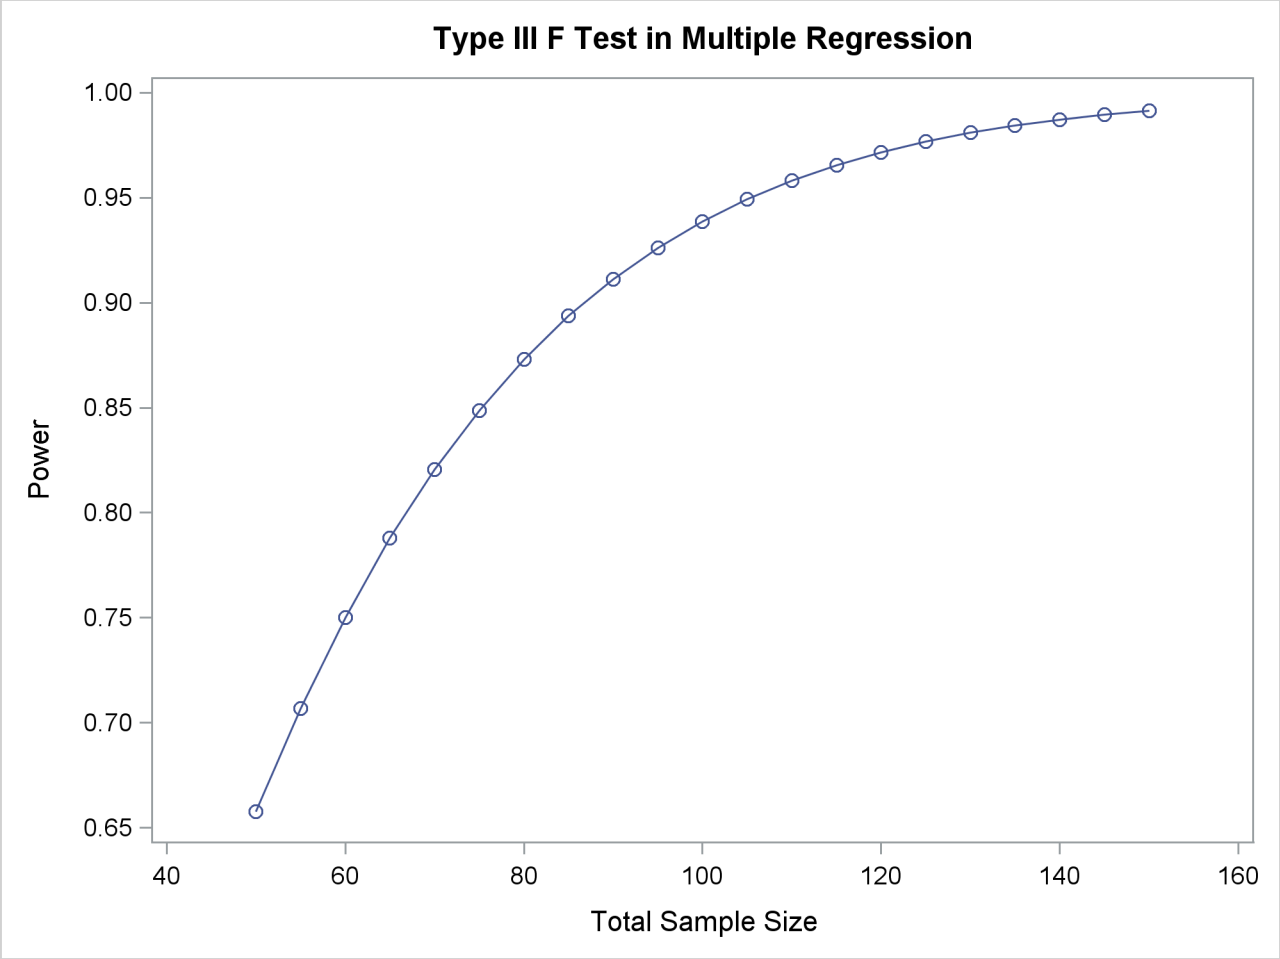
Fixed Scenario Elements

Method	Exact
Model	Random X
Number of Predictors in Full Model	7
Number of Test Predictors	1
Partial Correlation	0.35
Total Sample Size	100
Alpha	0.05

Computed Power

Power
0.939

Output 70.5.2 Plot of Power versus Sample Size for Multiple Regression



For the sample size $N = 100$, the study is almost balanced with respect to Type I and Type II error rates, with $\alpha = 0.05$ and $\beta = 1 - 0.937 = 0.063$. The study thus seems well designed at this sample size.

Now suppose that in a follow-up meeting with the cardiologists, you discover that their specific intent is to demonstrate that the (partial) correlation between PBI and tHcy is greater than 0.2. You suggest changing the planned data analysis to a one-sided Fisher's z test with a null correlation of 0.2. The following statements perform a power analysis for this test:

```
proc power;
   onecorr dist=fisherz
      npvars = 6
      corr = 0.35
      nullcorr = 0.2
      sides = 1
      ntotal = 100
      power = .;
run;
```

The DIST=FISHERZ option in the ONECORR statement specifies Fisher's z test. The NPARTIALVARS= option specifies that six additional variables are adjusted for in the partial correlation. The CORR= option

specifies the conjectured correlation of 0.35, and the NULLCORR= option indicates the null value of 0.2. The SIDES= option specifies a one-sided test.

Output 70.5.3 shows the output.

Output 70.5.3 Power Analysis for Fisher's *z* Test

The POWER Procedure
Fisher's z Test for Pearson Correlation

Fixed Scenario Elements

Distribution	Fisher's z transformation of r
Method	Normal approximation
Number of Sides	1
Null Correlation	0.2
Number of Variables Partialled Out	6
Correlation	0.35
Total Sample Size	100
Nominal Alpha	0.05

Computed Power

Actual Alpha	Power
0.05	0.466

The power for Fisher's z test is less than 50%, the decrease being mostly due to the smaller effect size (relative to the null value). When asked for a recommendation for a new sample size goal, you compute the required sample size to achieve a power of 0.95 (to balance Type I and Type II errors) and 0.85 (a threshold deemed to be minimally acceptable to the team). The following statements perform the sample size determination:

```
proc power;
   onecorr dist=fisherz
      npvars = 6
      corr = 0.35
      nullcorr = 0.2
      sides = 1
      ntotal = .
      power = 0.85 0.95;
run;
```

The NTOTAL=. option identifies sample size as the parameter to compute, and the POWER= option specifies the target powers.

Output 70.5.4 Sample Size Determination for Fisher's *z* Test

The POWER Procedure
Fisher's z Test for Pearson Correlation

Fixed Scenario Elements

Distribution	Fisher's z transformation of r
Method	Normal approximation
Number of Sides	1
Null Correlation	0.2
Number of Variables Partialled Out	6
Correlation	0.35
Nominal Alpha	0.05

Computed N Total

Index	Nominal Power	Actual Alpha	Actual Power	N Total
1	0.85	0.05	0.850	280
2	0.95	0.05	0.950	417

The results in Output 70.5.4 reveal a required sample size of 417 to achieve a power of 0.95 and a required sample size of 280 to achieve a power of 0.85.

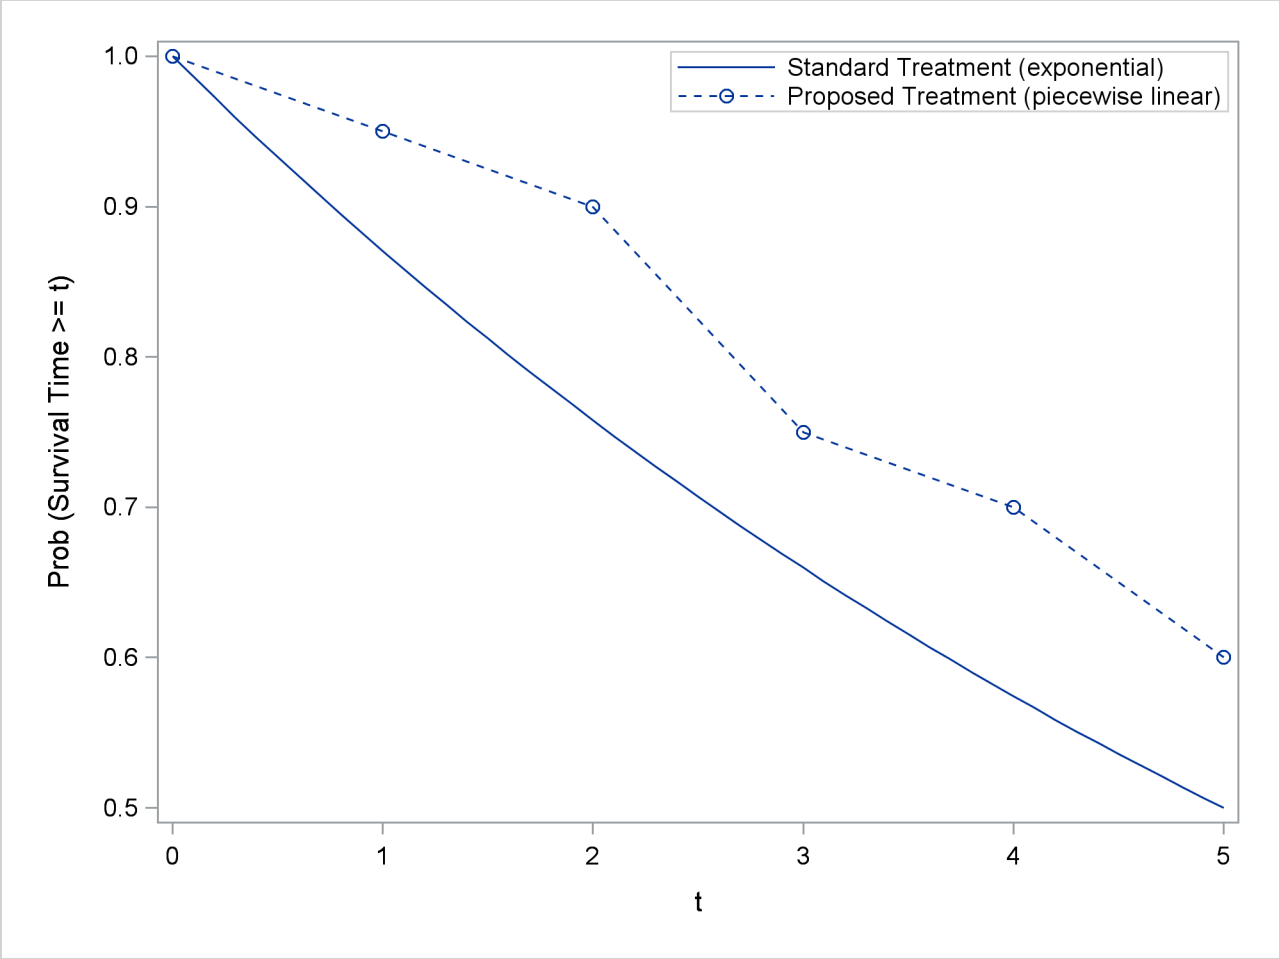
Example 70.6: Comparing Two Survival Curves

You are consulting for a clinical research group planning a trial to compare survival rates for proposed and standard cancer treatments. The planned data analysis is a log-rank test to nonparametrically compare the overall survival curves for the two treatments. Your goal is to determine an appropriate sample size to achieve a power of 0.8 for a two-sided test with $\alpha = 0.05$ by using a balanced design.

The survival curve for patients on the standard treatment is well known to be approximately exponential with a median survival time of five years. The research group conjectures that the new proposed treatment will yield a (nonexponential) survival curve similar to the dashed line in Figure 70.6.1.

Patients will be accrued uniformly over two years and then followed for an additional three years past the accrual period. Some loss to follow-up is expected, with roughly exponential rates that would result in about 50% loss with the standard treatment within 10 years. The loss to follow-up with the proposed treatment is more difficult to predict, but 50% loss would be expected to occur sometime between years 5 and 20.

Output 70.6.1 Survival Curves



Use the TWOSAMPLESURVIVAL statement with the TEST=LOGRANK option to compute the required sample size for the log-rank test. The following statements perform the analysis:

```
proc power;
   twosamplesurvival test=logrank
      curve("Standard") = 5 : 0.5
      curve("Proposed") = (1 to 5 by 1):(0.95 0.9 0.75 0.7 0.6)
      groupsurvival = "Standard" | "Proposed"
      accrualtime = 2
      followuptime = 3
      groupmedlosstimes = 10 | 20 5
      power = 0.8
      npergroup = .;
run;
```

The CURVE= option defines the two survival curves. The "Standard" curve has only one point, specifying an exponential form with a survival probability of 0.5 at year 5. The "Proposed" curve is a piecewise linear curve defined by the five points shown in Figure 70.6.1. The GROUPSURVIVAL= option assigns the survival curves to the two groups, and the ACCRUALTIME= and FOLLOWUPTIME= options specify the accrual and follow-up times. The GROUPMEDLOSSTIMES= option specifies the years at which 50%

loss is expected to occur. The POWER= option specifies the target power, and the NPERGROUP=. option identifies sample size per group as the parameter to compute. Default values for the SIDES= and ALPHA= options specify a two-sided test with $\alpha = 0.05$.

Output 70.6.2 shows the results.

Output 70.6.2 Sample Size Determination for Log-Rank Test

The POWER Procedure
Log-Rank Test for Two Survival Curves

Fixed Scenario Elements

Method	Lakatos normal approximation
Accrual Time	2
Follow-up Time	3
Group 1 Survival Curve	Standard
Form of Survival Curve 1	Exponential
Group 2 Survival Curve	Proposed
Form of Survival Curve 2	Piecewise Linear
Group 1 Median Loss Time	10
Nominal Power	0.8
Number of Sides	2
Number of Time Sub-Intervals	12
Alpha	0.05

Computed N Per Group

Index	Median Loss Time 2	Actual Power	N Per Group
1	20	0.800	228
2	5	0.801	234

The required sample size per group to achieve a power of 0.8 is 228 if the median loss time is 20 years for the proposed treatment. Only six more patients are required in each group if the median loss time is as short as five years.

Example 70.7: Confidence Interval Precision

An investment firm has hired you to help plan a study to estimate the success of a new investment strategy called "IntuiVest." The study involves complex simulations of market conditions over time, and it tracks the balance of a hypothetical brokerage account starting with $50,000. Each simulation is very expensive in terms of computing time. You are asked to determine an appropriate number of simulations to estimate the average change in the account balance at the end of three years. The goal is to have a 95% chance of obtaining a 90% confidence interval whose half-width is at most $1,000. That is, the firm wants to have a 95% chance of being able to correctly claim at the end of the study that "Our research shows with 90%

confidence that IntuiVest yields a profit of $X +/– $1,000 at the end of three years on an initial investment of $50,000 (under simulated market conditions)."

The probability of achieving the desired precision (that is, a small interval width) can be calculated either unconditionally or conditionally given that the true mean is captured by the interval. You decide to use the conditional form, considering two of its advantages:

- The conditional probability is usually lower than the unconditional probability for the same sample size, meaning that the conditional form is generally conservative.
- The overall probability of achieving the desired precision *and* capturing the true mean is easily computed as the product of the half-width probability and the confidence level. In this case, the overall probability is $0.95 \times 0.9 = 0.855$.

Based on some initial simulations, you expect a standard deviation between $25,000 and $45,000 for the ending account balance. You will consider both of these values in the sample size analysis.

As mentioned in the section "Overview of Power Concepts" on page 5831, an analysis of confidence interval precision is analogous to a traditional power analysis, with "CI Half-Width" taking the place of effect size and "Prob(Width)" taking the place of power. In this example, the target CI Half-Width is 1000, and the desired Prob(Width) is 0.95.

In addition to computing sample sizes for a half-width of $1,000, you are asked to plot the required number of simulations for a range of half-widths between $500 and $2,000. Use the ONESAMPLEMEANS statement with the CI=T option to implement the sample size determination. The following statements perform the analysis:

```
ods listing style=htmlbluecml;
ods graphics on;

proc power;
   onesamplemeans ci=t
      alpha = 0.1
      halfwidth = 1000
      stddev = 25000 45000
      probwidth = 0.95
      ntotal = .;
   plot x=effect min=500 max=2000;
run;

ods graphics off;
```

The ODS LISTING STYLE=HTMLBLUECML statement specifies the HTMLBLUECML style, which is suitable for use with PROC POWER because it allows both marker symbols and line styles to vary. See the section "ODS Styles Suitable for Use with PROC POWER" on page 5897 for more information.

The NTOTAL=. option identifies sample size as the parameter to compute. The ALPHA=0.1 option specifies a confidence level of $1 - \alpha = 0.9$. The HALFWIDTH= option specifies the target half-width, and the STDDEV= option specifies the conjectured standard deviation values. The PROBWIDTH= option specifies the desired probability of achieving the target precision. The default value PROBTYPE=CONDITIONAL specifies that this probability is conditional on the true mean being captured by the interval. The default of SIDES=2 indicates a two-sided interval.

Output 70.7.1 shows the output, and Output 70.7.2 shows the plot.

Output 70.7.1 Sample Size Determination for Confidence Interval Precision

The POWER Procedure
Confidence Interval for Mean

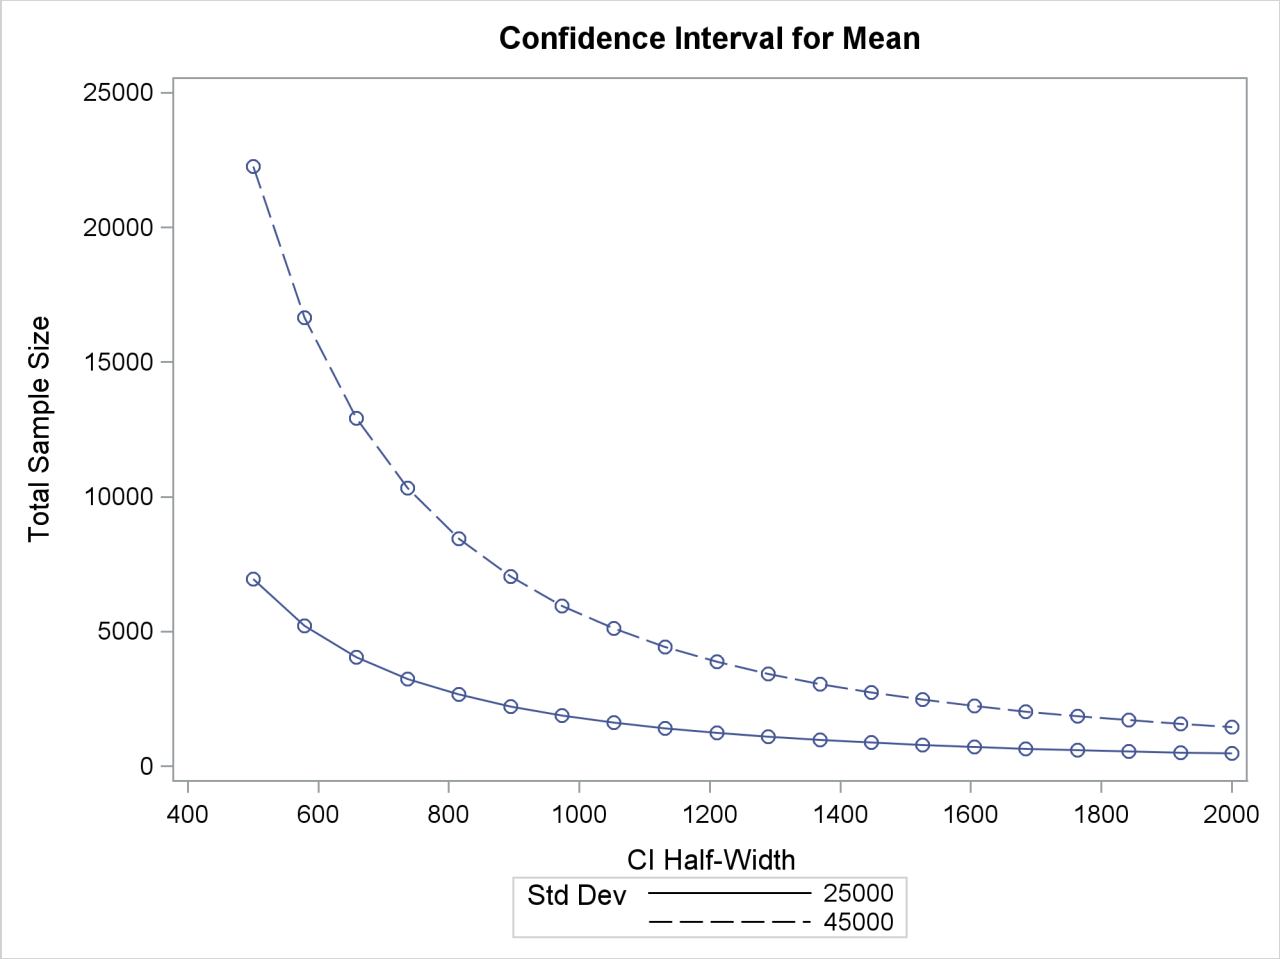
Fixed Scenario Elements

Distribution	Normal
Method	Exact
Alpha	0.1
CI Half-Width	1000
Nominal Prob(Width)	0.95
Number of Sides	2
Prob Type	Conditional

Computed N Total

Index	Std Dev	Actual Prob (Width)	N Total
1	25000	0.951	1788
2	45000	0.950	5652

Output 70.7.2 Plot of Sample Size versus Confidence Interval Half-Width



The number of simulations required in order to have a 95% chance of obtaining a half-width of at most 1000 is between 1788 and 5652, depending on the standard deviation. The plot reveals that more than 20,000 simulations would be required for a half-width of 500, assuming the higher standard deviation.

Example 70.8: Customizing Plots

This example demonstrates various ways you can modify and enhance plots:

- assigning analysis parameters to axes
- fine-tuning a sample size axis
- adding reference lines
- linking plot features to analysis parameters
- choosing key (legend) styles

- modifying symbol locations

The example plots are all based on a sample size analysis for a two-sample t test of group mean difference. You start by computing the sample size required to achieve a power of 0.9 by using a two-sided test with $\alpha = 0.05$, assuming the first mean is 12, the second mean is either 15 or 18, and the standard deviation is either 7 or 9.

Use the TWOSAMPLEMEANS statement with the TEST=DIFF option to compute the required sample sizes. Indicate total sample size as the result parameter by supplying a missing value (.) with the NTOTAL= option. Use the GROUPMEANS=, STDDEV=, and POWER= options to specify values of the other parameters. The following statements perform the sample size computations:

```
proc power;
   twosamplemeans test=diff
      groupmeans   = 12 | 15 18
      stddev       = 7 9
      power        = 0.9
      ntotal       = .;
run;
```

Default values for the NULLDIFF=, SIDES=, GROUPWEIGHTS=, and DIST= options specify a null mean difference of 0, two-sided test, balanced design, and assumption of normally distributed data, respectively.

Output 70.8.1 shows that the required sample size ranges from 60 to 382, depending on the unknown standard deviation and second mean.

Output 70.8.1 Computed Sample Sizes

The POWER Procedure
Two-Sample t Test for Mean Difference

Fixed Scenario Elements

Distribution	Normal
Method	Exact
Group 1 Mean	12
Nominal Power	0.9
Number of Sides	2
Null Difference	0
Alpha	0.05
Group 1 Weight	1
Group 2 Weight	1

Computed N Total

Index	Mean2	Std Dev	Actual Power	N Total
1	15	7	0.902	232
2	15	9	0.901	382
3	18	7	0.904	60
4	18	9	0.904	98

Assigning Analysis Parameters to Axes

Use the PLOT statement to produce plots for all power and sample size analyses in PROC POWER. For the sample size analysis described at the beginning of this example, suppose you want to plot the required sample size on the Y axis against a range of powers between 0.5 and 0.95 on the X axis. The X= and Y= options specify which parameter to plot against the result and which axis to assign to this parameter. You can use either the X= or the Y= option, but not both. Use the X=POWER option in the PLOT statement to request a plot with power on the X axis. The result parameter, here total sample size, is always plotted on the other axis. Use the MIN= and MAX= options to specify the range of the axis indicated with either the X= or the Y= option. Here, specify MIN=0.5 and MAX=0.95 to specify the power range. The following statements produce the plot:

```
ods listing style=htmlbluecml;
ods graphics on;

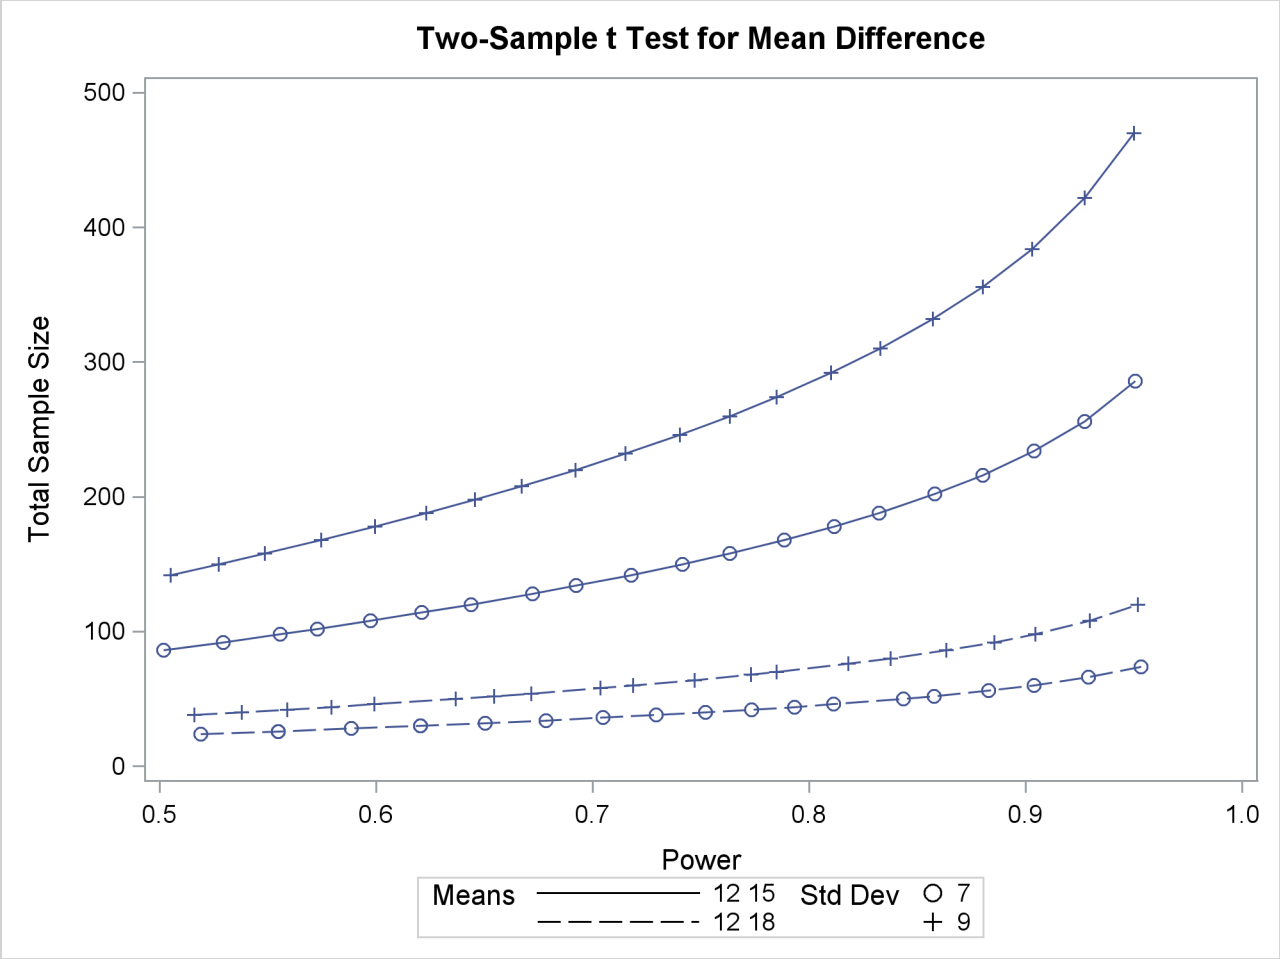
proc power plotonly;
   twosamplemeans test=diff
      groupmeans   = 12 | 15 18
      stddev       = 7 9
      power        = 0.9
      ntotal       = .;
   plot x=power min=0.5 max=0.95;
run;
```

The ODS LISTING STYLE=HTMLBLUECML statement specifies the HTMLBLUECML style, which is suitable for use with PROC POWER because it allows both marker symbols and line styles to vary. See the section "ODS Styles Suitable for Use with PROC POWER" on page 5897 for more information.

Note that the value (0.9) of the POWER= option in the TWOSAMPLEMEANS statement is only a placeholder when the PLOTONLY option is used and both the MIN= and MAX= options are used, because the values of the MIN= and MAX= options override the value of 0.9. But the POWER= option itself is still required in the TWOSAMPLEMEANS statement, to provide a complete specification of the sample size analysis.

The resulting plot is shown in Output 70.8.2.

Output 70.8.2 Plot of Sample Size versus Power

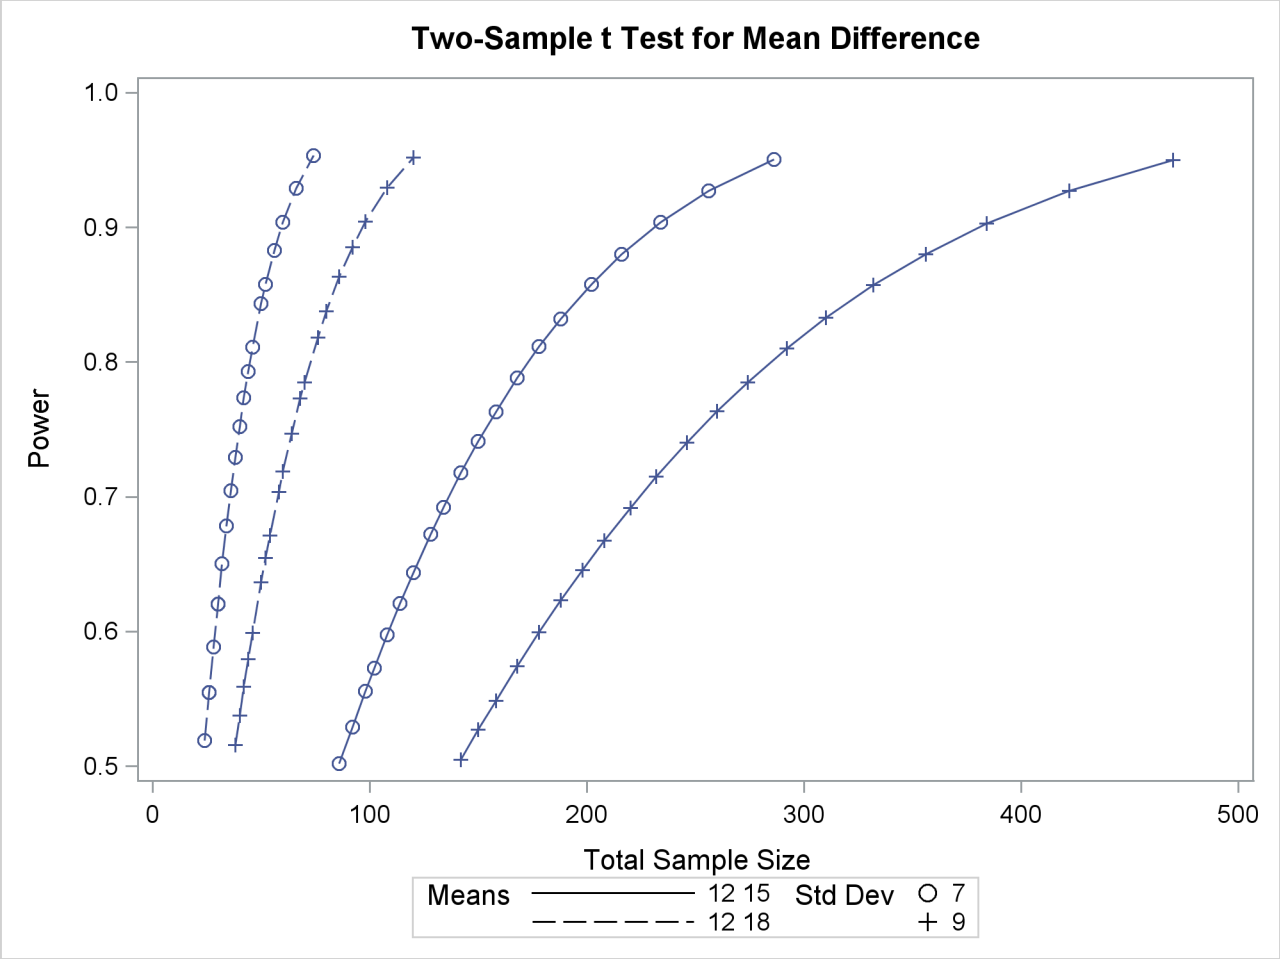


The line style identifies the group means scenario, and the plotting symbol identifies the standard deviation scenario. The locations of plotting symbols indicate computed sample sizes; the curves are linear interpolations of these points. By default, each curve consists of approximately 20 computed points (sometimes slightly more or less, depending on the analysis).

If you would rather plot power on the Y axis versus sample size on the X axis, you have two general strategies to choose from. One strategy is to use the Y= option instead of the X= option in the PLOT statement:

```
plot y=power min=0.5 max=0.95;
```

Output 70.8.3 Plot of Power versus Sample Size using First Strategy



Note that the resulting plot (Output 70.8.3) is essentially a mirror image of Output 70.8.2. The axis ranges are set such that each curve in Output 70.8.3 contains similar values of Y instead of X. Each plotted point represents the computed value of the X axis at the input value of the Y axis.

A second strategy for plotting power versus sample size (when originally solving for sample size) is to invert the analysis and base the plot on computed power for a given range of sample sizes. This strategy works well for monotonic power curves (as is the case for the *t* test and most other continuous analyses). It is advantageous in the sense of preserving the traditional role of the Y axis as the computed parameter. A common way to implement this strategy is as follows:

- Determine the range of sample sizes sufficient to cover at the desired power range for all curves (where each "curve" represents a scenario for standard deviation and second group mean).
- Use this range for the X axis of a plot.

To determine the required sample sizes for target powers of 0.5 and 0.95, change the values in the POWER= option as follows to reflect this range:

```
proc power;
   twosamplemeans test=diff
      groupmeans   = 12 | 15 18
      stddev       = 7 9
      power        = 0.5 0.95
      ntotal       = .;
run;
```

Output 70.8.4 reveals that a sample size range of 24 to 470 is approximately sufficient to cover the desired power range of 0.5 to 0.95 for all curves ("approximately" because the actual power at the rounded sample size of 24 is slightly higher than the nominal power of 0.5).

Output 70.8.4 Computed Sample Sizes

The POWER Procedure
Two-Sample t Test for Mean Difference

Fixed Scenario Elements

Distribution	Normal
Method	Exact
Group 1 Mean	12
Number of Sides	2
Null Difference	0
Alpha	0.05
Group 1 Weight	1
Group 2 Weight	1

Computed N Total

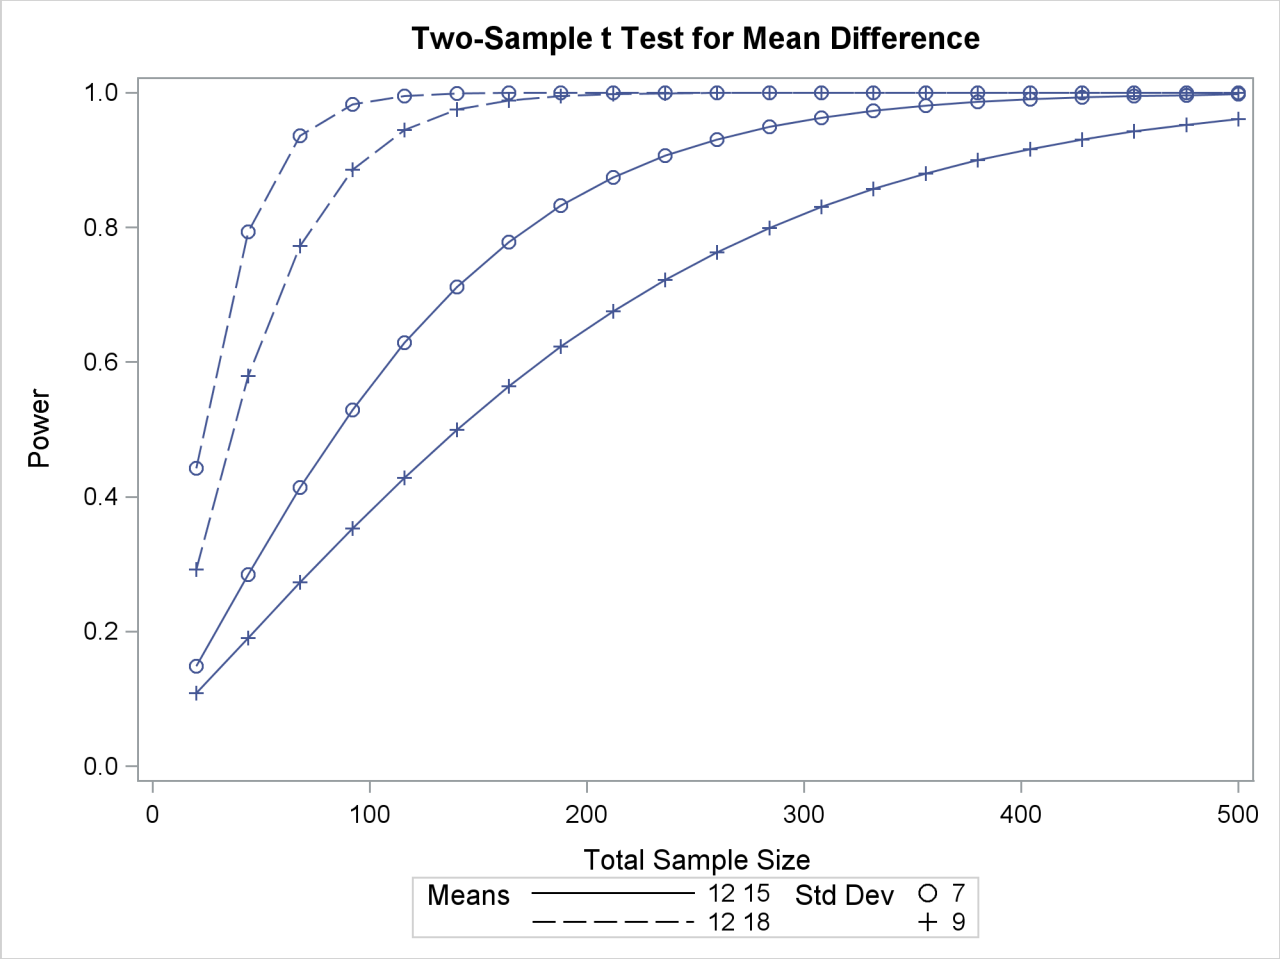
Index	Mean2	Std Dev	Nominal Power	Actual Power	N Total
1	15	7	0.50	0.502	86
2	15	7	0.95	0.951	286
3	15	9	0.50	0.505	142
4	15	9	0.95	0.950	470
5	18	7	0.50	0.519	24
6	18	7	0.95	0.953	74
7	18	9	0.50	0.516	38
8	18	9	0.95	0.952	120

To plot power on the Y axis for sample sizes between 20 and 500, use the X=N option in the PLOT statement with MIN=20 and MAX=500:

```
proc power plotonly;
   twosamplemeans test=diff
      groupmeans   = 12 | 15 18
      stddev       = 7 9
      power        = .
      ntotal       = 200;
   plot x=n min=20 max=500;
run;
```

Each curve in the resulting plot in Output 70.8.5 covers at least a power range of 0.5 to 0.95.

Output 70.8.5 Plot of Power versus Sample Size Using Second Strategy

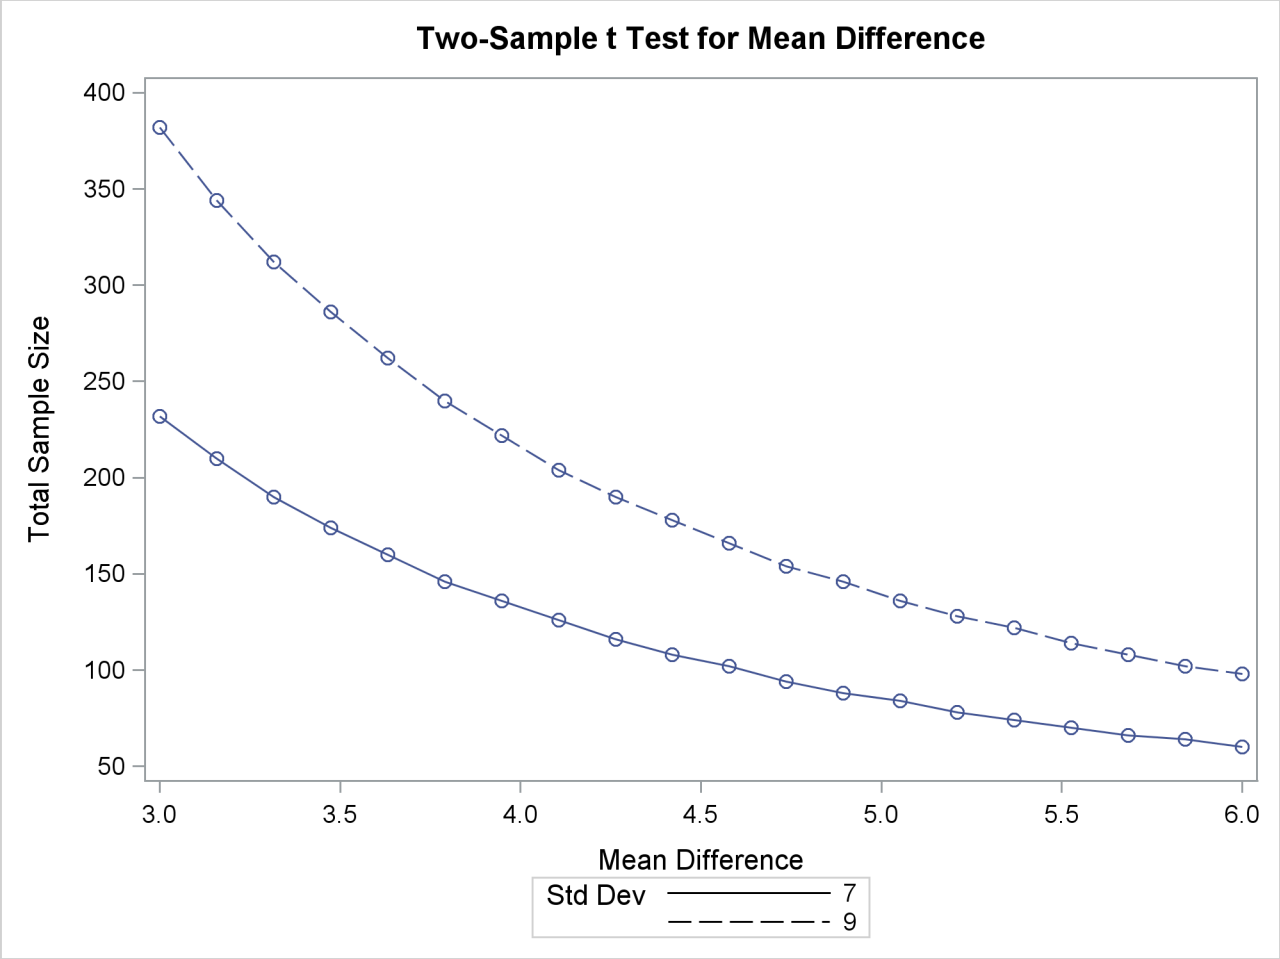


Finally, suppose you want to produce a plot of sample size versus effect size for a power of 0.9. In this case, the "effect size" is defined to be the mean difference. You need to reparameterize the analysis by using the MEANDIFF= option instead of the GROUPMEANS= option to produce a plot, since each plot axis must be represented by a scalar parameter. Use the X=EFFECT option in the PLOT statement to assign the mean difference to the X axis. The following statements produce a plot of required sample size to detect mean differences between 3 and 6:

```
proc power plotonly;
   twosamplemeans test=diff
      meandiff     = 3 6
      stddev       = 7 9
      power        = 0.9
      ntotal       = .;
   plot x=effect min=3 max=6;
run;
```

The resulting plot Output 70.8.6 shows how the required sample size decreases with increasing mean difference.

Output 70.8.6 Plot of Sample Size versus Mean Difference



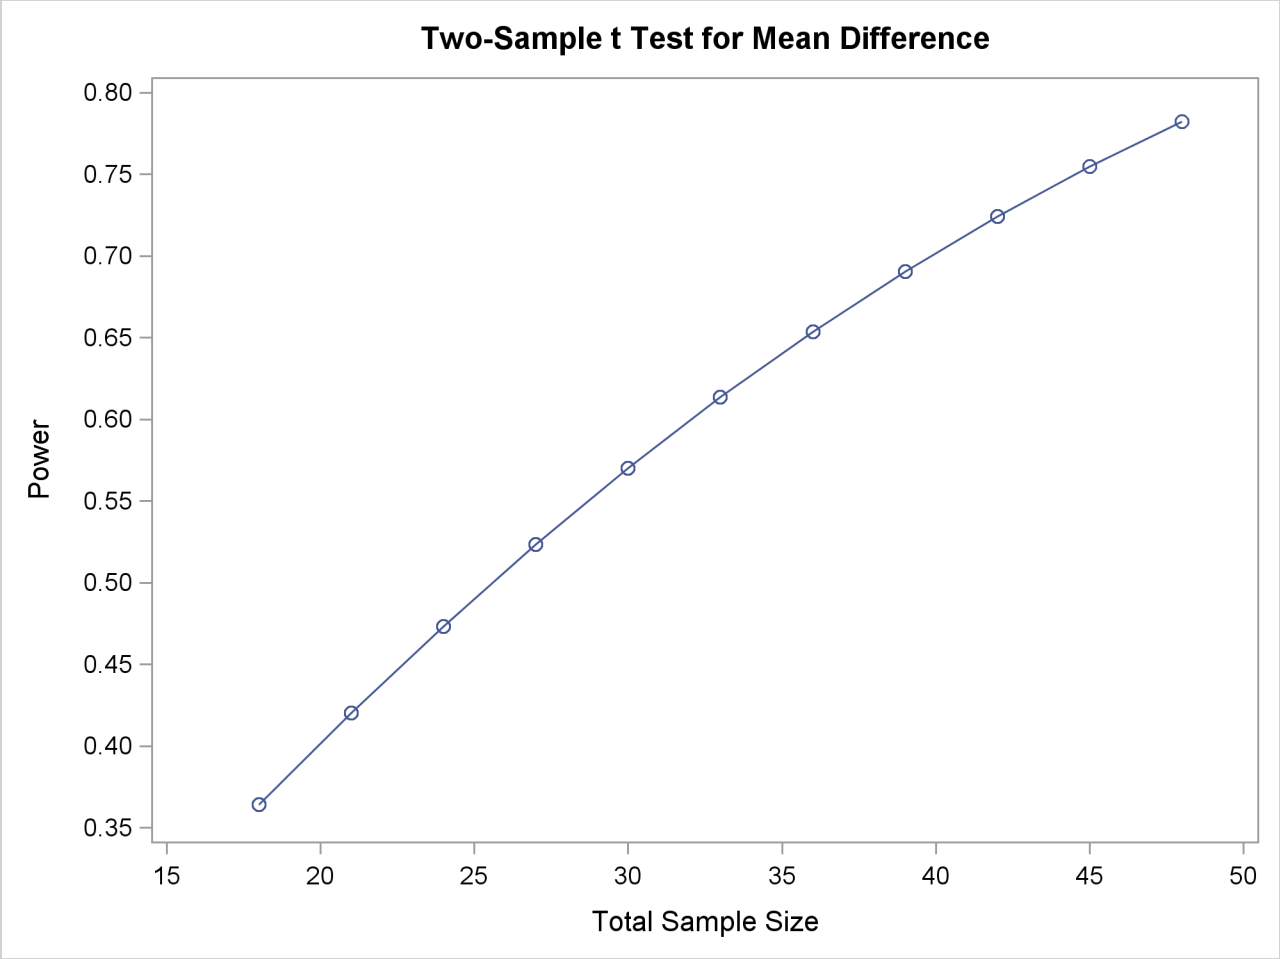
Fine-Tuning a Sample Size Axis

Consider the following plot request for a sample size analysis similar to the one in Output 70.8.1 but with only a single scenario, and with unbalanced sample size allocation of 2:1:

```
proc power plotonly;
   ods output plotcontent=PlotData;
   twosamplemeans test=diff
      groupmeans   = 12 | 18
      stddev       = 7
      groupweights = 2 | 1
      power        = .
      ntotal       = 20;
   plot x=n min=20 max=50 npoints=20;
run;
```

The MIN=, MAX=, and NPOINTS= options in the PLOT statement request a plot with 20 points between 20 and 50. But the resulting plot (Output 70.8.7) appears to have only 11 points, and they range from 18 to 48.

Output 70.8.7 Plot with Overlapping Points



The reason that this plot has fewer points than usual is due to the rounding of sample sizes. If you do not use the NFRACTIONAL option in the analysis statement (here, the TWOSAMPLEMEANS statement), then the set of sample size points determined by the MIN=, MAX=, NPOINTS=, and STEP= options in the PLOT statement can be rounded to satisfy the allocation weights. In this case, they are rounded down to the nearest multiples of 3 (the sum of the weights), and many of the points overlap. To see the overlap, you can print the NominalNTotal (unadjusted) and NTotal (rounded) variables in the PlotContent ODS object (here saved to a data set called PlotData):

```
proc print data=PlotData;
   var NominalNTotal NTotal;
run;
```

The output is shown in Output 70.8.8.

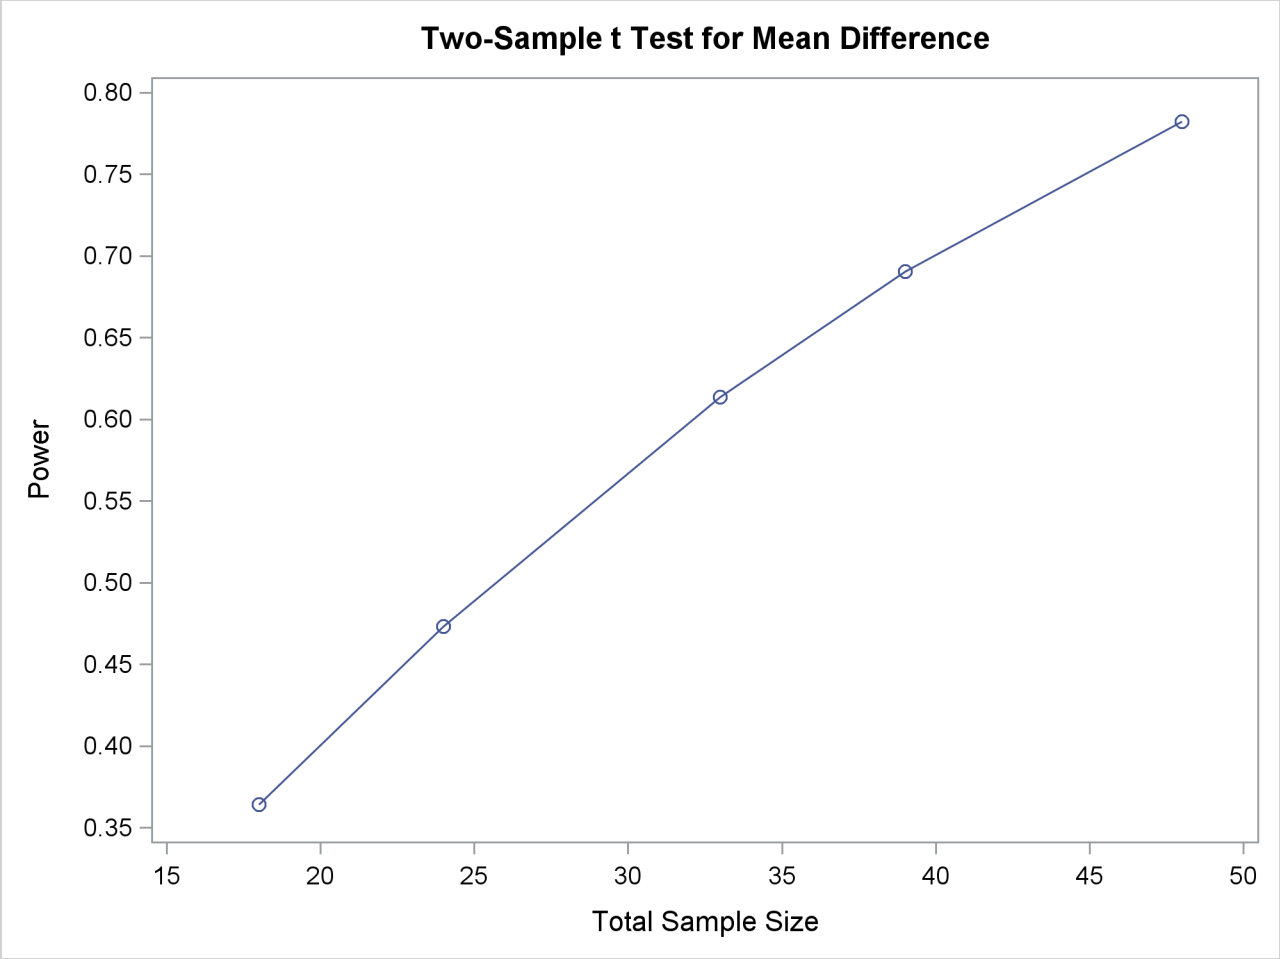
Output 70.8.8 Sample Sizes

Obs	Nominal NTotal	NTotal
1	18.0	18
2	19.6	18
3	21.2	21
4	22.7	21
5	24.3	24
6	25.9	24
7	27.5	27
8	29.1	27
9	30.6	30
10	32.2	30
11	33.8	33
12	35.4	33
13	36.9	36
14	38.5	36
15	40.1	39
16	41.7	39
17	43.3	42
18	44.8	42
19	46.4	45
20	48.0	48

Besides overlapping of sample size points, another peculiarity that might occur without the NFRACTIONAL option is unequal spacing—for example, in the plot in Output 70.8.9, created with the following statements:

```
proc power plotonly;
   twosamplemeans test=diff
      groupmeans   = 12 | 18
      stddev       = 7
      groupweights = 2 | 1
      power        = .
      ntotal       = 20;
   plot x=n min=20 max=50 npoints=5;
run;
```

Output 70.8.9 Plot with Unequally Spaced Points

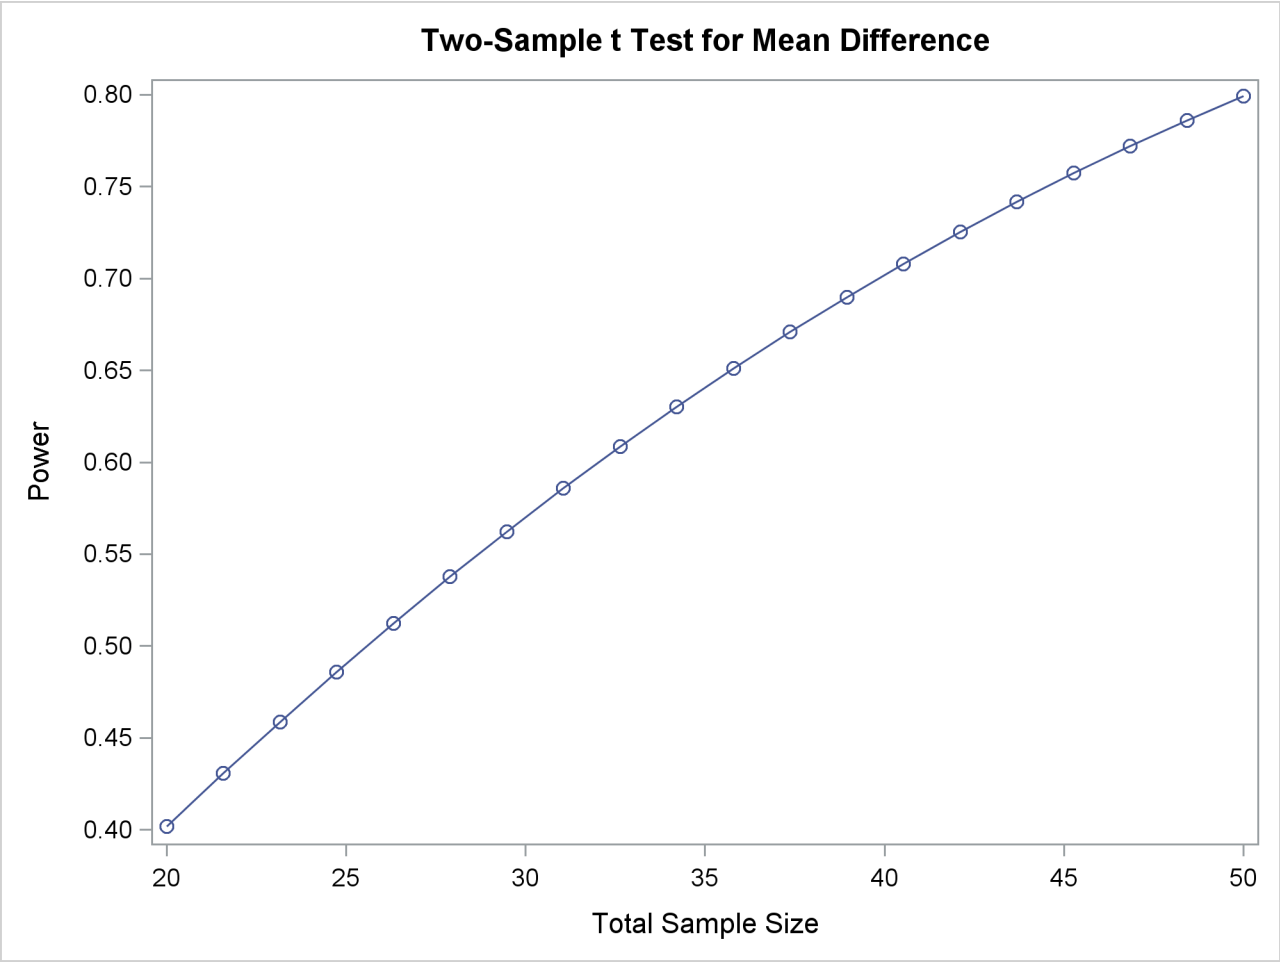


If you want to guarantee evenly spaced, nonoverlapping sample size points in your plots, you can either (1) use the NFRACTIONAL option in the analysis statement preceding the PLOT statement or (2) use the STEP= option and provide values for the MIN=, MAX=, and STEP= options in the PLOT statement that are multiples of the sum of the allocation weights. Note that this sum is simply 1 for one-sample and paired designs and 2 for balanced two-sample designs. So any integer step value works well for one-sample and paired designs, and any even step value works well for balanced two-sample designs. Both of these strategies will avoid rounding adjustments.

The following statements implement the first strategy to create the plot in Output 70.8.10, by using the NFRACTIONAL option in the TWOSAMPLEMEANS statement:

```
proc power plotonly;
   twosamplemeans test=diff
      nfractional
      groupmeans   = 12 | 18
      stddev       = 7
      groupweights = 2 | 1
      power        = .
      ntotal       = 20;
   plot x=n min=20 max=50 npoints=20;
run;
```

Output 70.8.10 Plot with Fractional Sample Sizes



To implement the second strategy, use multiples of 3 for the STEP=, MIN=, and MAX= options in the PLOT statement (because the sum of the allocation weights is $2 + 1 = 3$). The following statements use STEP=3, MIN=18, and MAX=48 to create a plot that looks identical to the plot in Output 70.8.7 but suffers no overlapping of points:

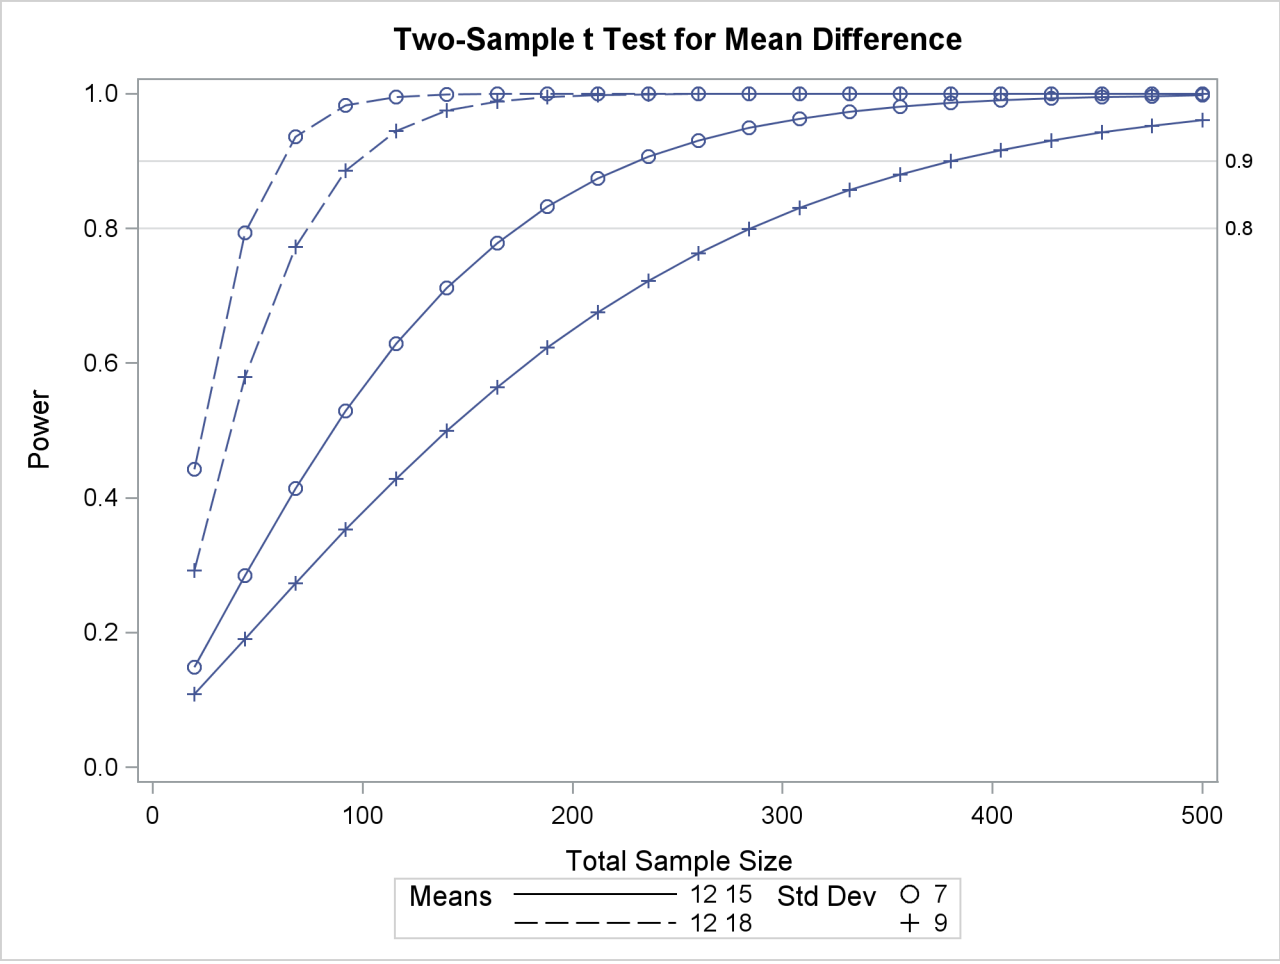
```
proc power plotonly;
   twosamplemeans test=diff
      groupmeans   = 12 | 18
      stddev       = 7
      groupweights = 2 | 1
      power        = .
      ntotal       = 20;
   plot x=n min=18 max=48 step=3;
run;
```

Adding Reference Lines

Suppose you want to add reference lines to highlight power=0.8 and power=0.9 on the plot in Output 70.8.5. You can add simple reference lines by using the YOPTS= option and REF= suboption in the PLOT statement to produce Output 70.8.11, with the following statements:

```
proc power plotonly;
   twosamplemeans test=diff
      groupmeans   = 12 | 15 18
      stddev       = 7 9
      power        = .
      ntotal       = 100;
   plot x=n min=20 max=500
      yopts=(ref=0.8 0.9);
run;
```

Output 70.8.11 Plot with Simple Reference Lines on Y Axis



Or you can specify CROSSREF=YES to add reference lines that intersect each curve and cross over to the other axis:

```
plot x=n min=20 max=500
   yopts=(ref=0.8 0.9 crossref=yes);
```

The resulting plot is shown in Output 70.8.12.

Output 70.8.12 Plot with CROSSREF=YES Style Reference Lines from Y Axis
